dust (less than 1%) was found in any of the main rings. The dustiest feature was found in one of the most prominent of the new rings (1986U1R). Researchers found the lack of dust in the main rings rather surprising, as compared to what would have been expected from extrapolations of Saturn ring data. As currently explained, the planet's considerably denser atmosphere drags microscopic dust particles out of their orbits within a matter of a few hundred years.

Voyager 2 instrumentation showed that the sizes of the largest particles in the rings average about 2 meters and thus are comparable to particles found in Saturn's rings. Unlike the material in Saturnian rings, however, the rings of Uranus contain relatively few millimeter- and centimeter-size particles. Thus, the mass density of the Uranian rings is markedly greater than, for example, Saturn's B ring.

The darkness and lack of color of the Uranian rings essentially matches the planet's moons. Several hypotheses concerning this observation have been proposed and described in the literature. In particular, see the Cuzzi/Esposito 1987 reference.

Satellites of Uranus

Prior to the *Voyager 2* encounter, studies of the Uranian satellites were confined to dynamical analyses and disk-integrated photometry, radiometry, and spectroscopy. The orbits of the five largest satellites are all of low inclination, with the exception of Miranda with an inclination 4 degrees. As described in the following paragraphs, while the Uranian satellites are similar in some respects, in other qualities they differ radically from one another. *Voyager 2* data requires a different model for each of the satellites. As observed by the *Voyager 2* imaging team (May 1986), caution must be exercised in interpreting the *Voyager* observations of the satellites as being representative of their entire surface. Because the subsolar points on Uranus and its satellites are currently close to their south poles, Voyager images covered only the southern hemisphere. Also, the terrain types of many objects in the solar system display global dichotomies (for example, the southern highlands and the northern lowlands of Mars and the dark leading and bright trailing hemispheres of Iapetus (a Saturnian moon). A summary of the physical properties of the Uranian satellite system is given in Table 2. See also Fig. 5.

Oberon. The outermost and second largest of the moons of Uranus is of a gray, rather uniform appearance. The surface is generously covered with large, old craters. They range in size from quite small, less than 12 km (7.5 mi) up to large, exceeding 100 km (60+ mi). The large craters do not appear to have been covered over by fresh material and thus most likely represent the formation by heliocentric bombardment some 4 billion years ago. There is very dark material on a few of the largest craters, of a type familiar to that found on 1985U1. Thus, it is likely that Oberon was somewhat active in the past. However, with present knowledge, it appears that Oberon mainly has been a passive target for occasional incoming projectiles. A high-resolution image of Oberon is shown in Fig. 6.

Titania. The second-outermost and the largest of the moons of Uranus (only slightly larger than Oberon) displays evidence of global tectonics and thus is in marked contrast with Oberon. The surface is heavily cratered, indicating bombardment by impactors from a second group of planetocentric objects, as well as by earlier heliocentric impactors. Unlike Oberon, heliocentric bombardment of Titania is not so evident, probably because of the obliteration of such craters by some poorly understood resurfacing process. Models constructed by researchers suggest that the resurfacing resulted from extensive volcanic extrusion of material onto the surface. The model assumes that such volcanic activity commenced even before the ending of the heliocentric bombardment. In this scenario, large craters would have been flooded, thence frozen in a relatively smooth ice surface, or because the planet was relatively warm, the crust would have been softened and simply collapsed. Later tectonic activity produced a network of extensional faults, with blocks of crust dropping down along the faults, thus creating grabens. It has been estimated that Titania has been a quiet body for the past 3 billion years, with only possible interruptions caused by the impacts of a relatively few comets. In another possible scenario, E.M. Shoemaker (U.S. Geological Survey), an authority on planetary cratering, suggests that the early cratering of

TABLE 2. PHYSICAL DATA OF URANIAN SATELLITE SYSTEM

Satellite Name	Diameter (km)	Distance from Uranus Center (10^3 km)	Orbital Period (Hours)	$G \times$ Mass (km^2 sec^{-2})	Density (G cm^{-3})	Normal Albedo

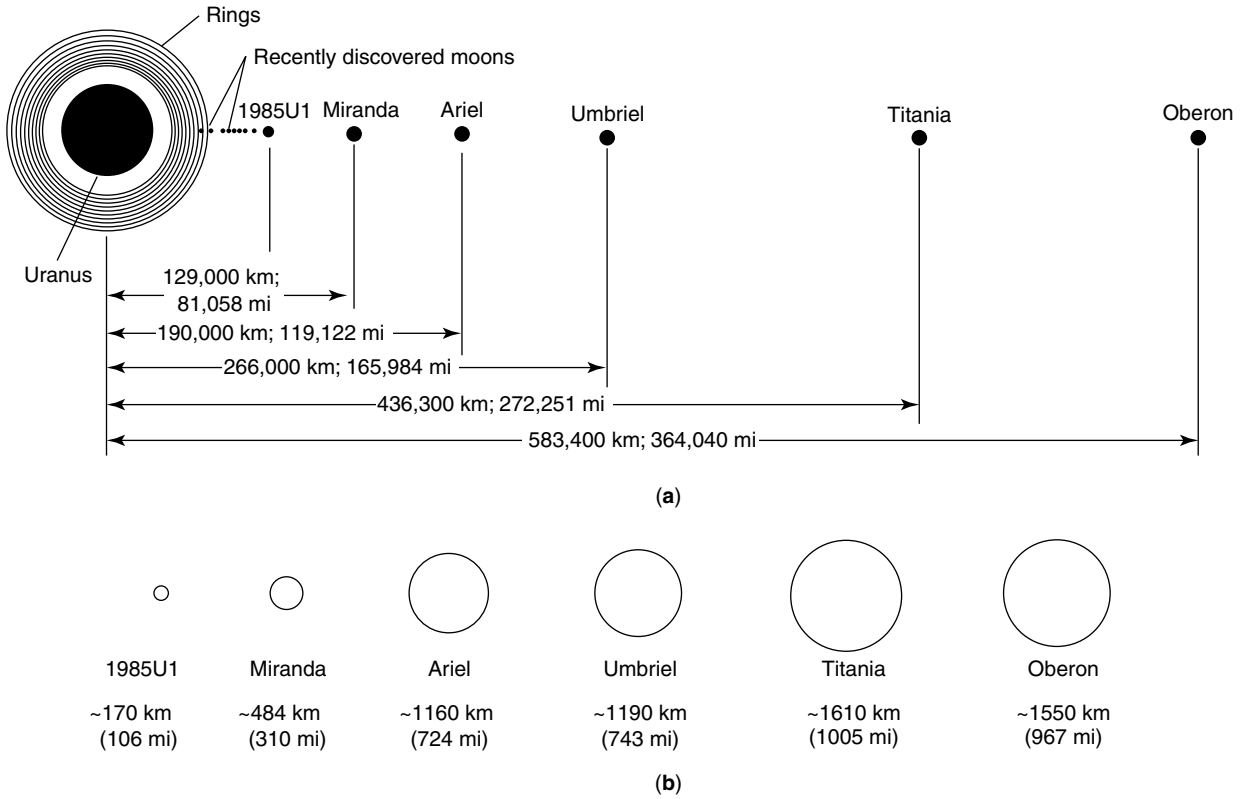

Fig. 5. The five principal satellites of Uranus and the recently discovered small moon 1985U1: (**a**) distance from center of Uranus to lunar orbits. Several very small satellites were discovered by *Voyager 2* as it approached the planet, one or more of which has been designated as a shepherding moon within the ring structure. (**b**) relative size of satellites (diameters indicated).

Titania by heliocentric objects was so intense that a large, late-arriving impactor may have blasted the moon apart. Pieces of material resulting from this shattering would have remained in an orbit about Titania, from which they were later reassembled into a "new" moon, which we now call Titania. Obviously this recreated moon would have a new surface without any trace of the early heliocentric bombardment. Because Oberon and Titania have similar bulk properties and yet are so different in appearance, this scenario offers an explanation of their striking differences. Further, it has been suggested that inasmuch as Titania is closer to Uranus, the probable gravitational focus of an impacting object would have been closer to Titania than to Oberon. A high-resolution image of Titania is given in Fig. 7.

Umbriel. The third outermost and third-largest of the moons of Uranus is described as the least distinctive of the planet's moon and has been described as some observers as "very bland." The satellite lacks global-scale variations in brightness and is not marked by bright ray craters. High-resolution images of the moon (made during *Voyager 2 's* closest approach) reveal that the surface of Umbriel is dominated by large but rayless craters, attributed to very early bombardment. Researchers to date have found it difficult to explain satisfactorially the bland character of the moon. One hypothesis suggests that the bright rays around Umbriel's craters may have been erased by micrometeroids, which not only ravaged the surface in great numbers, but also mixed dark underlying material with debris from the bombardment. This process is sometimes referred to as "impact gardening." Another scenario postulates that the rays of the craters contained methane that has become darkened by energetic radiation. Neither of these postulations, however, explain why rays are absent on Umbriel, but present on the other moons of Uranus. Possibly, a more logical explanation may be that rays never did exist on Umbriel. Perhaps dark material on the moon blankets the moon for several kilometers in depth and hence the ejecta from impacts would be dark and thus light rays would not be observable. A moon of this type, Ganymede, was discovered in the Jovian system. The reflectance of Umbriel is only about 20%, indicating that the material near its surface is composed of dark, carbon-rich substances.

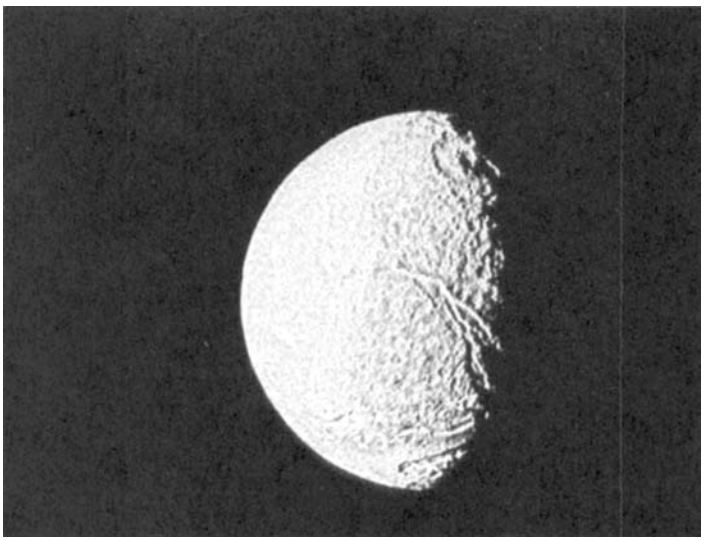

Fig. 6. Best image of Oberon obtained by *Voyager 2* on January 24, 1986. Note cratering and large peak on moon's lower limb. Range: 660,000 km (410,000 mi). (*Jet Propulsion Laboratory, Pasadena, California*.)

To compound the current mysteries of Umbriel, there are two outstanding bright features near the equator of the satellite. One of these is a ring some 80 km in diameter. It appears to cover the floor of an impact crater. Some researchers have proposed that the bright material in this feature probably originated below the surface of the body. Umbriel also features a spot on the peak of another large crater. With reference to the aforementioned underlying dark material, these latter two features may be exceptions to the rule. A high-resolution image of Umbriel is given in Fig. 8.

Ariel. Not counting the recently discovered very small moon, 1985U1, Ariel is the second moon outward from the planet. It is very slightly (some 30 km) smaller (diameter) than Umbriel. This satellite appears to

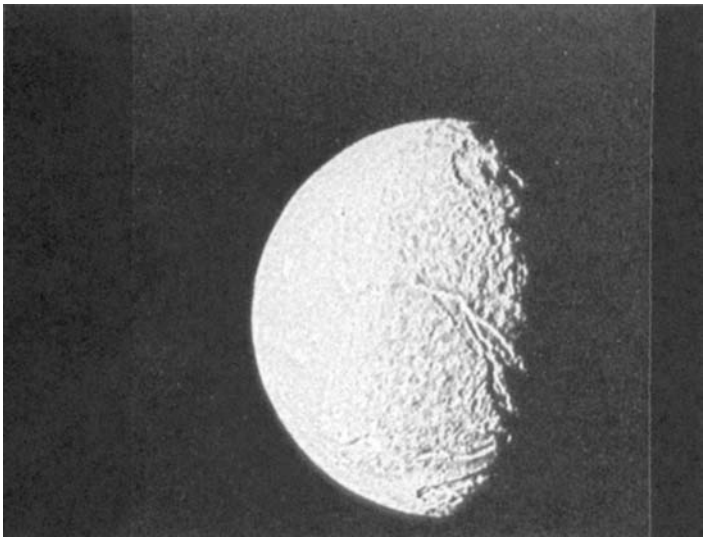

Fig. 7. High-resolution image of Titania obtained by *Voyager 2* on January 24, 1986. Range: 368,000 km (229,000 mi). Note prominent fault valleys nearly 1600 km (1000 mi) in length. (*Jet Propulsion Laboratory, Pasadena, California.*)

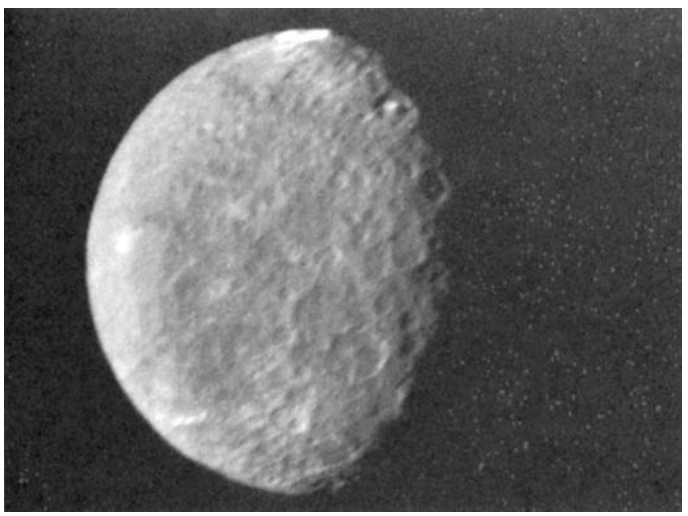

Fig. 8. The most detailed image of Umbriel made by *Voyager 2* on January 24, 1986. Range: 557,000 km (346,000 mi). The surface is a dark, nearly uniform gray coloration. There is an abundance of large, ancient craters. Note the two brightest features: (1) A bright ring at a longitude of 270° (top of view) which appears to lie in an 80 km (50 mi) crater. (2) Bright spot on the central peak of another crater at a longitude of about 310° (central left of view). (*Jet Propulsion Laboratory, Pasadena, California*.)

have been quite active, with features indicating crustal rifting and icy volcanic flows. Ariel is the brightest of the Uranian moons, quite in contrast with Umbriel, the darkest. Reflectance is approximately 40%. Researchers have concluded thus far that Ariel may be the youngest and least cratered of the Uranian satellites. Ariel has been compared with the Jovian satellites, Europa and Ganymede, and Saturn's Enceladus. It has been proposed that Ariel's history may parallel that of Titania, previously described, with the exception that the geologic activity on Ariel has been more pronounced and occurred over a longer time span. There is little evidence of heliocentric bombardment of Ariel, featuring only about a third of the number of such craters found on Titania. Thus, Ariel's surface has been restructured over a broader area and for a longer period. Ariel features a global network of fault valleys, some of which are estimated to be tens of kilometers in depth. Images have provided strong evidence that Ariel's resurfacing has been accomplished by way of volcanic activity. Considerable upwelling of material on Ariel has occurred. However, most researchers do not believe that the material was molten rock, but rather a relatively warm, plastic mixture of ice and rock that behaved much like a glacier on Earth. An image of Ariel is given in Fig. 9.

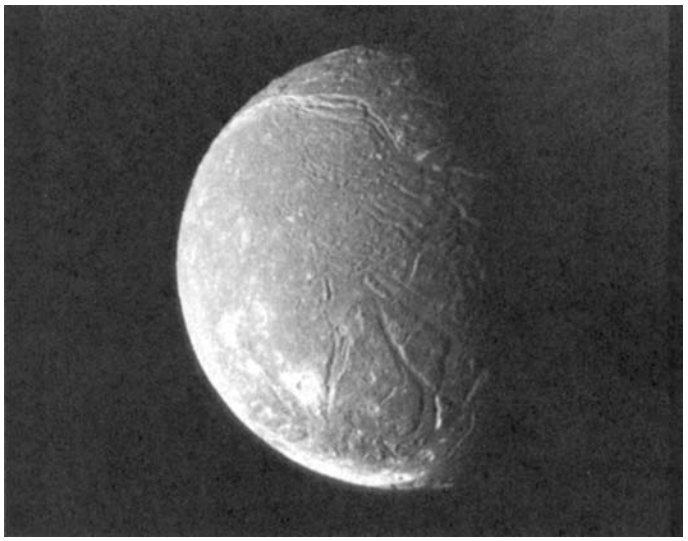

Fig. 9. The most detailed view (mosaic) of Ariel obtained by *Voyager 2* on January 24, 1986. Range: 128,700 km (80,000 mi). Image shows numerous faults and valleys. Most prominent features are the broad, crisscrossing grabens, or fault valleys, along the equator (near right of photograph). The supposition that much of Ariel was re-covered (resurfaced) after the heliocentric bombardment is based upon the almost total absence of large craters. (*Jet Propulsion Laboratory, Pasadena, California*.)

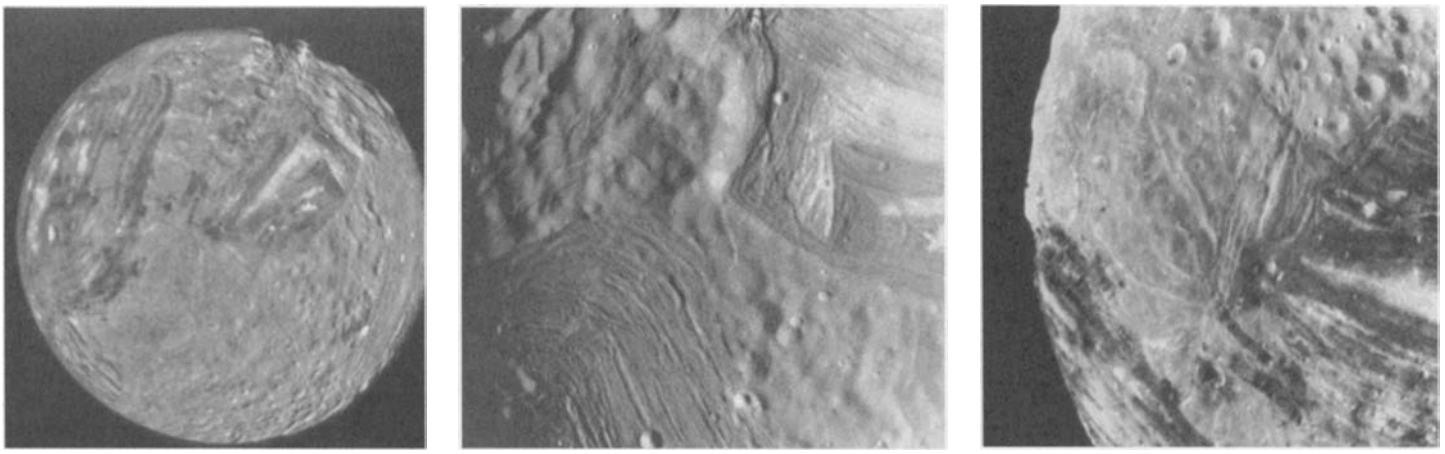
Miranda. The smallest of the five principal Uranian moons (about 3% of the diameter of Titania) has proved to be one of the most interesting of the planet's moons, as determined by *Voyager 2* data. The most ancient geologic feature on the satellite is a series of densely cratered rolling plains packed by the planetocentric bombardment. Most of the surface visible to *Voyager 2* is covered in this manner, but there are a few very fascinating features superposed on the rolling plains. Called *ovoids* by some researchers, there are three huge, oval-to-trapezoidal regions, which range between 200 and 300 km (125 and 187 mi) in diameter. Considering the diameter of Miranda (484 km; 310 mi), these indeed are immense features. Within the perimeters of the ovoids, numerous craters (considered much younger than the plains) are found. As described by Johnson, et al. (see reference), the ovoids consist of locally parallel belts of ridges, grooves, and scarps that abut one another at odd angles. Bright material as well as dark material is exposed along the scarps and in fresh craters inside the ovoids. In contrast, the rolling plains have a fairly uniform reflectance. There is an additional fascinating feature. The ovoids and the plains are cut by huge fracture zones that circle the satellite, creating fault valleys whose steep, terraced cliffs are as much as 10 to 20 km (~6 to 12 mi) high.

As with the strange features on Titania, early postulations concerning Miranda have developed. One researcher suggests that Miranda was blasted apart, as Titania, several times instead of just once for Titania. After each occasion, the moon reassembled itself, during which time rock and ice became partially separated. Then, when the reassembled moon was fractured again, the pieces that were generated consisted, not of a mixture of rock and ice, but of one or the other materials. Because the satellite, at that time, still had some internal heat, viscous flow in its interior was possible. Thus rock masses commenced to sink again toward the center of the body, with the lighter ice rising and flowing into the space behind them. This caused the surface to crack along concentric stress lines. Thus, the surface disturbances evidenced by the ovoids were left by sinking rock masses. To some researchers, this postulation does not take into account the probability that large pieces of rock would not retain their identity in



(**a**) (**b**) (**c**)

Fig. 10. Images of Miranda taken by *Voyager 2* on January 24, 1986. (**a**) A computer mosaic of the satellite shows varied geologic regions at high resolution. Range: 18,700 to 30,090 km (25,000 to 40,225 mi). (**b**) Unusual "chevron" feature seen on *Voyager 2's* approach to Miranda. Range: 41,830 km (26,000 mi). (**c**) Image taken shortly before closest approach by *Voyager 2*. Range: 30,570 km (19,000 mi). (*Jet Propulsion Laboratory, Pasadena, California*.)

the type of cataclysm which normally would be presumed to create very small pieces of resulting material.

The other scenario suggests that when Miranda accreted, it consisted of a relatively uniform mixture of rock and ice and that from that point, the satellite commenced to differentiate. The rock sand moved toward the center and ice masses rose toward the surface. Since the patterns of the ovoids are roughly similar, it is suggested that some "internal organization" to the flow (a form of convection cell) created the "typical" ovoidal pattern.

Some authorities suggest that the ovoids are only about a billion years old; others suggest that the evolution of the moon ceased some 3 to 4 billion years ago. Three striking images of Miranda are given in Fig. 10.

Editorial limitations do not permit presenting further details concerning the analysis of *Voyager 2* data in connection with the Uranian satellites. Considerably more detail can be found in the excellent Johnson, et al. reference (1987). As more time permits further modeling of the moons and scientific exchanges of viewpoints, some of the current hypotheses will gain increased acceptance, while others will be disproved or at least become more speculative.

Newly Discovered Uranian Satellites. The five major satellites of Uranus were discovered and briefly described from Earth observations prior to receiving information from *Voyager 2*. On its early approach to the planet in 1985, *Voyager 2* discovered the satellite 1985U1. The satellite appears to be made of the same primordial ice-rock material of the other moons, but surprisingly it is not so bright as the other moons. Some researchers suggest that 1985U1 is a homogeneous mixture of ice and rock, in contrast with the major moons which have undergone differentiation. It is assumed that much of the dense rock on the larger moons has settled toward their center, with brighter ice rising to the surface and thus the lighter appearance. At the time of the encounter with the planet, *Voyager 2* discovered nine additional small satellites (named, respectively, 1986U1 through 1986U9). The diameters of these smaller satellites range from about 1/3 to 1/4 the size (diameter) of 1985U1, which has a diameter of 170 ± 10 km ($\sim$106 mi). The ten new satellites orbit between Uranus and Miranda. As with the major satellites, the recently discovered satellites are in synchronous rotation, with one side always facing Uranus. It is presumed that the newly found satellites are also in locked rotation. Two of the ten smaller satellites (1986U7 and 1986U8) are shephering moons on each side of the planet's epsilon ring and it is suggested that the two moons keep the ring particles in place by exerting gravitational forces on them. Data from *Voyager 2* did not indicate any shepherding moons near any of the other eight rings, although they may exist and are too small to detect.

Magnetosphere of Uranus

The Uranian magnetic field was first detected by radio emissions five days prior to *Voyager's* closest approach to the planet — at a distance of about 275 Uranian radii (R_U). As reported by Stone and Miner, *Voyager* subsequently crossed a well-defined, detached bow shock at $23.5R_U$ and entered a fully developed magnetosphere at $18R_U$, revealing a magnetic dipole field with an axis at an unexpected large angle of 60° with respect to the rotation axis of the planet and offset from the center of Uranus by $0.3R_U$. The dipole moment was measured at $0.23GR_U$, giving a surface magnetic field ranging from 0.1 to 1.1 G. The intensity of the field and its offset suggested that it is generated at an intermediate depth where water may be under sufficient pressure to be electrically conductive. The rotation period of the magnetic field, presumed to be that of this interior region, was measured at 17.24 ± 0.01 hours. Researchers report that the dipole field appears to be deformed by the incident solar wind, resulting in a magnetotail geometry similar to that at Earth. The tail has a radius of $42R_U$ at a distance of $67R_U$ behind Uranus and has a plasma sheet about $10R_U$ thick. In as much as the planetary rotation axis is directed virtually sunward at the time of the Uranian year when measured, the magnetotail is estimated to rotate about the antisun line with the same period as the planet.

It has been reported that within the magnetosphere there is an extensive distribution of charged particles, mainly hydrogen ions and electrons. Two main plasma ion populations were determined: (1) a warm ($\sim$10 eV) component within about $7R_U$, with a maximum density of about 2 cm^{-3} planetward of Miranda's orbit; and (2) a hot (1000 eV) component that is confined outside approximately $5R_U$. It is suggested that ionization of the extended hydrogen corona may be the principal source of the plasma. However, the ionosphere and the solar wind also may be sources. The energy density of the plasma is small as compared with that of the magnetic field.

A Jet Propulsion Laboratory (JPL) report of May 1986 observes that the orientation of the rotation axis results in sunward convection of the plasma. This is quite different from that in the magnetosphere of Jupiter and Saturn, in which radial transport is dominated by diffusion. It is suggested that the rapid convective time scale of approximately 40 hours probably precludes the accumulation of a significant density of heavy ions sputtered from the surfaces of the moon, Miranda.

The trapped ion population at higher energies outside Miranda's orbit was found to be dominated by protons, with spectra characterized by temperatures of 4 to 30 keV. The proton fluxes are too small to cause significant distortion of the magnetic field, but are sufficient to modify and darken any methane on the surfaces of the satellite in a span of less than 100,000 years. The JPL report also notes that energetic electrons with temperatures greater than 20 keV were observed throughout the magnetosphere, terminating abruptly at about $18R_U$ on the dark side of the planet where the magnetotail commences. The approximately 1-MeV electron fluxes peak inside Miranda's orbit because of the adiabatic acceleration that occurs as the electrons diffuse radially inward from the outer magnetosphere. Intense whistler-mode hiss and chorus

emissions were found inside $8R_U$. These radio emissions cause electron precipitation, which, in turn, may contribute to nightside ultraviolet emissions.

Radio emissions from Uranus also occur, but they are of lower average power than found at Saturn and are detectable only near the planet.

UREA. [CAS: 57-13-6]. $H_2N \cdot CO \cdot NH_2$, formula weight 60.06, colorless crystalline solid, mp 132.7 °C (270.8 °F), sublimes unchanged under vacuum at its melting point, sp gr 1.335. Heating above the mp at atmospheric pressure causes decomposition, with the production of NH_3, isocyanic acid HNCO, cyanuric acid $(HNCO)_3$, biuret $NH_2CONHCONH_2$, and other products. Also known as carbamide, urea is very soluble in H_2O, soluble in alcohol, and slightly soluble in ether. The compound was discovered by Hilaire Rouelle in 1773 as a constituent of urine. See also **Urine**. Historically, urea was the first organic compound to be artificially synthesized from inorganic starting materials, in 1828 by Friedrich Woehler, who prepared it by the reaction of potassium cyanate with ammonium sulfate. Although Woehler was attempting to prepare ammonium cyanate, he inadvertently disproved the theory that the chemicals of living organisms are fundamentally different from inanimate matter by forming urea, thus starting the discipline of organic chemistry. However, a century passed before the compound was manufactured on a large scale.

Because of the reactivity and versatility of its derivatives, urea is a very high-tonnage chemical. The compound and its derivatives are widely used in fertilizers, pharmaceuticals (e.g., barbiturates), and synthetic resins and plastics (urethanes). Although there are several chemical engineering approaches to the synthesis of urea, the principal reaction is that of combining NH_3 with CO_2 in a first step to form ammonium carbamate. In a second step, dehydrating the ammonium carbamate to yield urea: (1) $2NH_3 + CO_2 \rightarrow NH_2COONH_4$, (2) $NH_2COONH_4 \rightarrow NH_2CONH_2 + H_2O$. The processing is complicated because of the severe corrosiveness of the reactants, usually requiring reaction vessels that are lined with lead, titanium, zirconium, silver, or stainless steel. The second step of the process requires a temperature of about 200 °C (392 °F) to effect the dehydration of the ammonium carbamate. The processing pressure ranges from 160 to 250 atmospheres. Only about one-half of the ammonium carbamate is dehydrated in the first pass. Thus, the excess carbamate, after separation from the urea, must be recycled to the urea reactor or used for other products, such as the production of ammonium sulfate.

Some of the reactions of urea and derivatives include: (1) as a weak mono-acid base, urea forms stable salts, such as urea nitrate $CO(NH_2)_2 \cdot HNO_3$ and urea oxalate $2CO(NH_2)_2 \cdot H_2C_2O_4$; (2) urea reacts with malonic acid to form barbituric acid $CO(NHCO)_2CH_2$, the derivatives of which are barbiturates (sedative drugs); (3) with alcohols, urea reacts to form urethanes; (4) with formaldehyde, urea forms ureaforms which can be used as slow-release fertilizers and also as ingredients for adhesives and plastics; (5) with hydrogen peroxide, urea forms a useful crystalline oxidizing agent; (6) with straight-chain alkanes, urea forms crystalline complexes (clathrates) which are used in the petroleum industry for separating straight- and branched-chain hydrocarbons; (7) when heated rapidly to about 350 °C in a fluidized bed at atmospheric pressure, urea decomposes to isocyanic acid and NH_3. The latter products, when passed over a catalyst at 400 °C, yield melamine $(NCH_2)_3$ which is the triamide of cyanuric acid and widely used in plastics; (8) with acids or bases, urea hydrolyzes, yielding NH_3 and CO_2. Hydrolysis in aqueous solutions is accelerated by the presence of urease (an enzyme). This reaction frequently is used for the quantitative determination of urea; (9) upon heating aqueous solutions of urea, biuret is formed. When crystallizing urea from aqueous solutions, the presence of about 5% biuret alters the crystals from long needles to short rhombic prisms, the latter greatly enhancing the handling properties of the final product. A content of up to 1.5% biuret is satisfactory for most fertilizer applications, although for citrus fruits, coffee plants, and cherry trees, the biuret content must remain below 0.3%. As a feed supplement for ruminants, pure biuret has proved advantageous because

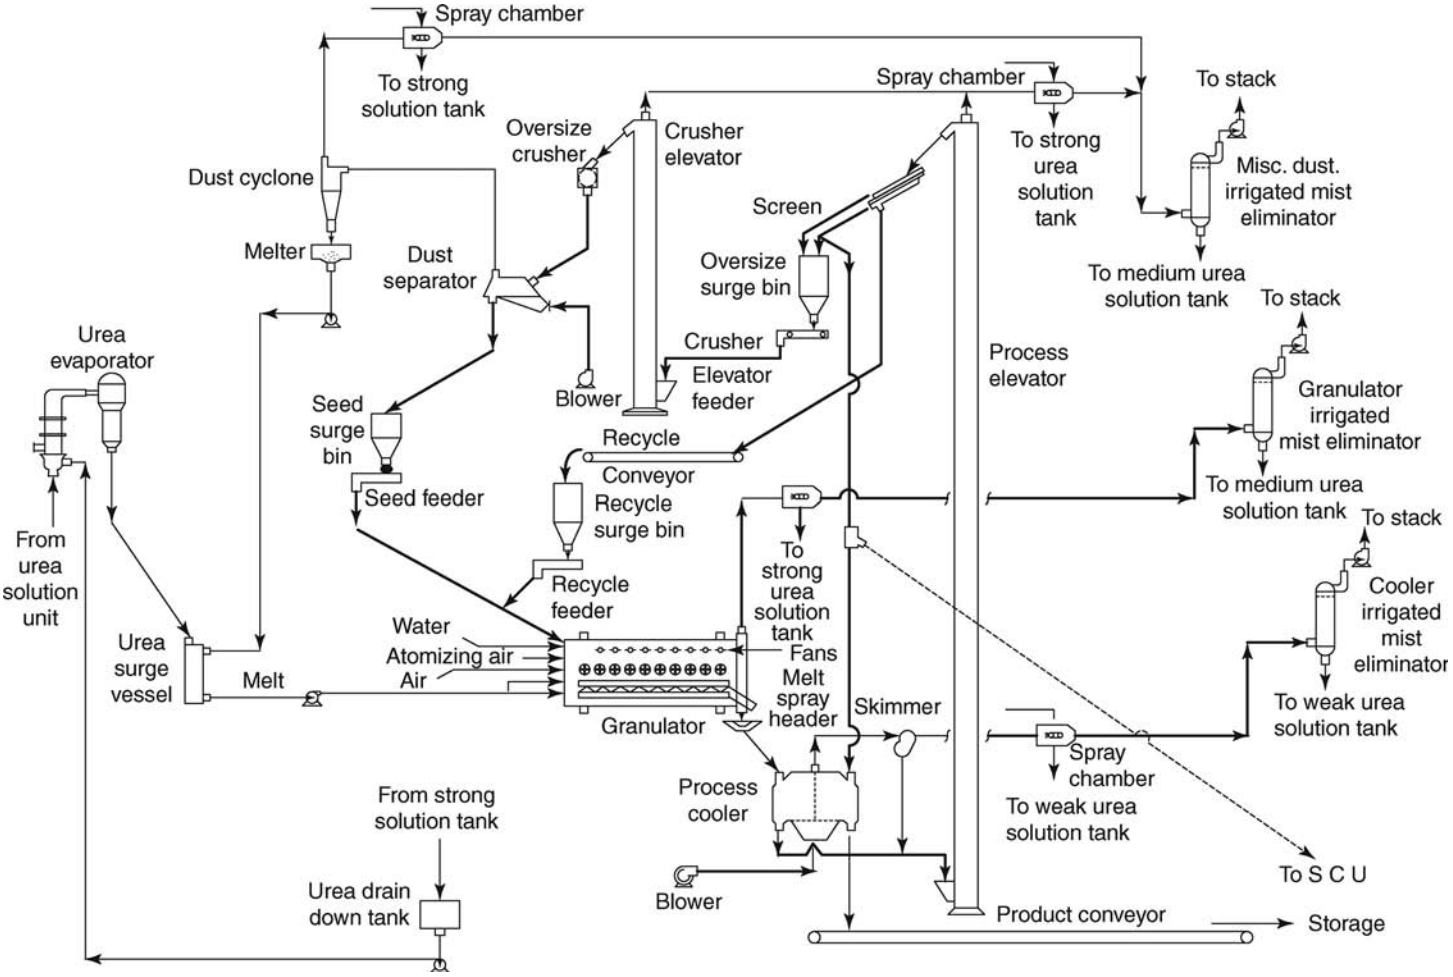

Fig. 1. A new process (*Urea Technologies*) developed for the Tennessee Valley Authority operates at considerable energy savings. Urea is produced in an overall exothermic reaction of ammonia and carbon dioxide at elevated pressure and temperature. In a highly exothermic reaction, ammonium carbamate is first formed as an intermediate compound, followed by its dehydration to urea and water, which is a slightly endothermic reaction. The conversion of CO_2 and NH_3 to urea depends on the ammonia-to-carbon dioxide ratio, temperature, and water-to-carbon dioxide ratio, among other factors. The new process makes maximum use of the heat created in the initial reaction, including heat recycling. (*Urea Technologies and Tennessee Valley Authority*.)

of the slower release rate of NH_3 from biuret as compared with urea. See also **Fertilizer**.

There are several different processes for making urea fertilizer. One process designed for energy savings is shown in Figs. 1 and 2.

Arginine-Urea Cycle (Ornithine Cycle). In adult animals, including humans, the characteristic tissue-specific levels of different enzymes are maintained by a dynamic balance between the independently controlled rates of biosynthesis and degradation of each enzyme. A dynamic rather than a static system most likely emerged because it enables organisms to adapt to widely different nutritional conditions and other environmental changes. Depending upon the physiological state of the animal at a given moment, amino acids derived from the hydrolysis of exogenous or endogenous protein may be predominantly utilized for *synthesis* of tissue-specific proteins. Or, their carbon chains may be *metabolized* further to provide energy (ATP) or intermediates for synthesis of other cellular constituents. When the carbon chains of amino acids are utilized to provide energy, some provision must be made for disposal of the reduced nitrogen components. Animal tissues in general cannot tolerate accumulation of ammonia. Aquatic animals, which are surrounded by a convenient diluent, can simply excrete ammonia as rapidly as it is formed. In contrast, land-based animals have devised other solutions to this problem. They convert amino acid nitrogen and ammonia into nitrogen-rich, nontoxic compounds, such as *urea* and *uric acid*. These are then excreted at intervals. Synthesis of urea, the primary nitrogenous excretory product of mammals, is efficiently accomplished in the liver by combining a portion of the already established pathway of arginine biosynthesis with the hydrolytic degradative enzyme, arginase.

Some of the enzymes required are widely distributed, but *ornithine carbamoyltransferase* occurs only in the liver and thus the complete urea cycle occurs only in that organ.

In human liver, a given molecule of arginine has four possible metabolic fates. It can be converted to (1) argininosuccinic acid, or (2) argininyl-sRNA, or (3) ornithine plus urea, or (4) ornithine plus glycocyamine, the precursor of creatine. The flow along the pathway to (4) is regulated by feedback repression in which the steady-state level of the enzyme involved (arginine:glycine amidinotransferase) is regulated by the concentration of liver creatine. Thus, runaway synthesis of creatine is prevented. The flow along the pathway is regulated by supply and demand.

Experimentally, it has been observed that above a certain basal level, the quantity of urea excreted is proportional to the amount of ingested protein.

The enzyme urease was not discovered until 1926 (by Sumner). It was the first enzyme to be isolated as a crystalline protein. Sumner's accomplishment confirmed the then growing belief that enzymes, the biological catalysts, were indeed from the chemical standpoint protein molecules. Urease catalyzes the cleavage of urea to ammonia and carbon dioxide.

For related information and references, see articles on **Fertilizer**; and **Gene Science**.

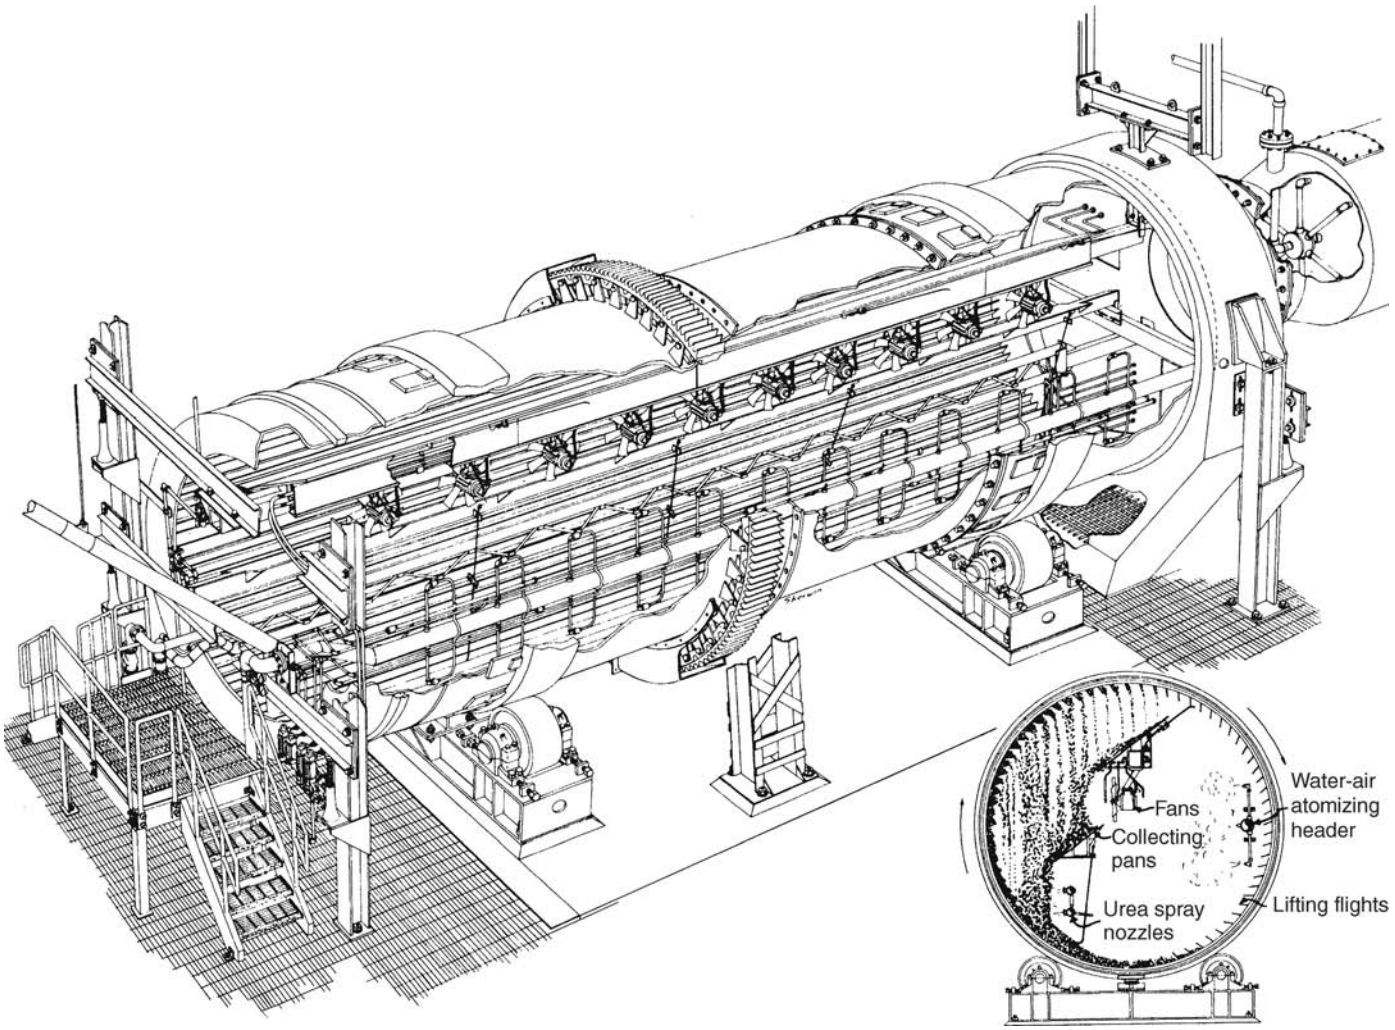

Fig. 2. In the urea process shown in Fig. 1, a falling-curtain granulation technique is used. The granulator drum is shown here. The key to the process is the rotary drum, with specially designed components, including collecting pans, air-circulation fans, urea spray header, and water spray header. As the drum rotates, seed particles, recycled undersize granules, and intermediate-size granules are lifted by flights and discharged onto inclined collecting pans. The material forms a dense falling curtain of granules as it slides from the collecting pans. The urea melt is sprayed through hydraulic atomizing nozzles onto this falling curtain and quickly solidifies. Controls over several variables in the process make it possible to form granules within narrow size specifications. Further details of process are given by Kirkland (*R.W. Kirkland, "Energy-efficient route to granular urea," Chemical Engineering Progress, April, 1984, pp. 49–53, April 1984*)

UREA-AMMONIUM ORTHOPHOSPHATE. A fertilizer developed especially for food-deficient regions, particularly rice-dependent areas. Several grades contain all three primary plant nutrients (nitrogen, phosphorus, and potassium). Contains up to 60% nitrogen, phosphoric anhydride and potassium oxide.

See also **Fertilizer**.

UREA-AMMONIUM POLYPHOSPHATE. A fertilizer similar to urea–ammonium orthotrophospate except that about half the phosphorus is in polyphosphate form, which gives improved sequestering action and solubility. It is excellent for use as a liquid fertilizer.

See also **Fertilizer**.

UREA (Fertilizer). See **Fertilizer**.

UREAFORM. A urea-formaldehyde reaction product that contains more than one molecule of urea per molecule of formaldehyde. It can be used as a fertilizer because of its high nitrogen content, its insolubility in water, and its gradual decomposition in the soil during the growing season to yield soluble nitrogen.

UREA-FORMALDEHYDE RESIN. An important class of amino resin. Urea and formaldehyde are united in a two-stage process in the presence of pyridine, ammonia, or certain alcohols with heat and control of pH to form intermediates (methylolurea, dimenthylolurea) that are mixed with fillers to produce molding powders. These are converted to thermosetting resins by further controlled heating and pressure in the presence of catalysts. These were first plastics that could be made in white, pastel, and colored products.

See also **Amino Acids**; and **Melamine**.

UREASE. Enzyme present in low-percentages in jackbean and soybean; water soluble, its action is inhibited by heavy-metal ions. Its principal use is in the determination of urea in urine, blood, and other body fluids; it splits urea into ammonia and carbon dioxide or ammonium carbonate.

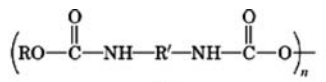
See also **Urea**.

URETHANE. [CAS: 51-79-6]. $CO(NH_2)OC_2H_5$, also referred to as ethyl carbamate or ethyl urethane. Its structure is typical of the repeating unit in polyurethane resins. Colorless crystals or white powder, odorless, saltpeter-like taste, D 0.9862, mp 49 °C (120 °F), bp 180 °C (356 °F), solutions neutral to litmus, soluble in water, alcohol, ether, glycerol, and chloroform; slightly soluble in olive oil. Formed by the heating of ethanol [CAS: 64-17-5] and urea nitrate [CAS: 124-47-0] to 120-130 °C (248-266 °F) or by the action of ammonia [CAS: 7664-41-7] on ethyl carbonate [CAS: 105-58-8] or ethyl chloroformate [CAS: 541-41-3].

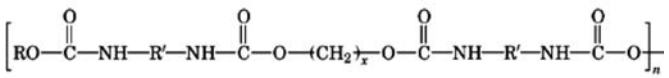
See also **Polyurethanes**; and **Urethane Polymers**.

URETHANE POLYMERS. The rapid formation of high molecular weight urethane polymers from liquid monomers, which occurs even at ambient temperature, is a unique feature of the polyaddition process, yielding products that range from cross-linked networks to linear fibers and elastomers. The enormous versatility of the polyaddition process allowed the manufacture of a myriad of products for a wide variety of applications. The addition polymerization of diisocyanates with macroglycols to produce urethane polymers was pioneered in 1937.

Polyurethanes contain carbamate groups, −NHCOO−, also referred to as urethane groups, in their backbone structure. They are formed in the reaction of a diisocyanate with a macroglycol, a so-called polyol, or with a combination of a macroglycol and a short-chain diol extender. In the latter case, segmented block copolymers are generally produced. The macroglycols are based on polyethers, polyesters, or a combination of both. A linear polyurethane polymer has the structure of (**1**), whereas a linear segmented copolymer obtained from a diisocyanate, a macroglycol, and a diol extender, $HO(CH_2)_xOH$, has the structure of (**2**).

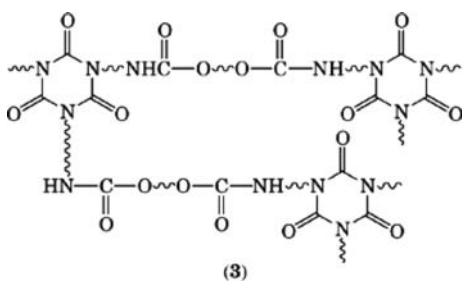


(**1**)



(**2**)

In addition to the linear thermoplastic polyurethanes obtained from difunctional monomers, branched or cross-linked thermoset polymers are made with higher functional monomers. Linear polymers have good impact strength, good physical properties, and excellent processibility, but, owing to their thermoplasticity, limited thermal stability. Thermoset polymers, on the other hand, have higher thermal stability but sometimes lower impact strength (rigid foams). The higher functionality is obtained with higher functional isocyanates (polymeric isocyanates), or with higher functional polyols. Cross-linking is also achieved by secondary reactions. Urea-modified segmented polyurethanes are manufactured from diisocyanates, macroglycols, and diamine extenders. Urethane network polymers are also formed by trimerization of part of the isocyanate groups. This approach is used in the formation of rigid polyurethane-modified isocyanurate (PUIR) foams (**3**).



(**3**)

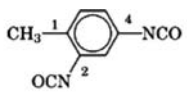
Formation

The polarization of the isocyanate group enhances the addition across the carbon-nitrogen double bond, which allows rapid formation of addition polymers from diisocyanates and macroglycols.

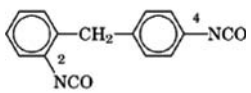
The liquid monomers are suitable for bulk polymerization processes. The reaction can be conducted in a mold (casting, reaction injection molding), continuously on a conveyor (block and panel foam production), or in an extruder (thermoplastic polyurethane elastomers and engineering thermoplastics). Also, spraying of the monomers onto the surface of suitable substrates provides insulation barriers or cross-linked coatings.

The polyaddition reaction is influenced by the structure and functionality of the monomers, including the location of substituents in proximity to the reactive isocyanate group (steric hindrance) and the nature of the hydroxyl group (primary or secondary). Impurities also influence the reactivity of the system.

The steric effects in isocyanates are best demonstrated by the formation of flexible foams from TDI. In the 2,4-isomer (**4**), the initial reaction occurs at the nonhindered isocyanate group in the 4-position. The unsymmetrically substituted ureas formed in the subsequent reaction with water are more soluble in the developing polymer matrix. Low density flexible foams are not readily produced from MDI or PMDI; enrichment of PMDI with the 2, 4′-isomer of MDI (**5**) affords a steric environment similar to the one in TDI, which allows the production of low density flexible foams that have good physical properties. The use of high performance polyols based on a copolymer polyol allows production of high resiliency (HR) slabstock foam from either TDI or MDI.

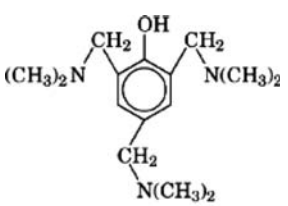


(**4**)

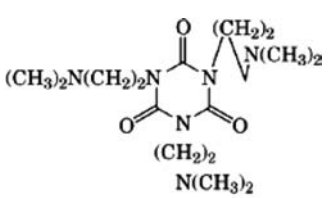


(**5**)

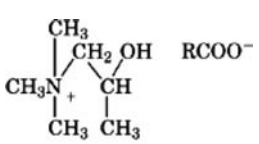
Tailoring of performance characteristics to improve processing and properties of polyurethane products requires the selection of efficient catalysts. In flexible foam manufacturing a combination of tin and tertiary amine catalysts are used in order to balance the gelation reaction (urethane formation) and the blowing reaction (urea formation). The tin catalysts used include dibutyltin dilaurate, dibutylbis(laurylthio)stannate, dibutyltinbis(isooctylmercapto acetate), and dibutyltinbis(isooctylmaleate). Strong bases, such as potassium acetate, potassium 2-ethylhexoate, or amine–epoxide combinations are the most useful trimerization catalysts. Also, some special tertiary amines, such as 2,4,6-tris(*N*,*N*-dimethylaminomethyl)phenol (DMT-30) (**6**), 1,3,5-tris(3-dimethylamino propyl)hexahydro-*s*-triazine (**7**), and ammonium salts (Dabco TMR) (**8**) are good trimerization catalysts.



(**6**)



(**7**)



(**8**)

The formation of cellular products also requires surfactants to facilitate the formation of small bubbles necessary for a fine-cell structure. The

most effective surfactants are polyoxyalkylene–polysiloxane copolymers. The physical properties of polyurethanes are derived from their molecular structure and determined by the choice of building blocks as well as the supramolecular structures caused by atomic interaction between chains. The ability to crystallize, the flexibility of the chains, and spacing of polar groups are of considerable importance, especially in linear thermoplastic materials. In rigid cross-linked systems, e.g., polyurethane foams, other factors such as density determine the final properties.

Properties

Thermoplastic Polyurethanes. The unique properties of polyurethanes are attributed to their long-chain structure. In segmented polyether- and polyesterurethane elastomers, hydrogen bonds form between −NH− groups (proton donor) and the urethane carbonyl, polyether oxygen, or polyester carbonyl groups. The symmetrical MDI is more suitable for the preparation of segmented polyurethane elastomers having excellent physical properties. Segmented polyurethanes are also obtained from 2,6-TDI, but an economically attractive separation process for the TDI isomers has yet to be developed.

The melt viscosity of a thermoplastic polyurethane (TPU) depends on the weight-average molecular weight and is influenced by chain length and branching. TPUs are viscoelastic materials, which behave like a glassy, brittle solid, an elastic rubber, or a viscous liquid, depending on temperature and time scale of measurement. With increasing temperature, the material becomes rubbery because of the onset of molecular motion. At higher temperatures a free-flowing liquid forms. The melt temperature of a polyurethane is important for processibility. Melting should occur well below the decomposition temperature.

Thermoset Polyurethanes. The physical properties of rigid urethane foams are usually a function of foam density. A change in strength properties requires a change in density. Rigid polyurethane foams that have densities of <0.064 g/cm^5, used primarily for thermal insulation, are expanded with HCFCs, HFCs, or hydrocarbons. See also **Insulation (Thermal)**. Often water or a carbodiimide catalyst is added to the formulation to generate carbon dioxide as a coblowing agent. In addition to density, the strength of a rigid foam is influenced by the catalyst, surfactant, polyol, isocyanate, and the type of mixing. By changing the ingredients, foams can be made that have high modulus, low elongation, and some brittleness (friability), or relative flexibility and low modulus. See also **Foamed Plastics**.

The properties of thermoset flexible polyurethane foams are also related to density; load-bearing properties are likewise important. Under normal service temperatures, flexible foams exhibit rubber-like elasticity to deformations of short duration, but creep under long-term stress. Maximum tensile strength is obtained at densities of ca 0.024–0.030 g/cm^3· g/cm^3. The densities are controlled by the amount of water in the formulation and may range from 0.045 to 0.020 g/cm^3 by raising the amount of water from 2 to 5%. Auxiliary blowing agents are also used to reduce density and control hardness. The size and uniformity of the cells are controlled by the efficiency of mixing and the nucleation of the foam mix.

Hyperbranched polyurethanes are constructed using phenol-blocked trifunctional monomers in combination with 4-methylbenzyl alcohol for end capping. Polyurethane interpenetrating polymer networks (IPNs) are mixtures of two cross-linked polymer networks, prepared by latex blending, sequential polymerization, or simultaneous polymerization. IPNs have improved mechanical properties, as well as thermal stabilities, compared to the single cross-linked polymers. In pseudo-IPNs, only one of the involved polymers is cross-linked. Numerous polymers are involved in the formation of polyurethane-derived IPNs.

Raw Materials

The commodity isocyanates TDI and PMDI are most widely used in the manufacture of urethane polymers. See also **Isocyantes, Organic**. The former is an 80:20 mixture of 2,4- and 2,6-isomers, respectively; the latter a polymeric isocyanate obtained by phosgenation of aniline–formaldehyde-derived polyamines. A coproduct in the manufacture of PMDI is 4, 4′-methylenebis(phenyl isocyanate) (MDI). The manufacture of TDI involves the dinitration of toluene, catalytic hydrogenation to the diamines, and phosgenation. Separation of the undesired 2,3-isomer is necessary because its presence interferes with polymerization. Polymeric isocyanates (PMDI) are crude products that vary in exact composition. The basic raw materials for the manufacture of PMDI and its coproduct MDI is benzene. Nitration and hydrogenation affords aniline. See also **Amines**; and **Aromatic Compound**.

Liquid MDI products are also made by reaction of the diisocyanate with small amounts of glycols. These products are called prepolymers.

Urethanes obtained from aromatic diisocyanates undergo slow oxidation in the presence of air and light, causing discoloration, which is unacceptable in some applications. Polyurethanes obtained from aliphatic diisocyanates are color-stable, although it is necessary to add antioxidants and UV-stabilizers to the formulation to maintain the physical properties with time. The least costly aliphatic diisocyanate is hexamethylene diisocyanate (HDI). Isophorone diisocyanate (IPDI) and its derivatives are also used in the formulation of rigid coatings; hydrogenated MDI (HMDI) and cyclohexane diisocyanate (CHDI) are used in the formulation of flexible coatings and polyurethane elastomers. See also **Antioxidants**.

Polyether polyols are addition products derived from cyclic ethers. The alkylene oxide polymerization is usually initiated by alkali hydroxides, especially potassium hydroxide. In the base-catalyzed polymerization of propylene oxide, some rearrangement occurs to give allyl alcohol.

Polyether polyols are high molecular weight polymers that range from viscous liquids to waxy solids, depending on structure and molecular weight. Most commercial polyether polyols are based on the less expensive ethylene or propylene oxide or on a combination of the two. Block copolymers are manufactured first by the reaction of propylene glycol with propylene oxide to form a homopolymer.

With amine initiators the so-called self-catalyzed polyols are obtained, which are used in the formulation of rigid spray foam systems. The rigidity or stiffness of a foam is increased by aromatic initiators, such as Mannich bases derived from phenol, phenolic resins, toluenediamine, or methylenedianiline (MDA). In the manufacture of highly resilient flexible foams and thermoset RIM elastomers, graft or polymer polyols are used.

Polyester polyols are based on saturated aliphatic or aromatic carboxylic acids and diols or mixtures of diols. The carboxylic acid of choice is adipic acid because of its favorable cost/performance ratio. For elastomers, linear polyester polyols of ca 2000 mol wt are preferred. Branched polyester polyols, formulated from higher functional glycols, are used for foam and coatings applications. Phthalates and terephthalates are also used.

In addition, polyester polyols are made by the reaction of caprolactone with diols. Poly(caprolactone diols) are used in the manufacture of thermoplastic polyurethane elastomers with improved hydrolytic stability. The hydrolytic stability of the poly(caprolactone diol)-derived TPUs is comparable to TPUs based on the more expensive long-chain diol adipates. Polyether/polyester polyol hybrids are synthesized from low molecular weight polyester diols, which are extended with propylene oxide.

Uses

Recycling. The methods proposed for the recycling of polyurethanes include pyrolysis, hydrolysis, and glycolysis. Regrind from polyurethane RIM elastomers is used as filler in some RIM as well as compression molding applications. The RIM chips are also used in combination with rubber chips in the construction of athletic fields, tennis courts, and pavement of working roads of golf courses.

The use of rebound flexible foam for carpet underlay and for high load-bearing padding for furniture or for gymnasium mats is already a reality. Rebound flexible foam can also be used for sound dampening in cars. Rebounding of rigid foam particles with PMDI produces polyurethane particle boards. These boards are unaffected by water and are therefore used in furniture aboard ships. Rigid foam scrap is also used as filler in the manufacture of building products. The most convenient chemical recycling process, consists of glycolysis of solid polyurethane products. Heating of polyurethane scrap in a mixture of glycols and diethanolamine converts the cross-linked polymers into linear soluble oligomers via a transesterification process.

Health and Safety

Fully cured polyurethanes present no health hazard; they are chemically inert and insoluble in water and most organic solvents. Dust can be generated in fabrication, and inhalation of the dust should be avoided.

Polyether-based polyurethanes are not degraded in the human body, and are therefore used in biomedical applications. Some of the chemicals used in the production of polyurethanes, such as the highly reactive isocyanates and tertiary amine catalysts, must be handled with caution. The other polyurethane ingredients, polyols and surfactants, are relatively inert materials having low toxicity.

Isocyanates in general are toxic chemicals and require great care in handling. Respiratory effects are the primary toxicological manifestations of repeated overexposure to diisocyanates.

There are a multitude of governmental requirements for the manufacture and handling of isocyanates. The U.S. EPA mandates testing and risk management for TDI and MDI under Toxic Substance Control Administration (TSCA). Annual reports on emissions of both isocyanates are required by the EPA under SARA 313.

The liquid tertiary aliphatic amines used as catalysts in the manufacture of polyurethanes can cause contact dermatitis and severe damage to the eye. Inhalation can produce moderate to severe irritation.

Polyurethanes can be considered safe for human use. However, exposure to dust, generated in finishing operations, should be avoided. Polyurethanes are combustible. An approved fire-resistive thermal barrier must be applied over foam insulation on interior walls and ceilings. Under no circumstances should direct flame or excessive heat be allowed to contact polyurethane or polyisocyanurate foam.

Uses

Flexible Foam. The largest markets for flexible polyurethane foam are in the furniture, transportation, and bedding industries. Most furniture cushioning is made of polyurethane foam, predominantly cut from slabs or buns having a density of 0.0192–0.0288 g/cm^3. Polyurethane foam core mattresses are used increasingly in bedding. High resiliency flexible foam having a density of 0.040 g/cm^3 is used for seat cushions in higher priced furniture. Molded flexible polyurethane foam is used in the automotive industry for seating, instrument panels, head rests, and arm rests applications. Semiflexible molded polyurethane foams are used in dashboards and door liners. Semiflexible foams are also formulated for sound and vibrational control in automotive applications. Other foam uses include carpet underlay, packaging, textile laminates, and interior padding. Specialty applications include reticulated foams for filtration and foams for such consumer products as sponges, scrubbers, squeegees, and paint applicators.

Rigid Foam. The bulk of the rigid polyurethane and polyisocyanurate foam is used in insulation. See also **Insulation (Thermal)**. Commercial buildings are often covered with polyurethane spray foam. Pour-in-place foam is typically integrated in large-scale assembly operations, such as aircraft carriers. Insulation of truck trailers, truck bodies, railroad freight cars, and cargo containers are some of the other spray or pour-in-place applications. Tank and pipe insulation is either spray-applied or cut from bun stock.

Ships transporting liquid natural gas (LNG) are usually insulated with rigid PUIR foam laminates, which provide temperature stabilities from −180 to 150 °C (−292 to 302 °F). The main fuel tank of the National Aeronautics and Space Administration (NASA) space shuttles is also insulated with PUIR foam. See also **Space Shuttle**. Rigid polyurethane foam is used in engineered foamed-in-place packaging of industrial or scientific equipment and in the molding of furniture, simulated-wood ceiling beams, and a variety of decorative and structural furniture components. Rigid foam is also used in movie props, for the repair of river barges, and in boat flotation applications.

Polyurethane Coatings. Polyurethane surface coatings are used wherever applications require abrasion resistance, skin flexibility, fast curing, good adhesion, and chemical resistance. See also **Coatings**. The polyaddition process allows formulation of solvent-based or solventless liquid two-component systems, water-based dispersions, or powder coatings. Water-based coatings, formulated from polyurethane ionomers, are used for aircraft, appliances, as well as automotive, industrial, and farm machinery applications. For baking enamels, wire and powder coatings blocked isocyanates are used. Blocking agents include caprolactam, phenol, oximes, malonates, and 3,5-dimethylpyrazole. Unlike the other polyurethane coatings, blocked urethane coatings do not cure below a certain threshold baking temperature. Catalysts, such as tertiary amines or organometallic tin compounds, are used to lower the curing temperature. Blocked isocyanates are also used in the formulation of one-component systems.

Synthetic leather products are also produced using a urethane binder. These poromeric materials are produced from textile-length fiber mats impregnated with DMF solutions of polyurethanes. Permeability to moisture vapor is the key property needed in synthetic leather. In addition to shoe applications, poromerics are used for handbags, luggage, and apparel. Polyurethane films having oxygen and water permeability are applied in bandages and wound dressings and as artificial skin for burn victims.

Polyurethane Elastomers. Polyurethane elastomers are used in applications where toughness, flexibility, strength, abrasion resistance, and shock-absorbing qualities are required. Thermoplastic polyurethane elastomers and polyurethane engineering thermoplastics are molded or extruded to produce elastomeric products used as automobile parts, shoe soles, ski boots, roller skate and skateboard wheels, pond liners, cable jackets, and mechanical goods. Cast and RIM elastomers are used in auto fascia, bumper and fender extensions, printing and industrial rolls, industrial tires, and industrial and agricultural parts, such as oil well plugs and grain buckets. Elastomeric spandex fibers are used in hosiery and sock tops, girdles, brassieres, support hose, and swim wear. The use of spandex fibers in sport clothing is increasing.

UREY, HAROLD C. (1894–1981). An American chemist who received the Nobel Prize in chemistry in 1934 for his discovery of the heavy isotopes of hydrogen and oxygen. His discovery became and important factor in the development of nuclear fission and fusion and made possible the production of the transuranic element Pu. He was one was one of the leaders of the Manhattan Project, which constructed the first nuclear reactor at the University of Chicago and eventually produced the first atomic bomb. Obtaining his doctorate at the University of California in 1923, he taught at several leading universities, including Columbia where he discovered deuterium D oxide (heavy water), used as a moderator in early types of nuclear reactors. Later he devoted much study to the origin of the universe and the origin of life on earth. He was the author of many scientific treatises and made notable contributions to the cosmological theories.

URIC ACID. See **Gout**; **Purines**; and **Water**.

URIC ACID STONES. See **Gout**; and **Kidney and Urinary Tract**.

URINE. The liquid waste excreted by the kidneys and is produced by the process of filtration. This waste is eventually expelled from the body in a process known as urination. Most commonly the excretion of urine serves for flushing waste molecules collected from the blood by the kidneys, and for the homeostasis of the body liquids; however, many species also use it for olfactory communication.

Urine is a transparent solution that is clear to amber in color, and usually is light yellow. It is the byproduct or waste fluid secreted by the kidneys, transported by the ureters to the urinary bladder where it is stored until it is voided through the urethra. Urine is made up of a watery solution of metabolic wastes (such as urea), dissolved salts and organic materials. Fluid and materials being filtered by the kidneys, destined to become urine, comes from the blood or interstitial fluid. The composition of urine is adjusted in the process of reabsorption when essential molecules needed by the body, such as glucose, are reabsorbed back into the blood stream via carrier molecules. The remaining fluid contains high concentrations of urea and other excess or potentially toxic substances that will be released from the body via urination. Urine flows through these structures: the kidney, ureter, bladder, and finally the urethra. Urine is produced by a process of filtration, reabsorption, and tubular secretion.

Urination is the primary method for excreting chemicals and drugs from the body. These chemicals can be detected and analysed by urinalysis. About 1,250 milliliters of urine are excreted in 24 hours by normal humans, with specific gravities usually between 1.018 and 1.024 extremes: 1.003–1.040). Flow ranges from 0.5–20 milliliters/minute with extremes of dehydration and hydration. Maximum osmolar concentration is 1,400, compared to plasma osmolarity of 300. In diabetes insipidus, characterized by inadequate antidiuretic hormone (ADH) production, volumes of 15–25 liters/day of dilute urine may be formed. In addition to the substances listed in Table 1, there are trace amounts of purine bases and methylated purines, glucuronates, the pigments urochrome and urobilin, hippuric acid, and amino acids. In pathological states, other substances may appear: proteins (nephrosis); bile pigments and salts (biliary obstruction); glucose, acetone, acetoacetic acid and betahydroxybutyric acid (diabetes mellitus). The U/P ratios of the substances in the table vary widely because of differential handling by the kidney. Quantitative knowledge of glomerular filtration, tubular reabsorption, and secretion of these requires an understanding of the concept of renal plasma clearance.

TABLE 1. COMPOSITION OF 24-HOUR URINE IN THE NORMAL ADULT[a]

Substance	Amount (Grams)	U/Pb[b]
Urea	6.0–180.0 (nitrogen)	60.0
Creatinine	0.3–0.8 (nitrogen)	70.0
Ammonia	0.4–1.0 (nitrogen)	—
Uric acid	0.08–0.2 (nitrogen)	20.0
Sodium	2.0–4.0	0.8–1.5
Potassium	1.5–2.0	10.0–15.0
Calcium	0.1–0.3	—
Magnesium	0.1–0.2	—
Chloride	4.0–8.0	0.8–2.0
Bicarbonate	—	0.0–2.0
Phosphate	0.7–1.6 (phosphorus)	25.0
Inorganic sulfate	0.6–1.8 (sulfur)	50.0
Organic sulfate	0.06–0.2 (sulfur)	—

[a] Based upon data by White, Handler, Smith, and Stetten.
[b] U/P ratio = ratio of urinary to plasma concentration.

The rate at which a substance (X) is excreted in the urine is the product of its urinary concentration, U_x (milligram/milliliter), and the volume of urine per minute, V. The rate of excretion (U_xV) depends, among other factors, upon the concentration of X in the plasma, P_x (milligram/milliliter). It is therefore reasonable to relate U_xV to P_x and this is called the clearance ratio: $(U_x \cdot V)/P_x$, or more generally, UV/P. This has the dimensions of volume and is in reality the smallest volume from which the kidneys can obtain the amount of X excreted per minute. The kidneys do not usually clear the plasma completely of X, but clear a larger volume incompletely. The clearance is therefore not a real, but a virtual volume. When substances are being cleared simultaneously, each has its own clearance rate, depending upon the amount absorbed from the glomerular filtrate or added by tubular secretion. The former will have the lower clearance, the latter the higher. Those cleared only by glomerular filtration will be intermediate, and their clearance will in effect measure the rate of glomerular filtration in milliliters/minute.

The best-known substance that can be infused into blood to provide a clearance equal to glomerular filtration rate is *inulin*, a polymer of fructose containing 32 hexose molecules (molecular weight 5,200). Strong evidence indicates that it is neither reabsorbed nor secreted, is freely filterable, is not metabolized, and has no physiological influences. Its clearance in humans is 120–130 milliliters/minute. This is taken to be the glomerular filtration rate (GFR) or C_F (amount of plasma water filtered through glomeruli/minute). Besides inulin in the dog and other vertebrates, creatinine, thiosulfate, ferrocyanide, and mannitol also fulfill these requirements.

Knowing the glomerular filtration rate permits quantification of the amount of any substance freely filtered (C_F (milliliters/minute) $\times P_x$ (milligrams/milliliter)). Subtracting from this one minute's excretion, U_xV, would give the amount reabsorbed in milligrams/minute. A classical example is the glucose mechanism. At normal plasma concentrations, none or a trace appears in the urine. When plasma glucose is elevated to about 180–200 milligram percent (the "threshold"), the amount appearing in the urine begins to increase. As concentration is raised more, the nephrons become progressively saturated until the rate of reabsorption becomes constant and maximal. This indication of saturation of the transport system is referred to as the T_m ("tubular maximum — T_{mG}). In humans, T_{mG} has the value of 340 milligrams/minute. Absorption occurs in the proximal convoluted tubules. See also **Excretory System**; and **Kidney and Urinary Tract**.

URONIC ACID. Any of a class of compounds similar to sugars but differing from them in that the terminal carbon has been oxidized from an alcohol to carboxyl group. The most common are galacturonic acid and glucuronic acid.

URSA MAJOR (the greater bear). A constellation best known in the United States as the Big Dipper and in England as the Plow or the Wagon. Ursa Major is circumpolar for both Europe and North America, and two of its stars, known as the pointers, are very useful in locating the bright star Polaris, since the line joining them, if extended, will pass close to the celestial pole. The star Mizar (ζ Ursae Majoris) at the bend of the handle of the dipper is an easy visual double star. (See map accompanying entry on **Constellations**.)

URSA MINOR (the smaller bear). A constellation frequently referred to as the Little Dipper. Ursa Minor is best known for the fact that the bright star Polaris at the end of the handle of the asterism is, at present, the closest bright star to the north celestial pole of rotation. (See map accompanying entry on **Constellations**.)

URSINES. See **Bears**.

URTICARIA. Commonly called *hives*, this is an allergic response characterized by the appearance on the skin of firm, elevated, circumscribed lesions, varying from the size of a small pea to several inches in diameter. Usually, the eruption is characterized by intense itching. Each lesion undergoes its own cycle, ranging from redness to swelling, followed by formation of a pink halo, and then gradually fading. Several lesions in different stages of the cycle sometimes give a blotchy appearance to the affected area. Hives may last only several hours, or they may persist for

many months. The condition stems from a variety of causes, some of which are not well understood. In general, urticaria occurs when a hypersensitive individual comes in contact with a specific protein substance. Certain protein foods, serum or blood injections, or certain drugs may cause this type of eruption. Hives of large size, sometimes termed *angioneurotic edema*, may cause secondary problems when certain areas are affected — as impairment of vision when an eyelid may be involved, or impairment of swallowing and breathing where the throat and larynx may be involved. While the most certain route to successful treatment is that of patiently determining the causative substance and then avoiding future contact with it, more immediate measures are required for angioneurotic edema and for alleviating the discomfort where large areas are covered by smaller hives, particularly when present in the groin and on the hands and feet.

Drugs found useful in controlling severe urticaria attacks include epinephrine, aminophylline, intravenous and intramuscular antihistamines, such as diphenylhydramine, and intravenous and intramuscular hydrocortisone. For milder forms of the disease, antihistamines usually suffice. Topical agents include calamine lotion, corticosteroids, or menthol, phenol, and camphor in alcohol. These remedies reduce itching, but do not control the condition.

It is interesting to note that an individual may suddenly develop an allergic reaction in the form of hives to a substance (food, drug, serum, etc.) to which he has been exposed over a number of years without any reaction. In the first occurrence of hives in reaction to a given substance, the hives may not appear for several days after exposure. Subsequent exposures may produce hives within a few minutes or hours. In addition to foods and drugs as offending materials, hives may result from prolonged exposure to light, extremes of heat or cold, animal dander, plants, fungi, bites, and serums. *Papular urticaria* is a form of hives that occurs in young children, normally in the spring, and generally attributed to insects. The eruptions appear mainly on the arms and legs and are small, hard papules.

U.S. GLOBAL CHANGE RESEARCH PROGRAM (USGCRP). The U.S. Global Change Research Program (USGCRP) supports research on the interactions of natural and human-induced changes in the global environment and their implications for society. The USGCRP began as a presidential initiative in 1989 and was codified by Congress in the Global Change Research Act of 1990 (P.L. 101-606) http://www.gcrio.org/gcact1990.html, which mandates development of a coordinated interagency research program. Participants in the USGCRP include:

- Agency for International Development
- Dept. of Agriculture
- Dept. of Commerce, Natl. Oceanic & Atmospheric Admin.
- Dept. of Defense
- Dept. of Energy
- Dept. of Health and Human Services, National Institutes of Health
- Dept. of State
- Dept. of Transportation
- Dept. of the Interior, US Geological Survey
- Environmental Protection Agency
- National Aeronautics & Space Administration
- National Science Foundation
- Smithsonian Institution

The Office of Science and Technology Policy, the Office of Management and Budget, and the Council on Environmental Quality provide oversight on behalf of the Executive Office of the President.

Since its inception, the USGCRP has supported research and observational activities, in collaboration with several other national and international science programs, has documented and characterized important aspects of the sources, abundances, and lifetimes of greenhouse gases; mounted extensive space-based systems for global monitoring of climate and ecosystem parameters; begun to address the complex issues of various aerosol species that may significantly influence climate parameters; advanced understanding of the global water and carbon cycles; and taken major strides in computer modeling of the global climate.

For greater detail, see the Overview of U.S. Research on Climate and Global Change http://www.climatescience.gov/about/overview-a.htm, on the site of the Climate Change Science Program. See also Participating US Agencies and their Programs http://www.usgcrp.gov/usgcrp/agencies/default.htm.

UTTER CHAOS. Since the formative years of science, the precepts of classical mechanics were entrenched firmly in the pursuit of dynamic systems and guided by the unwavering notion that the behavior of complex systems could be predicted accurately provided that one had enough information and intelligence. The concept (or theory) of chaos has challenged this historic approach. The ground rules are changing!

The "sufficient information" doctrine first was challenged at the atomic level by quantum mechanics in the 1920s. In the 1980s, prior tenets received another setback with the emergence of chaos theory. This theory holds that for microscopic or macroscopic systems, tiny variations in initial conditions sometimes may create unexpected, radically different outcomes, seemingly making it impossible to predict fully the behavior of some systems. Perhaps most startling of all, such behavior can arise in relatively simple systems governed by a few uncomplicated equations. Thus, relatively simple or highly complex systems can exhibit chaos. During the course of the first score of years of its existence, chaos theory generated wide interest in academia, but relatively few practical examples. However, quite recently, the science of system dynamics has entered a new era, one that is comparable to the time frame when quantum mechanics was "fleshing out."

A physicist at the Electric Power Research Institute recently observed, "With chaos, we're on the brink of a new classical dynamics and people thought that classical physics was dead." Another scientist has observed, "It's called the curse of dimensionality" — the amount of data you need to understand a system rises exponentially with the system's dimensionality, that is, the number of independent variables or degrees of freedom needed to describe it. Some of the projects involving what we thought would be simple questions have turned out to be very difficult. And, of course, there's the problem of noise. In many cases, it may be very hard to get data sets that are sufficiently tidy for understanding chaos. On the other hand, chaos theory can help us learn the limits of predictability for very complex systems, such as the weather, and may even give us new tools for controlling these systems.

The implications of chaos theory for electric power equipment and networks are both disturbing and exciting. On the one hand, an unsuspected potential for instability may lurk among the operating conditions of systems thought to be well understood. Sudden voltage collapses on power grids, for example, may indicate the presence of underlying chaotic dynamics. On the other hand, understanding chaos may provide unprecedented control over some of the most complex and elusive natural processes, such as combustion, corrosion, and superconductivity.

Researchers observe, "The problem is how to distinguish 'deterministic chaos' from stochastic, or totally random behavior. Chaos has an underlying order, a pattern that's not periodic, but is not completely random

either. In any real system, however, some stochastic processes are also likely to be present as noise. It's like looking for a fuzzy pattern through a fog."

As early as 1899, Jules-Henri Poincaré (France) recognized the possibility for chaotic behavior in dynamics systems. However, it was not until 1961 that the meteorologist, Edward Lorenz, observed the phenomenon when he was attempting to construct a simple computer model of weather on the basis of convection currents in the earth's atmosphere.

Lorenz mapped a three-dimensional pattern (called a butterfly) that commonly appears when plotting chaotic data. The development of chaos science to where it is today is exquisitely summarized: "It took more than a decade and a half for this phenomenological pattern to gain enough recognition to be named and it took even longer for investigation of chaos to earn scientific respectability."

Processes currently under investigation with reference to chaos include fluidized-bed combustion, electric power grids, and chaos as related to fractal geometry.

UVEITIS. Uveitis refers to an inflammation of the middle layer of the eye, the uvea the part of the eye that supplies blood and nutrients to the eye. Any damage to this part of the eye can affect vision. Blood vessels must remain out of the way of the cornea and lens in order for people to have clear vision. When the vessels become irritated or inflamed, blood cells and other matter can leak out and cause cloudiness, blurring, redness and other symptoms.

There are two forms of uveitis:

Anterior uveitis, the most common form, occurs in the iris. It is often associated with autoimmune diseases, such as rheumatoid arthritis and Lupus, and Lyme disease. Anterior uveitis usually occurs in people 20 to 50 years old, and it can affect one or both eyes. It usually lasts a few days to a few weeks even with treatment, and recurrences are common. See also **Lyme Disease**.

Posterior uveitis refers to the inflammation of the uvea that is in the back portion of the eye. Posterior uveitis is often associated with body infections, but many systemic diseases can be the cause. Uveitis is one of the leading causes of blindness in the United States.

It may be caused with an underlying systemic disease, or it may occur as a result of trauma to the eye.

Uveitis can either be acute or chronic. Acute uveitis is a result most often associated with blunt trauma. The chronic form is more often associated with other systemic disorders.

It is important to note, however, that many patients do not have obvious underlying causes for their uveitis and must undergo a comprehensive evaluation to determine the cause, if possible.

Symptoms of uveitis can include pain, redness, sensitivity to light and blurring. It can occur suddenly. Some patients complain of a deep, dull aching of the eye.

The first step in treating uveitis is detection. When treating anterior uveitis, eye care professionals aim at first reducing the inflammation and any discomfort, and second, preventing worsening of the condition. Treatment varies from patient to patient based, of course, on the patient's history and severity of the condition. Frequently, treatment includes the use of a steroid eye medicine to reduce the inflammation, a pain medicine for comfort, and possibly other medicines depending upon other present conditions. Patients are generally re-evaluated by their eye care professional within a range of one to seven days after beginning treatment.

To treat posterior uveitis, the physician must first discover the systemic disease that may be causing the inflammation. Then the disease can be treated. Antiinflammatory medications, steroids, and even in some cases, chemotherapy can help decrease inflammation in the eye.

Posterior uveitis usually lasts much longer than anterior uveitis, continuing for months to years, and it can cause permanent vision loss despite treatment.

As with many vision problems, uveitis can result in other complications such as glaucoma, retinal damage and vision loss if left untreated. Patients with symptoms should consult their eye care professional immediately. See also **Glaucoma**; **Retina**; and **Vision and the Eye**.

V

VACCINATION. Vaccination is the generic term applied to immunization procedures, in the first instance to protect against communicable diseases. Vaccination and immunization are used almost synonymously. The former word derives from vaccinia or cowpox. It was in tribute to Edward Jenner's introduction of vaccination (by vaccinia) against smallpox that Louis Pasteur coined the generic term **vaccine**. In 1796, Jenner achieved his success through the realization that milkmaids who had been exposed to cowpox rarely came down with smallpox, but he did not know that fluid from a cowpox lesion contained what we now term a live, attenuated virus. Pasteur, on the other hand, discovered the microbial origin of putrefaction and infectious diseases. In 1880, he noted further that multiple passages of pathogens through culture media, or, in the case of rabies, through rabbit spinal cords, altered the infectious agent so as to render it avirulent but still capable of evoking an immune response. This protected an animal challenged later with fully virulent microbes. Thus, Jenner and Pasteur each has a legitimate claim to be regarded as the father of immunization. See also **Immunology (The History)**; **Jenner, Edward (1749–1823)**; and **Pasteur, Louis (1822–1895)**.

It had been known for centuries that immunity was specific. An attack of measles protects against measles, not poliomyelitis. In 1890, von Behring and Kitasato discovered antibodies; molecules (later shown to be proteins) present in serum after infection or immunization, which could neutralize toxins of the particular, but not an unrelated, bacterium. When they immunized horses against diphtheria, serum from the horse could be administered to a patient suffering from diphtheria, in some cases neutralizing the diphtheria toxin sufficiently to prevent a fatal outcome. In 1901, von Behring received the first ever Nobel Prize in Medicine for this work on what came to be called passive immunization. See also **Antibody**; **Kitasato, Shibasaburo (1852–1931)**; and **Von Behring, Emil Adolf (1854–1917)**.

Pasteur originally believed that microbes had to be alive to cause immunity. Nevertheless, killed whole-cell bacterial vaccines against cholera, typhoid and plague were introduced as early as 1896, and achieved some measure of protection. The next surprising finding was that animals could generate antibodies not just to infectious microbes but also to the cells of other animals, or even to molecules synthesized by organic chemists, which had never before existed in nature. The overall term **antigen** was used to describe a substance that caused antibody formation, and with which antibodies could react specifically. A later semantic refinement was to refer to antigens when evoking an immune response as "immunogens." The fact that noninfectious entities can be immunogenic means that one can conceive of vaccines that Pasteur never dreamt of, for example, against cancer or against pregnancy, provided that a suitable target antigen can be identified. It is worth noting that pure protein and other nonliving antigens were soon used to ask questions not about protection against infections but about the nature of immune responses and the cells and molecules of the immune system. Before long, an independent discipline of academic immunology flourished and came into its own, far removed from medical microbiology. The rapid development from the 1950s of transplantation immunology, autoimmunity research, tumor immunology and allergology separated mainstream immunology still further from its traditional roots. Indeed, great triumphs such as poliomyelitis and hepatitis vaccines came from virologists and molecular biologists, not immunologists. It is gratifying to record that, over the last decade, leading immunologists have rejoined the fray for new and improved vaccines, spurred on by the devastating impact of human immunodeficiency virus (HIV) and the acquired immune deficiency syndrome (AIDS), as well as by the still unconquered problems of malaria and tuberculosis. Vaccinology is now recognized as a major specialty within the broad umbrella of immunology. See also **Antigen**.

Passive Versus Active Immunization

Passive immunization is the term applied to the transfer, into a person or an animal, of purified antibodies or of serum-containing antibodies (Table 1). In contrast to von Behring's early experimental therapy for diphtheria, horse serum is now rarely used for humans because humans in turn make antibodies to the horse antibody, and serious allergic reactions can occur. Treatment for snake or spider bites represents the exception. Human immunoglobulin or "gamma globulin," on the other hand, has a number of important applications. Regular injections of gamma globulin from pools of certified HIV- and hepatitis B- and C-virus-free serum constitute the standard therapy for agammaglobulinaemia, a condition where children are immunodeficient because of a defect in the bone marrow-derived or B lymphocytes, the white blood cells responsible for antibody formation. Gamma globulin contains antibodies against many microbes circulating in the community. Passive immunization with pooled normal gamma globulin or, preferably, gamma globulin prepared from humans recently immunized with hepatitis A vaccine, is still sometimes used for travelers to countries where water supplies are contaminated and hygienic conditions poor. Active immunization, however, is rapidly replacing this approach. The trouble with passive immunization is that antibodies are catabolysed relatively rapidly, and prophylactic protection lasts only 6–8 weeks.

Human antibodies are still used sometimes for the treatment of severe infections. One area of great potential, still somewhat nascent, is that of specific human monoclonal antibodies. These can be prepared through specialized genetic engineering techniques, or, still in the experimental phase, through fusing a single human antibody-forming cell coming from a recently infected or recently immunized person with a cancer cell, producing a "hybridoma," which can be cultured in the test tube to mass-produce the relevant human antibody. Children with cystic fibrosis or other chronic lung disorders benefit greatly from monoclonal antibodies against respiratory viruses.

Production of monoclonal antibodies is much more established for cells coming from the mouse. There are also genetic engineering techniques for "humanizing" monoclonal antibodies, that is, for retaining the specific antibody-combining site from the mouse antibody molecule but ensuring that most of the rest of the molecule is human-like. This materially reduces the tendency for the monoclonal antibody to cause antibody production against itself. Injection of such monoclonal antibodies into humans is now in use for a number of purposes that cannot really be called passive immunization, because infection is not involved. Examples include inhibition of kidney transplant rejection, neutralization of powerful inflammatory molecules in rheumatoid arthritis and prevention of platelet aggregation in threatened heart attacks.

Active immunization or vaccination is the term used for those procedures that seek to provoke an immune response in a person or animal resembling the immune response to an infection itself, or in some cases even improving on it. A key difference from passive immunization is the fact that many of the specific lymphocyte cells involved are very long-lived. This means that immunity lasts much longer than following passive immunization. Furthermore, one facet of active immune responses is the fact that a second exposure to the antigen in question provokes a more vigorous immune response than the first, the so-called *booster effect*. This means that when a virus such as measles enters the body of a person already immune to measles, any of the few viruses that survive neutralization by antibody immediately excite the prearmed lymphocytes and are then

TABLE 1. PASSIVE VERSUS ACTIVE IMMUNIZATION

Feature	Passive immunization	Active immunization
Agent used	Serum-containing antibodies, or purified antibody molecules	An antigen or antigens, living or dead
Duration of resulting immunity	Weeks	Years
Effect on immune system	Nil on first use. Repeated use of horse serum can cause allergy	Priming so that reexposure to antigen gives a booster response
Mechanism of action	Antibody molecules from the immune donor give temporary protection	B lymphocytes are induced to form antibodies and T lymphocytes are activated to mount a defensive inflammatory response

promptly destroyed before infection can become established. From a practical viewpoint, active immunization can protect for years or even for a lifetime if the correct schedule of infant and childhood immunizations is followed. For some diseases, booster doses of vaccine are needed in adult life, and the whole area of adult active immunization is now receiving much more attention, particularly for the aged and for pregnant women. In the latter case, the purpose is to produce antibodies in the mother's serum that pass, via the placenta, into the fetal circulation, thus protecting the newborn. Prophylaxis of neonatal tetanus in developing countries is a particularly important example, but there are also enthusiasts for the approach for the prevention of a variety of uncommon but serious neonatal viral and bacterial infections in industrialized countries.

In active immunization, the production of antibodies is not the only goal. A second major limb of the immune system depends on thymus-derived or T lymphocytes. T-cell immunity is particularly important for the conquest of infectious agents that live inside cells, such as tuberculosis, leprosy and certain parasites. A variety of T cells, termed a cytotoxic T cell, is especially important for the control of virus infections. A key goal of current vaccinology research is to learn more about how to guide the immune responses that various vaccines evoke into the most appropriate balance of B-cell and T-cell immunity.

Apart from passive and active immunization, there is a third procedure termed adoptive immunization. This involves the transfer of lymphocyte cells from an immunized to an unimmunized animal. Adoptive immunization has been an important research tool and has illuminated many facets of our understanding of the cellular basis of immunity, but it is not used in clinical medicine. On the other hand, the related field of bone marrow transplantation, which seeks to reconstitute a destroyed immune system, has a number of important applications.

See also **Anthrax**; **Chickenpox**; **Diphtheria**; **Liver**; **Influenza**; **Lyme Disease**; **Measles**; **Meningitis**; **Mumps**; **Pertussis (Whooping Cough)**; **Poliomyelitis**; **Rubella**; and **Tetanus**.

Prophylactic Versus Therapeutic Immunization

Overwhelmingly, the most common use of vaccination is for the prevention of disease. This means immunizing healthy individuals to prevent them from getting a serious infection. However, apart from the examples of therapeutic passive immunization, there are cases where a vaccine is used in a person who has already become infected. The best-known example is rabies. Individuals bitten by a rabid dog are given multiple doses of the rabies vaccine. This disease has a long incubation period; the idea is to get many lymphocytes activated before the virulent virus has had a chance to multiply extensively, thus aborting the infection. There are experimental examples of therapeutic anti-HIV vaccines that, it is hoped, may be able to strengthen the immune response, particularly the T-cell response, that, in conjunction with drug therapy, the virus could be controlled. Other infections have the capacity to lie dormant in the body but to break out from time to time. Herpes is a good example, and *Herpes simplex* type 2, the cause of genital herpes, represents a painful and distressing affliction. In this case, the purpose of therapeutic immunization would be to prevent or lower the frequency or severity of recurrent attacks. Several pharmaceutical firms are experimenting with such vaccines. In cases of leprosy, the immune system sometimes fails, and in India a therapeutic leprosy vaccine to strengthen the immunity of the patient is in an advanced stage of trial. See also **Acquired Immune Deficiency Syndrome (AIDS)**; **Leprosy**; and **Rabies**.

Other examples of therapeutic vaccines are in the field of cancer, where the aim is to strengthen the T-cell attack against molecules confined to, or overexpressed in, the cancer cell as opposed to normal tissue. Malignant melanoma is one cancer in which some limited success has been achieved. There are also examples of passive immunization in cancer, either with monoclonal antibodies *per se*, or with antibodies to which toxic molecules have been covalently conjugated. These so-called *immunotoxins* achieve a higher concentration of the toxic material on or in the cancer cell than in healthy tissues. A variation in the theme is to use a radioactive isotope rather than a toxin. This approach has achieved some success with minimal residual disease; that is, microscopic deposits of cancer cells that have moved from the site of origin into tissues such as the bone marrow or liver. Statistical reduction in recurrences has been noted in cancer of the colon and rectum, and breast cancer. Another area where some limited success has been achieved is in lymphomas of B lymphocytes. See also **Melanoma**.

Types of Vaccines

Table 2 summarizes the wide diversity of types of vaccines. Perhaps easiest to understand are the earliest vaccines used by Jenner and Pasteur, where a virulent microorganism has its teeth drawn but can still multiply in the human host and thus provide a powerful stimulus to the immune system. Some of the most successful vaccines belong to this category. The advantages include strength of the immune response, duration of immunity and relative infrequency of administration (with the exception of poliomyelitis). There are two chief disadvantages. Firstly, the living agent may cause a "miniversion" of the disease; for example, occasionally the measles vaccine may cause a mild fever and rash, which are trivial in healthy children but can be serious in any situation of immune deficiency, be this congenital, acquired or iatrogenic, for example, due to cancer chemotherapy. Secondly, and fortunately very rarely, the attenuated strain may mutate and revert to virulence. For example, the Sabin vaccine can actually cause paralytic poliomyelitis once for every 2.7 million doses used. See also **Poliomyelitis**; and **Vaccines**.

Adjuvants

Most pure proteins are not particularly immunogenic following subcutaneous or intramuscular injection. For this reason, a variety of processes have been devised over the past 70 years to increase immune responses to them. The term adjuvant is used to describe substances or formulations that have this capacity. Some adjuvants are listed in Table 3. A classification of adjuvants is difficult because in practice many adjuvants make use of several different principles.

The first adjuvant used, and in some countries still the only one licensed for humans, is alum precipitation. With the use of aluminium hydroxide or aluminium phosphate, the antigen in question becomes incorporated into or bound on to a gel-like precipitate consisting of particles 0.1–1 μm in diameter. Good antibody production follows this approach, but the T-cell response is less satisfactory.

Polymerization is another way of rendering antigens attractive to the dendritic cells, which are responsible for presenting antigen to lymphocytes, and thus for initiating the immune response. For example, the surface antigen of the hepatitis B virus self-assembles into a virus-like particle. An elaboration of this principle is the well-known adjuvant Immune Stimulating COMplex (ISCOM). ISCOMs consist of submicron particles that are formed when the virus is treated with saponin. An

TABLE 2. TYPES OF VACCINES

Type	Examples
Live-attenuated microorganisms	Measles, mumps, rubella
	Sabin oral poliomyelitis vaccine
	Bacille Calmette–Guérin (BCG) for tuberculosis
	Vaccine for rotavirus diarrhea
	Yellow fever vaccine
Killed microorganisms	Standard whole-cell pertussis vaccine
	Influenza vaccine
	Salk injectable poliomyelitis vaccine
Antitoxin vaccines	Diphtheria toxoid
	Tetanus toxoid
Subunit vaccines: protein	Acellular pertussis vaccine
Subunit vaccines: carbohydrate	Pneumococcal vaccine
	Some meningitis vaccines
Subunit vaccines: carbohydrate–protein conjugate	*Hemophilus influenza* B
	Experimental pneumococcal vaccines
Subunit vaccines: peptide	Experimental HIV, malaria and melanoma vaccines
Vectored vaccines	Experimental vaccines for numerous diseases, including HIV, malaria and various diarrhoeal diseases
Nucleic acid vaccines	Experimental vaccines for numerous diseases, including HIV and influenza
Edible vaccines	Experimental vaccines, e.g., for hepatitis B and enterotoxigenic *Escherichia coli*
Transdermal vaccines	Experimental vaccines delivered through the skin and including an adjuvant substance
Mucosal vaccines	Vaccines delivered via a mucous membrane, e.g. intranasally or orally. One licensed cholera vaccine works this way

TABLE 3. SOME APPROACHES TO INCREASING THE IMMUNOGENICITY OF ANTIGENS

Rendering antigens particulate
Polymers and polymerization of antigens
Emulsions and other adjuvant formulations
Microencapsulation
Bacteria and bacterial products
Other chemical adjuvants
Synthetic CpG oligodeoxynucleotides
Cytokines
Agents targeting antigens to scavenger cells
Mucosal adjuvants

ISCOM consists essentially of cholesterol, saponin, phospholipid and viral envelope proteins. These cage-like structures can be used as general adjuvants to which other proteins can be associated. Saponins derived from the South American tree *Quillaia saponaria* are particularly effective. Semipurified and purified derivatives have also been prepared. ISCOMs promote antibody formation and T-cell immunity. See also **Hepatitis Viruses**.

Promoting slow antigen release can aid immune induction. This was one of the ideas behind the work of Freund, who created adjuvants still in use experimentally, although not clinically. Incomplete Freund's adjuvant consists of antigen in tiny watery droplets embedded in an oily emulsion, using mineral oil. The much stronger complete Freund's adjuvant made use of the fact that bacteria have adjuvant properties. It was a water-in-oil emulsion to which killed tubercle bacilli were added. Local reactions were too severe to permit clinical use. Oil-in-water emulsions can also be used, for example, Chiron's adjuvant MF 59, which has undergone extensive clinical trials and is now in routine use in Italy.

Microencapsulation offers the hope of both particulate nature and slow release. The maximum work has been performed on biodegradable microcapsules containing antigen, the polymer poly (lactide-co-glycolide) being used as the coating because its safety as a biodegradable suture material had been established. It is possible to vary the rate of degradation of the microcapsule, and thus the time of antigen release, both by varying the polymer chain length and the ratio of lactide to glycolide. In the long term, capsules releasing their contents at different times might achieve an effect similar to booster injections. Mixtures of capsules could constitute a "one-shot" vaccine.

In experimental immunology, bacteria other than mycobacteria have been used as adjuvants. These include *Bordetella pertussis* and *Corynebacterium parvum*. Even parasite materials, such as extracts of *Nippostrongylus brasiliensis*, have been used. It has proven difficult to extract entirely nontoxic molecules from bacteria to produce pure adjuvant substances. The best-known examples are *N*-acetyl-muramyl-l-analyl-d-isoglutamine, or muramyl dipeptide for short; and monophosphoryl lipid A from the lipopolysaccharide endotoxins of Gram-negative bacteria.

There are many other chemicals that have been used as immunopotentiators. These include the polynucleotides poly-I:C and poly-A:U; dextran sulfate; carbohydrate polymers such as mannan; polyphosphazines and a protein from *Leishmania*, LeIF. Some of these are under active development by biotechnology companies.

Special mention must be made of a very powerful T-cell adjuvant, namely synthetic oligodeoxynucleotides (ODN) containing unmethylated CpG motifs. Such sequences are common in bacterial genes but are rare in mammalian DNA. It turns out that a very primitive pattern-recognition system, present even in invertebrates, can recognize these motifs via a receptor known as toll-like receptor 9 (TLR9). This receptor is present in dendritic scavenger cells, and when it encounters CpG-ODN, the cell becomes activated and ready to initiate the immune cascade.

As already mentioned, cytokines can act as adjuvants under some circumstances. They can stimulate antigen-presenting cells and lymphocytes, and they can guide the immune response in different directions, for example, more B-cell or more T-cell immunity, and even towards different subsets of T cells. Many cytokines are, unfortunately, rather toxic, obviously depending on dose. Among the cytokines of greatest interest in this regard are granulocyte-macrophage colony-stimulating factor (GM-CSF) and FLT-3 ligand, substances that stimulate different subtypes of dendritic cells, and IL-12, which powerfully promotes one type of T-cell activity. See also **Cytokines**; and **Interleukins**.

The molecular targeting of antigens is another active research area. For example, antigen-presenting cells have certain specific receptor molecules on their surface. One is for a portion of the antibody molecule known as the Fc piece. Another is for a serum protein known as C3d, which becomes attached to invading bacteria or viruses under some circumstances. If either Fc or C3d is covalently attached to a protein antigen, its immunogenicity can be enhanced 1000-fold or more because the protein goes straight to the antigen-presenting cell rather than diffusing randomly throughout the tissues.

Mucosal adjuvants represent an important, if somewhat obscure, category of substances. It has been estimated that the combined surface area

of the mucosas of the gastrointestinal, respiratory and urogenital tracts is 400 m^2. There are more lymphocytes within and close to the mucosa than in the rest of the body. Mucosal immunity is clearly important in preventing entry of pathogens via mucosal surfaces. Mucosal adjuvants are substances that enhance uptake of antigen by mucosal lymphoid tissue, particularly dendritic cells. Liposomes or biodegradable microspheres can act as mucosal adjuvants. Bacterial products capable of binding tightly to cell walls are important; cholera toxin is the most powerful known mucosal adjuvant but is too toxic to be of practical use. The B subunit of cholera toxin lacks toxicity but retains at least part of the adjuvant property. Genetic modification of cholera or *E. coli* toxins to retain structure but lose toxicity has resulted in molecules such as CTK 63 and LTK 63, which are in advanced preclinical research as mucosal adjuvants. Covalent coupling of mucosal adjuvants to the antigen in question can enhance mucosal immunity. See also **Liposomes**.

Vaccine Side Effects

Adverse effects of vaccines need to be taken very seriously. First, vaccines are normally given to healthy individuals for the prevention of a disease they may or may not get in the future; it is essential that the prophylaxis does not make them sick. Second, many vaccines are given to vulnerable infants. Third, in the industrialized countries, epidemics are now infrequent and some parents are skeptical about the benefits of vaccines. Fortunately, serious adverse events are rare. We have mentioned the occurrence of reversion to neurovirulence of the Sabin poliomyelitis vaccine once for 2.7 million doses used, mostly in subjects receiving their first dose and usually involving type 3 poliovirus. In the United States, it is now recommended that infants receive two doses of injectable Salk vaccine followed by either two oral or two more injectable doses. In some other countries, injectable polio vaccine is making a comeback because formulations including this plus diphtheria–pertussis–tetanus (DPT) vaccine plus *Hemophilus influenza* B are becoming available as a single injection.

The most controversial vaccine from the viewpoint of side effects has been whole-cell pertussis as part of DPT. Reactions such as fever, irritability, local redness, pain and swelling are quite common and can be easily ameliorated by a drug such as paracetamol. Febrile convulsions occur in one case in 2,000–3,000. The possibility of a serious acute neurological illness, for example, encephalopathy, has been raised. One British study, since withdrawn after reanalysis of the data, put the incidence at one per 320,000. A major survey by the US Institute of Medicine concluded that it was possible that all cases of encephalopathy following pertussis immunization were coincidental, and the maximum possible complication rate in this study was one in 200,000. The acellular, subunit pertussis vaccine is certainly less reactogenic. It is not yet clear whether the alleged serious side reactions will be less frequent — a nearly impossible question to pose as it is not certain that they exist!

Mild measles rash can follow the measles vaccine. Rare febrile convulsions have been noted. A temporary deficiency of blood platelets (thrombocytopenia) has been seen in one per half million cases for the measles vaccine alone, and one in 105,000 cases in a study with the combined measles–mumps–rubella vaccine. The mumps vaccine very occasionally causes aseptic meningitis; this was more of a problem with an early variant than with the present vaccine strain. See also **Measles**.

Vaccinia was a reasonably reactogenic vaccine and the generalized vaccinia in immunodeficient or immunosuppressed children was quite dangerous. Now that smallpox has been eradicated, vaccinia is no longer used. If it returns as a vector, it is likely that less reactogenic strains will be used.

Other rarely reported adverse events from vaccines include abscess formation, serious allergic reactions or acute arthritis. These serious complications occur less than one time per 100,000. In summary, vaccines are extremely safe. This does not prevent claims of disastrous consequences, which simply have to be carefully examined on a case-by-case basis.

The hazards, real or conjectural, have to be weighed against the incredible benefits of vaccines, including the eradication of smallpox, the elimination of poliomyelitis from most countries in the world and its likely eradication within a few years, and the dramatic lowering of incidence of diseases like diphtheria, pertussis, tetanus, measles, mumps, rubella, infantile tuberculosis and one form of meningitis. The Global Programme for Vaccines and Immunization of the World Health Organization seeks to bring the common childhood vaccines to the total birth cohort of about 130,000,000 infants born worldwide each year. It has achieved some notable successes but still needs further support to achieve its goals.

Scope of Immunization

Immunization is established for viral and bacterial diseases, but not yet for human parasitic diseases. Considerable work is going on in malaria and schistosomiasis. The scope of research extends beyond infectious diseases, as shown in Table 4. This table is by no means exhaustive. One note to introduce is that antigens can, under some circumstances, reduce immune responses rather than inducing them. Examples include intravenous injection of aggregate-free antigen or feeding of antigen without a mucosal adjuvant. So far, attempts to treat autoimmune diseases by such negative vaccines have been disappointing, but it is early days yet. The field of cancer immunology is an enormous one. Suffice it to record here that vaccination against microorganisms that can cause cancer is already proving to be an effective strategy (e.g. the prevention of primary hepatocellular carcinoma by the hepatitis B vaccine), but approaches seeking to treat established cancers are still in the experimental stage. Allergy is another controversial area, but the pace of research with genetically engineered proteins from allergens is accelerating. Birth control vaccines remain a promising avenue for the future. As knowledge of immunoregulation increases and as adjuvants become more predictable in their effects, the scope of immunization will doubtless increase further. Finding the resources to bring the fruits of the present and impending

TABLE 4. IMMUNIZATION APPROACHES TO CANCER, OTHER DISEASES AND BIRTH CONTROL

Type of disease or other pu1	Antigens	Status
Cancer as an end result of chronic infection	*Hepatitis B virus*	Established vaccine
	Hepatitis C virus	In clinical trial
	Helicobacter pylori	In clinical trial
	Human papilloma virus	In clinical trial
	Epstein–Barr virus	In clinical trial
Cancers displaying tumor-specific or tumor-associated antigens	MAGE peptides and related	In clinical trial
Malignant melanoma	Cellular extracts	In clinical trial
Colorectal and breast	Muc-1 protein or peptides	In clinical trial
B-cell lymphomas	B-cell surface antigens, e.g. CD19 or CD20	Passive antibodies or immunotoxins in clinical use
Autoimmune diseases	Various oral antigens to engender a negative immune response	Clinical trials in multiple sclerosis and rheumatoid arthritis have been disappointing so far
Autoimmune diseases	Multivalent B-cell paralyzing antigens	In clinical trial
Allergy	Extracts of allergens or pure proteins/peptides from allergens, usually multiple injections	Desensitization of proven value for honeybee venom, more speculative in other cases
Birth control	Human chronic gonadotrophin	Proven in phase II clinical trial
	Sperm antigen SAGA-1	In clinical trial
	Other antigens of sperm or oocyte	In late preclinical research

revolution in vaccinology to all the world's citizens remains a major challenge. See also **Allergens**; and **Allergy**.

VACCINES. A preparation which on injection will induce and active immunity in the body. Vaccines are made up of dead or attenuated infectious agents, bacteria or viruses, and each one is specific: the intracutaneous inoculation of tetanus vaccine protects the individual against tetanus, and the rabies vaccine protects against rabies, etc.

Perhaps the greatest success story in public health is the reduction of infectious diseases resulting from the use of vaccines. Routine immunization has eradicated smallpox from the globe and led to the near elimination of wild polio virus. Vaccines have reduced preventable infectious diseases to an all-time low and now few people experience the devastating effects of measles, pertussis and other illnesses. Prior to approval by the Food and Drug Administration (FDA), vaccines are extensively tested by scientists to ensure that they are effective and safe. Vaccines are the best defense we have against infectious diseases. However, no vaccine is 100% safe or effective. Differences in the way individual immune systems react to a vaccine account for rare occasions when people are not protected following immunization or when they experience side effects.

As infectious diseases continue to decline, some people have become less interested in the consequences of preventable illnesses like diphtheria and tetanus. Instead, they have become increasingly concerned about the risks associated with vaccines. After all, vaccines are given to healthy individuals, many of whom are children, and therefore a high standard of safety is required. Since vaccination is such a common and memorable event, any illness following immunization may be attributed to the vaccine. While some of these reactions may be caused by the vaccine, many of them are unrelated events that occur after vaccination by coincidence. Therefore, the scientific research that attempts to distinguish true vaccine side effects from unrelated, chance occurrences is crucial. This knowledge is necessary in order to maintain public confidence in immunization programs. As science continues to advance, we are constantly striving to develop safer vaccines and improve delivery in order to better protect ourselves against disease.

More than two hundred years ago, Edward Jenner, a country physician practicing in England, noted that milkmaids rarely suffered form smallpox, a disease that was known to kill up to 40 percent of those who contracted it. The milkmaids often did get cowpox, a related but far less serious disease, and those who did, never became ill with smallpox. In an experiment that was to prove a revelation, Jenner took a few drops of fluid from a skin sore of a woman who had cowpox and injected the fluid into the arm of healthy young boy who had never had cowpox or smallpox. Six weeks later, Jenner injected the boy with fluid from a smallpox sore, but the boy remained free of the dreaded smallpox. Dr. Jenner had discovered one of the fundamental principles of immunization. He had used a relatively harmless foreign substance to evoke an immune response that would protect someone from a disease-causing *microbe*.

In those days, a million people died from smallpox each year in Europe alone, most of them children. Those who survived were often left with grim reminders of their ordeals: blindness, deep scars, deformities. When Jenner laid the foundation for modern vaccines in 1796, he started on a course that would ease the suffering of people around the world. By the beginning of this century, vaccines for rabies, diphtheria, typhoid fever and plague were in use, in addition to the vaccine for smallpox.

Yet vaccination was not immediately accepted. The idea of deliberately introducing a potentially harmful microbe into people was met with suspicion and even outrage by many in the medical and scientific communities and public opinion was bitterly divided over the merits of vaccination. It took some time to convince people that the benefits of vaccination outweigh the few risks. Today vaccines are far safer and more protective than those early vaccines. And as science advances, we are developing even better vaccines to protect ourselves from disease.

Benefits

Disease prevention is the key to public health. Vaccines benefit in particular the people who receive them, and in turn those people cannot spread disease to others who have not been vaccinated. Infection cannot spread if it never gains a foothold. Infectious diseases cause enormous suffering, strain the capabilities of our health care system, and deplete financial resources. For the individual, the health care provider, and in the interest of conserving human and financial resources, it is always better to prevent a disease than to treat it.

Veterinary vaccines benefit people, too. Some diseases, such as rabies, anthrax, certain types of encephalitis, and Rift Valley fever, are readily transmissible from animal species to humans. In many instances, livestock and pets are vaccinated not only for their own health, but also for that of their owners.

In the United States, federal and state public health programs help assure that children receive vaccines. Many childhood diseases that were a normal part of growing up just 50 years ago are now preventable. Measles, rubella (German measles), mumps, pertussis, (whooping cough), and chickenpox were almost unavoidable. Most people did not reach adulthood without their families or circle of friends being touched by a serious illness or death caused by an infectious disease. For the most part, children suffered through the course of the disease and were left with *naturally acquired immunity*, some schoolwork to catch up on, and perhaps a little pockmark somewhere on their skin. However, in some cases, children died, or they were left with permanent loss of hearing or sight or other tragic effects of serious infections.

Adult Immunization

Although most of us receive the great majority of our immunizations during childhood, it is important to remember that vaccines are not just for young children. Adolescents and adults should keep up-to-date on tetanus and diphtheria immunizations. Adults, who have not had diseases such as measles or chickenpox during childhood, or the vaccines to prevent them, should consider being immunized. Ironically, childhood diseases such as measles, mumps, and chickenpox can be far more serious in adults.

People who travel overseas should determine, together with their physicians or at international travel clinics, which vaccines would be appropriate based on their destinations. Effective vaccines are available to prevent yellow fever, polio, typhoid fever, hepatitis A, cholera, and other bacterial and viral diseases that are more prevalent abroad than in the United States.

Each year, as we prepare for winter and the flu season, many adults should consider the benefits of the flu vaccine. In addition to flu vaccine, immunizations for pneumococcal pneumonia, hepatitis A, and hepatitis B are recommended for people who may be at risk.

Evaluating a Vaccine

Variations in individuals and their immune systems are many and subtle; thus no vaccine is totally effective. In the United States, a vaccine is approved for general use if it fulfills several stringent requirements.

- The vaccine must be safe. Although it is quite unlikely that a vaccine will ever be 100 percent safe, it must produce *protective immunity* with only minimal side effects (such as redness and soreness at the vaccination site) for the overwhelming majority of those who receive it. More discomfort

in side effects can be acceptable, however, depending upon the severity of the disease the vaccine is designed to prevent. For example, most people would consider vaccine side effects that mimicked the symptoms of a bad cold acceptable if the vaccine protected them from HIV disease.

- The vaccine must be *immunogenic*, that is, it must cause a strong and measurable immune response. Vaccines usually contain *antigens*, bits of material, sometime form the disease-causing microbe itself, which can stimulate the immune system to respond and fight off a potential infection. When a vaccine is immunogenic, it primes the recipient's immune system to recognize the disease-causing microbe and launch a counterattack before illness can occur. In addition, the vaccine must induce the right type of immunity. When microbes invade, they cause disease in different ways, and different parts of the immune system respond to fight them. Vaccines must stimulate the specific parts of the immune system that protect against a particular kind of organism.
- The vaccine must be stable during its shelf life, that is to say, its *potency* must remain at the proper level for the vaccine to evoke an immune response. Many *inactivated vaccines* are simple to store, since they are in powdered form and are reconstituted with the appropriate fluid before they are given. *Live*, *attenuated vaccines*, however, require refrigeration from manufacturer to clinic to maintain stability and potency.

All approaches to vaccine development focus on the immune system and the body's natural defenses against foreign invaders. To understand something of how vaccines work, it is best to start with the immune system. See **The Immune System** discussed later in the entry. Together, your immune system and vaccines are powerful allies in the fight against disease.

Protection Against Microbes

The body has an arsenal of defenses that it uses to ward off foreign invaders. Healthy immune systems recognize as foreign many things that are not self.

Most of the foreign invaders that confront the human immune system are microscopic. Fungi, parasites, bacteria, and viruses populate our planet in far greater numbers than any other living organisms. Some are beneficial. We coexist quite happily with certain types of bacteria that live in our gastrointestinal and genital tracts. These bacteria help prevent infection by harmful organisms. We are even dependent on some microorganisms that inhabit our gastrointestinal tracts for their help in digesting food. Whether beneficial or harmful, however, all foreign microbes in the human body display special markers on antigens called *antigenic determinants* or *epitopes*. It is these antigens and their determinants that the immune system may recognize as harmful and identify for destruction.

The Immune System

Organs of the Immune System. The immune system is complex of organs — highly specialized cells and even a circulatory system separate from blood vessels — all of which work together to clear infection.

The organs of the immune system, positioned throughout the body, are called *lymphoid organs*. The word "lymph" in Greek means a pure, clear stream — and appropriate description considering its appearance and the purpose of our immune system.

Lymphatic vessels and *lymph nodes* are the parts of the special circulatory system that carries lymph, a transparent fluid containing white blood cells, chiefly *lymphocytes*. Lymph bathes the tissues of the body, and the lymphatic vessels collect and move it eventually back into the blood circulation. Lymph nodes dot the network of lymphatic vessels and provide meeting grounds for the immune system cells that defend against invaders. The *spleen*, at the upper left of the abdomen, is also a staging ground and a place where immune system cells confront foreign microbes. Both immune cells and foreign molecules enter the lymph nodes via blood vessels or lymphatic system and eventually return to the bloodstream. Once in the bloodstream, lymphocytes are transported to tissues throughout the body, where they act as sentries on the lookout for foreign antigens.

How the Immune System Works. Cells will grow into the many types of more specialized cells that circulate throughout the immune system are produced in the bone marrow. This nutrient-rich, spongy tissue is found in the center shafts of certain long, flat bones of the body, such as the bones of the pelvis. The cells most relevant for understanding vaccines are the lymphocytes, numbering close to one trillion.

The two major classes of lymphocytes are *B cells*, which grow to maturity in the bone marrow, and *T cells*, which mature in the thymus, high in the chest behind the breastbone.

B cells produce *antibodies* that circulate in the blood lymph streams and attach to foreign antigens to mark them for destruction by other immune cells. B cells are part of what is known as *antibody-mediated* or *humoral immunity*, so called because the antibodies circulate in the blood and lymph, which the ancient Greeks called, the body's "humors." Certain T cells, which also patrol the blood and lymph for foreign invaders, can do more than mark the antigens; they attack and destroy diseased cells they recognize as foreign. T cell lymphocytes are responsible for *cell-mediated immunity* (or *cellular immunity*). T cells also orchestrate, regulate and coordinate the overall immune response. T cells depend on unique cell surface molecules called the *major histocompatibility complex* (MHC) to help them recognize antigen fragments.

Antibodies. The antibodies that B cells produce are basic templates with a special region that is highly specific to target a given antigen. Much like a car coming off a production line, the antibody's frame remains constant, but through chemical and cellular messages, the immune system selects a green sedan, a red convertible or a white truck to combat this particular invader. However, in contrast to cars, the variety of antibodies is very large. Different antibodies are destined for different purposes. Some coat the foreign invaders to make them attractive to the circulating scavenger cells, *phagocytes*, which will engulf an unwelcome microbe. When some antibodies combine with antigens, they activate a cascade of nine proteins, known as *complement*, that have been circulating in inactive form in the blood. Complement forms a partnership with antibodies, once they have reacted with antigen, to help destroy invaders and remove them form the body. Still other types of antibodies block viruses for entering cells.

T Cells. T cells have two major roles in immune defense. Regulatory T cells are essential for orchestrating the response of an elaborate system of different types of immune cells. *Helper T cells*, for example, also known as CD4 positive T cells (CD4+ T cells), alert B cells to start making antibodies; they also can activate other T cells and immune system scavenger cells called *macrophages* and influence which type of antibody is produced. Certain T cells, called CD8 positive T cells (CD8+ T cells), can become killer cells that attack and destroy infected cells. The *killer T cells* are also called *cytotoxic T cells* or CTLs (cytotoxic lymphocytes).

Naturally Acquired Immunity. As early as 2500 years ago in Greece, some people understood enough about contagion to know that a person who had recovered from plague would not get it again. Later, physicians recognized that a person acquires immunity to many diseases in this way.

This protection comes for another special cell of the immune system. Whenever B cells and T cells are summoned, they transform some of their numbers into *memory cells*. Although the army of antibodies necessary to destroy an infectious agent does not remain, the memory cells do. If the memory cells recognize the invader again, the immune system quickly mounts a defense and defeats the interlopers before illness can occur. This type of immunity is naturally acquired. Most of us benefit from naturally acquired immunity from our earliest days. Certain types of immune cells are passed form mother to fetus during pregnancy. Thus, most newborns, though vulnerable in many ways, have a head start in fighting disease.

Artificially Acquired Immunity. Artificially acquired immunity can be either passive or active. Artificially acquired passive immunity results when antibodies produced by another animal or human are given to someone to prevent or treat disease. For example, administering tetanus antitoxin or rabies immune globulin to someone is a way of conferring passive immunity. This type of immunization is effective very quickly, but since it lasts only a short time, it is used to protect people when they are particularly vulnerable, such as immediately after exposure to a serious disease.

Artificially acquired active immunity is achieved through safe and effective vaccines. Traditional vaccines are preparations of killed or weakened bacteria or viruses, or parts of these microbes, or *inactivated toxins* from the disease-causing agent. Recently, innovative vaccine technologies have revealed many more ways to give people active immunity to a disease. These include *subunit vaccines*, *conjugate vaccines* and *naked DNA vaccines*.

Different Types of Vaccines

When a new disease emerges or a familiar one becomes a more significant health threat than it has been in the past, scientists, physicians and public health workers recognize the need for a new way to prevent the disease. Once scientists have identified the organism or toxin that causes the illness, they pursue a number of approaches to develop a vaccine.

Vaccine development has its early roots in the work of Edward Jenner, who discovered how to protect people from smallpox, and Louis Pasteur, who developed a vaccine to protect from rabies. Those pioneering efforts subsequently led to vaccines for diseases that once claimed millions of lives worldwide.

The purpose of a vaccine is to bring about active immunity by provoking a response from a person's immune system — marshaling B and T cells to swing into action — and creating a memory within the immune system so that exposure to the active disease agent will stimulate an already primed immune system to fight the disease. Some vaccines are combinations that protect against several diseases. Most of us are familiar with the DTP (diphtheria, tetanus, pertussis) and MMR (measles, mumps, rubella) vaccines that children in the United States receive. Scientists extensively test these combination vaccines to make sure that none of the antigens detracts from the immune priming effect of the others. Thus the vaccines can provide triple protection, the recipients are spared extra needle sticks, and the public health costs are reduced.

Vaccines Licensed in the United States include:

- Adenovirus vaccine.
- Anthrax vaccine.
- Bacille Calmette-Guérin vaccine.
- Cholera vaccine.
- Diphtheria toxoid.
- Diphtheria and tetanus toxoids (DT).
- Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTP).
- Diphtheria and tetanus toxoids and whole cell pertussis vaccine.
- Diphtheria and tetanus toxoids and pertussis and *Haemophilus influenzae* b (Hib) conjugate vaccine.
- Hib conjugate vaccine (with diphtheria, meningococcal, and tetanus conjugates).
- Hepatitis A vaccine.
- Hepatitis B vaccine.
- Influenza virus vaccine.
- Japanese encephalitis virus vaccine.
- Measles virus vaccine.
- Measles and mumps virus vaccine.
- Measles, mumps, and rubella virus vaccine (MMR).
- Meningococcal vaccine, Group A.
- Meningococcal vaccine, Group C.
- Meningococcal vaccine, Groups A and C.
- Meningococcal vaccine, Groups A, C, Y, and W-135.
- Mumps virus vaccine.
- Pertussis vaccine (acellular).
- Pertussis vaccine (whole cell).
- Plague vaccine.
- Pneumococcal vaccine.
- Poliovirus vaccine — inactivated
- Poliovirus vaccine — live, attenuated.
- Rabies vaccine.
- Smallpox vaccine.
- Tetanus toxoid.
- Typhoid vaccine.
- Varicella (chickenpox) virus vaccine.
- Yellow fever vaccine.

Based on the biological and chemical characteristics of the disease-causing agent and on what type of immunity is desired, researchers begin to develop one of the following types of vaccines. Vaccines can be produced from 10 inactivated (killed), 2) live, attenuated (weakened), or 3) synthetic (laboratory-made) microbial materials.

Traditional Vaccines

Inactivated Vaccines. Inactivated vaccines are produced by killing the disease-causing microorganism with chemicals or heat. Such vaccines are stable and safe; they cannot revert to the *virulent* (disease-causing) form. They often do not require refrigeration, a quality that makes them accessible to the people of many developing countries, as well as practical for vaccinating people who are highly mobile, such as members of the armed forces. However, most inactivated vaccines stimulate a relatively weak immune response and must be given more than once. A vaccine that requires several doses (boosters) has a limited usefulness, especially in areas where people have less access to regular health care.

The flu shot is an inactivated vaccine, as are the vaccines for cholera, plague, and hepatitis A.

Live, Attenuated Vaccines. To make a live, attenuated vaccine, the disease-causing organism is grown under special laboratory conditions that cause it to lose its virulence, or disease-causing properties. Although live vaccines require special handling and storage in order to maintain their potency, they produce both antibody-mediated and cell-mediated immunity and generally require only one boost, or additional dose. Most live vaccines are injected; some, however, such as the polio vaccine, administered in the nose, show promise in preventing flu.

While there are advantages to live vaccines, there is one caution. It is the nature of living things to change, to *mutate*, and the organisms used in live vaccines are no different. There is a remote possibility that the organism may revert to a virulent form and cause disease. It is for this reason that live vaccines continue to be carefully tested and monitored.

For their own protection, people with compromised immune systems — such as people who are taking *immunosuppressive* drugs, people who have cancer or people living with HIV — are usually not given live vaccines.

The vaccines for yellow fever, measles, rubella, and mumps are all produced from live, attenuated organisms.

Toxoids. A *toxoid* is an inactivated toxin, the harmful substance produced by a microbe. Many of the microbes that infect people are not themselves harmful. It is the powerful toxins they produce that can cause illness. For example, the bacterium that causes tetanus is found everywhere in nature, and in an environment with plenty of oxygen, it is harmless. If that same organism is put into an environment without oxygen, however, the organism starts to change and produce tetanus toxin, a substance far more potent than the well-known poison sodium cyanide. To inactivate such powerful toxins, vaccine manufacturers treat them with materials known to completely cripple any disease-causing ability. *Formalin*, a solution of formaldehyde and sterile water, is most often used to inactivate toxins and produce toxoids.

Toxoids are used to immunize people against tetanus and diphtheria.

New and Second-Generation Vaccines

Scientists are using new technologies to improve traditional vaccines. These new second-generation vaccines, as well as vaccines for diseases that had not been preventable very long ago, are made using powerful techniques such as *recombinant genetic engineering* (also called recombinant DNA technology).

Conjugate Vaccines. The bacteria that cause some diseases, such as pneumococcal pneumonia and certain types of meningitis, have special outer coats. These coats disguise antigens so that the immature immune systems of infants and younger children are unable to recognize these harmful bacteria. In a conjugate vaccine, proteins or toxins from a second type of organism, one that an immature immune system can recognize, are linked to the outer coats of the disease-causing bacteria. This enables a young immune system to respond and defend against the disease agent.

Currently, conjugate vaccines are available to protect against a type of bacterial meningitis caused by *Haemophilus influenzae* type b (Hib). Meningitis, an inflammation of the fluid-filled membranes that protect the brain and spinal cord, can be fatal or it can cause severe, life-long disabilities such as deafness and mental retardation. Since Hib vaccines have been widespread use in the United States, Hib meningitis has nearly disappeared among babies and young children.

Subunit Vaccines. Sometimes vaccines developed form antigenic fragments are able to evoke an immune response, often with fewer side effects than might be caused by a vaccine made from the whole organism. Subunit vaccines can be made by taking apart the actual microbe, or they can be made in the laboratory using genetic engineering techniques.

Today, subunit vaccines are used to protect against pneumonia caused by *Streptococcus pneumoniae* and against a type of meningitis.

A *recombinant subunit vaccine* for hepatitis B virus infection is now licensed for use in the United States. The recombinant vaccine is made by inserting a tiny portion of the hepatitis B virus' genetic material into common baker's yeast. The process induces the yeast to produce an antigen, which is then purified. The purified antigen, when combined with an *adjuvant*, a substance that stimulates the immune system, results in a safe and very effective vaccine.

Recombinant Vector Vaccines. A vaccine *vector*, or carrier, is a weakened virus or bacterium into which harmless *genetic material* from another disease-causing organism can be inserted.

The vaccinia virus, the virus that caused cowpox, is now used to make *recombinant vector vaccines*. In the submicroscopic world of viruses, vaccinia is relatively large and has ample room to accept additional genetic fragments. A vaccinia virus with several genes from the human immunodeficiency virus (HIV) is currently being tested as a vaccine for acquired immune deficiency syndrome (AIDS). In addition, a close relative of vaccinia, canarypox virus, engineered with harmless fragments of HIV, is being tested in human volunteers as a vaccine for AIDS.

Similarly, scientists are testing a weakened bacterium — salmonella — to carry portions of such microbes as the hepatitis B virus. Currently no recombinant vector vaccines are licensed for general use in the United States.

Vaccine Development and Testing

To be approved for general use, a candidate vaccine must go through a long period of testing and validation. The time between discovery of a disease agent and production of a widely available vaccine has been as long as 50 years. Today, with biological synthesis and recombinant vaccine development techniques, the length of time from basic research to availability of licensed product can sometimes be greatly reduced.

Basic Research and Development. Basic research focuses on biochemistry and physiology, and on mechanisms that disease-causing microbes use to cause damage. Such research also takes into account the biophysical characteristics of the organisms that might be used in vaccines or drugs to prevent or interrupt the disease process.

To develop a candidate vaccine, scientists test vaccine preparations in cell-culture, and often eventually in animals such as mice, guinea pigs, or even monkeys. In some cases, computers can help researchers visualize the vaccine candidates in three dimensions to predict how vaccine antigens will interact with the immune system. If the vaccine candidate is shown to be promising throughout the *preclinical* evaluations, it can become an *investigational vaccine*.

An investigational vaccine is one that successfully has gone through basic research and developmental processes, often including preclinical trials in animals, and has been approved by the U.S. Food and Drug Administration (FDA) for use in human volunteers in clinical trials.

Clinical Studies. Clinical studies rely entirely upon the participation of volunteers, people who contribute their time and energy for the advancement of science and improved health care for all. Thousands of volunteers of all ages and from all walks of life have participated in these studies. A typical volunteer in a vaccine study agrees to be given the vaccine, makes frequent visits to a clinic for evaluation, participates in medical testing, and provides blood or tissue samples that will be used in assessing the vaccine's safety and potential effectiveness. Unlike the boy vaccinated by Dr. Jenner 200 years ago, volunteers today must sign an informed consent document indicating their understanding of the study, its risks, and their willingness to participate.

A candidate vaccine undergoes three phases of clinical trials before it can be licensed for public use. Phase I trials, to determine the safety of various doses of the vaccine, usually begin with small numbers of volunteers, and then expand to include more volunteers if the vaccine appears to be safe.

Phase II trials, to determine whether the vaccine is safe and immunogenic, are open to hundreds of volunteers. The vaccine is tested for safety, for its ability to evoke an immune response, and for its potential to prevent disease.

Phase III trials are large-scale efficacy studies, often in thousands of individuals, to confirm that the vaccine safely prevents disease. A vaccine is considered successful if its overall effect is beneficial; it should prevent disease, and any side effects should be minimal. If the disease the vaccine is designed to prevent is rare in the United States, Phase III trials may be conducted in a country where the disease is prevalent. In the cases of such international cooperation, each government signs an agreement and expects its citizens to benefit from the study.

Side Effects and Adverse Reactions. The most common side effects of vaccines include low-grade fever, soreness and redness at the site of the injection, or sometimes body aches for up to 24 hours after vaccination. These minor side effects of a vaccine are far preferable to having the disease.

The extensive testing that a vaccine undergoes before it is licensed for public use is conducted, in part to assure safety as much as possible by closely observing large numbers of volunteers for harmful side effects. But no matter how thorough the testing, it is impossible to allow completely for the extensive variation among individuals, their immune systems, and their reactions to the introduction of new substances into their bodies. Serious systemic reactions to vaccines can occur, although they are very rare. The FDA and the Centers for Disease Control and Prevention monitor vaccine distribution and use. Information about adverse reactions to a vaccine is collected even after the vaccine is licensed for general use. Both organizations record any incident of a serious reaction and follow up on any re-evaluation of the vaccine that is necessary.

Basic and Clinical Research

Basic research conducted and supported by the National Institute of Allergy and Infectious Diseases (NIAID's) is helping scientists understand more about infectious microbes and human immune responses. From this understanding has come the development of vaccines and other tools needed to prevent many infectious diseases and immune system disorders. The goal of these efforts is not only to protect individuals from serious infections; but eventually to eradicate diseases, as we have seen with smallpox.

In clinical research, NIAID revolutionized the classical but cumbersome, piecemeal approach to clinical vaccine studies by designing a network of vaccine and treatment evaluation units, and more recently, an international network for testing vaccines to prevent infection with HIV. Testing sites are based at leading university medical research centers, public health departments, and community clinics. Investigators working within these networks and other NIAID-supported researchers played major roles in the clinical studies required for licensing of vaccines for Hib meningitis and or new *acellular* pertussis vaccines.

The Children's Vaccine Initiative

NIAID has been recognized by Congress as the lead agency to provide the scientific and programmatic direction for the Children's Vaccine Initiative (CVI). The CVI, a worldwide public health effort, combines the efforts of many international scientists and representatives of the United Nations International Children's Emergency Fund, the World Health Organization, the World Bank, the United Nations Development Program, the Rockefeller Foundation and vaccine manufactures, biotechnology firms, and national research agencies. The CVI has made impressive strides towards its goal of universal immunization. Already 80 percent of all children in the United States receive their initial immunizations by their first birthdays. NIAID is making progress toward achievable goals, such as making existing vaccines safer and more effective and improving vaccines so that fewer doses will be needed.

Vaccines of the Future

Currently scientists are pursuing many promising new strategies in vaccine development and exploring novel ways to administer vaccines. The following descriptions of just a few of these innovative ideas provide a preview of safer, more effective ways to fight disease.

Exposing *mucosal membranes* to vaccines is a strategy that can produce an immune response in a less-stressful and better-targeted manner. Mucosal membranes are located throughout our bodies, but are most accessible in the lungs, nose, mouth, throat, gastrointestinal tract, rectum and vagina. The oral polio vaccine, in use since the 1950's, is an early example of the effectiveness of this strategy. Another possible mucosal route of

administration is through the nose, and flu vaccines may soon be widely available in a nasal spray. Researchers have shown that the route of entry a disease-causing organism takes is often an effective vaccine route as well.

Many vaccine improvements may result from progress in designing better adjuvants. At present, only an aluminum salt called *alum* is approved as an adjuvant by the FDA, but scientists are studying many new natural and synthetic compounds.

Scientists are also looking at new ways of presenting the vaccine to the immune system. *Microspheres*, tiny spheres containing bits of antigenic material, show promise in that they can release small doses of vaccine over extended periods of time as the microspheres gradually dissolve in the body. This means that someone may be able to receive two or three doses in just one administration of vaccine.

Perhaps the most exciting new vaccine technique is introducing pure genetic material directly into the body. This genetic material, called "naked DNA," encodes a few proteins from a disease-causing organism. The DNA is then incorporated into the body's own cells, which make the proteins encoded by the new DNA. It is these proteins that are recognized as foreign and stimulate the immune system. In this way, the DNA will have an effect similar to that of a live, attenuated vaccine. In effect, the DNA will produce antigens for years and induce strong, long-lasting immunity. At the same time, the exclusion of genes that are critical to the disease-causing organism's survival will assure that the vaccines are safe and do not actually cause disease.

Researchers are also exploring ways to create edible vaccines. By genetically engineering plants to incorporate synthetic antigens, scientists may be able to develop a banana or potato, for example, that will produce protective immunity when eaten. Obviously, such a vaccine technique would greatly simplify immunization for many people of the world.

Vaccines remain among the most powerful tools we have for disease prevention, and advances in biotechnology have ushered in a new era in vaccine development that holds even more promise for improving public health. NIAID remains a leader in the discovery and testing of new and improved vaccines and will continue to nourish this exciting renaissance in vaccine development.

See also **Immune System and Immunology**.

An abridged glossary of terms used to describe basic vaccine science and the immune system would include:

Acellular vaccine: Devoid of whole cells. Acellular vaccines contain only portions of cellular material.

Active immunity: Immunity produced by the body in response to stimulation by a disease-causing organism (naturally acquired active immunity) or by a vaccine (artificially acquired active immunity).

Adjuvant: A substance sometimes included in a vaccine formulation to enhance the immune-stimulating properties of a vaccine.

Antibody: Soluble protein molecule produced and secreted by B cells in response to an antigen and capable of binding to that specific antigen.

Antibody-mediated immunity (humoral immunity): Immune protection provided by B cells, which secrete antibodies in response to antigen (as distinct from that provided by the direct action of immune cells or cellular immunity).

Antigen: A substance that provokes an immune response.

B cells: Small white blood cells crucial to the immune defenses. Also known as B lymphocytes, they are derived from bone marrow and develop into plasma cells, which produce antibodies.

Bone marrow: Soft tissue located in the cavities of the bones. The bone marrow is the source of all blood cells.

Cell-mediated immunity (cellular immunity): Immune protection provided by the direct action of immune cells (as distinct from that provided by soluble molecules such as antibodies).

Complement: A complex series of blood proteins whose action "complements" the work of antibodies. Complement destroys antibody-coated cells, produces inflammation, and regulates immune reactions.

Conjugate vaccine: A vaccine in which proteins that are easily recognizable to the immune system are linked to the outer coat of the disease-causing organism to promote an immune response.

Cytotoxic T cells: A subset of T lymphocytes that can kill other cells infected by viruses, fungi or certain bacteria, or cells transformed by cancer.

Efficacy: In vaccine research, the ability of a vaccine to produce a desired clinical effect, such as protection against a specific disease, at the optimal dosage and schedule in a given population. A vaccine may be tested for efficacy in Phase III studies if it appears to be safe and shows promise in smaller Phase I and II studies.

Epitope: A unique shape or marker carried on an antigen's surface, which triggers a corresponding antibody response.

Formalin: A solution of water and formaldehyde, used as an antiseptic, disinfectant or fixative.

Genetic material: Deoxyribonucleic acid (DNA) that carries the directions a cell uses to perform a specific function, such as making a given protein.

Haemophilus influenzae type b (HIB): A bacterium found in the respiratory tract that causes acute respiratory infections, including pneumonia, and other diseases such as meningitis.

Helper T cells: A subset of T cells that typically carry the CD4 marker and are essential for turning antibody production on, activating cytotoxic T cells, and initiating many other immune responses.

Humoral immunity: Immune protection provided by soluble factors such as antibodies, which circulate in the body's fluids, primarily serum and lymph. See **Antibody-mediated immunity**.

Immunogenic: Capable of stimulating an immune response (immunogenicity).

Immunosuppressive: Capable of reducing immune responses. For instance, drugs given to prevent transplant rejection are immunosuppressive.

Inactivated toxins: Organic toxins, such as those produced by bacteria and viruses, that have been killed by chemical means, heat, or irradiation, and are no longer capable of causing disease.

Inactivated vaccine (Killed vaccine): A vaccine made from a whole virus or bacterium whose biological ability to grow or reproduce is ended.

Investigational vaccine: A vaccine that has been approved by the Food and Drug Administration for testing in humans, but that has not yet completed evaluation and been accepted for licensure and public use.

Killer T cells (cytotoxic T cells, cytotoxic lymphocytes, CTLs): A subset of T cells that can kill cancer cells and cells infected with viruses, fungi or certain bacteria.

Live, attenuated vaccine: A vaccine whose biological activity has not been inactivated, but whose ability to cause disease has been weakened.

Lymph: A transparent, slightly yellow fluid that carries lymphocytes, bathes the body tissues, and drains into the lymphatic vessels.

Lymph nodes: Small bean-shaped organs of the immune system, distributed widely throughout the body and linked by lymphatic vessels. Lymph nodes are gathering sites of B, T, and other immune cells.

Lymphatic vessels: A body-wide network of channels, similar to the blood vessels, that transport lymph to the immune organs and into the bloodstream.

Lymphocytes: Small white blood cells produced in the bone marrow and thymus that are essential in immune defense.

Lymphoid organs: Organs of the immune system, where lymphocytes develop and congregate. They include the bone marrow, thymus, lymph nodes, spleen, and various other clusters of lymphoid tissue, such as the appendix. The blood vessels and lymphatic vessels also can be considered lymphoid organs.

Major histocompatibility complex (MHC): A large set of cell surface molecules in each individual, encoded by genes. MHCs serve as unique biochemical markers of individual identity.

Macrophage: A large and versatile immune cell that acts as a microbe-devouring phagocyte, and antigen-presenting cell, or an important source of immune secretions.

Memory cell: A subset of T cells and B cells that have been exposed more readily when the immune system encounters the same antigens again.

Microbe: A minute living organism, such as a bacterium or virus.

Microspheres: Tiny, microscopic spheres that can carry vaccines or drugs and can pass easily through the body's tissues.

Mucosal membranes: The moist tissues lining body cavities or passages that have an opening to the external world, such as the mouth, nose, rectum or vagina. Mucosal immunity depends on immune cells and antibodies being present in the linings of the reproductive, respiratory, gastrointestinal tracts, and other mucosal membranes.

Mutate: To change a gene or unit of hereditary material that results in a new inheritable characteristic.

Naked DNA vaccine: Vaccine made up of deoxyribonucleic acid that is not encased or encapsulated. In naked DNA vaccines, genetic material is injected directly into the vaccine recipient.

Naturally acquired immunity: Immunity produced by immune cells passed from mother to fetus or by the body in response to exposure to a disease-causing organism.

Passive immunity: Immunity resulting from the transfer of cells or antibodies or antiserum produced by another individual.

Peyer's patches: A collection of lymphoid tissues in the intestinal tract.

Phagocyte: An immune cell that is able to ingest and destroy microbes and other foreign matter.

Potency: The strength of substance. In vaccines, one of the qualities, which makes a vaccine protective.

Preclinical: A phase of study of a vaccine or drug that is completed before clinical studies are carried out in people. Preclinical studies may be conducted in cells or in animals.

Protective immunity: Complete resistance to disease, whether long-lasting or temporary.

Recombinant DNA technology: The technique by which genetic material from one organism is inserted into a foreign cell or another organism in order to mass-produce the protein encoded by the inserted genes. (Also called recombinant genetic engineering.)

Recombinant subunit vaccine: A subunit vaccine made using recombinant DNA technology.

Recombinant vector vaccine: A vaccine that combines a vector — a harmless bacterium or virus used to transport an antigen into the body to stimulate protective immunity — and an antigen or immunogen from an organism other than the vector.

Subunit vaccine: A vaccine that uses one or more components of a disease-causing organism, rather than the whole, to stimulate an immune response.

T cells: Small white blood cells that orchestrate or directly participate in immune defenses. Also known as T lymphocytes, they mature in the thymus.

Thymus: A primary lymphoid organ, high in the chest, where T lymphocytes proliferate and mature.

Toxoid: An inactivated or killed organic toxin used to immunize against specific bacteria.

Vector: In vaccine technology, a bacterium or virus that does not cause disease in humans and is used in genetically engineered vaccines to transport genes coding for antigens into the body to induce an immune response.

Virulent: Toxic, causing disease.

VACCINIA (Cowpox). The skin reaction which follows the introduction of the virus of vaccinia into the body, and which is followed by the development of immunity against vaccinia itself and smallpox. This process may be effected, accidentally but is commonly deliberate, in the form of vaccination, in which the virus derived from lesions on the skin of calves or sheep is inoculated intradermally. The strains of virus so used have been artificially attenuated in virulence by repeated passage through animals; in consequence the lesion produced is of minimal size consistent with effective immunization. Vaccinia is occasionally complicated, especially by encephalitis, which may be fatal, and it is in part due to this that compulsory vaccination is on the decline.

VACUOLE. A small globule of clear fluid in the cytoplasm of a cell. In preparations for microscopic study the contents of the vacuole are usually dissolved away, so that an open space alone remains, but even vacuoles whose contents are undisturbed usually appear vacant because of their transparency. In the multicellular body fat cells afford a good illustration of vacuoles as globules of fat accumulate in them. One-celled animals also offer a good example in the contractile or pulsating vacuole. This is a globule of clear liquid that forms and discharges periodically, sometimes at a fixed point in the cell. It is interpreted as an organ for the removal of surplus water with dissolved wastes from the protoplasm. See also **Cell (Biology)**.

VACUUM. According to definition, a space entirely devoid of matter. The term is used in a relative sense in vacuum technology to denote gas pressures below the normal atmosphere pressure of 760 torr (1 torr = 1 millimeter of mercury). The degree or quality of the vacuum attained is indicated by the total pressure of the residual gases in the vessel that is pumped. Table 1 shows generally accepted terminology for denoting various degrees of vacuum, together with pertinent pressure ranges; the calculated molecular density (from the equation $p = nkT$, where p is the pressure n is the molecular density, i.e., number of molecules per cubic centimeter; k is the Boltzmann's constant; and T is the absolute temperature taken to be 293 K (20 °C); and the mean free path λ from the approximate equation for air: $\lambda = 5/p$ centimeters, where p is the pressure in millitorr).

In the quantum field theories that describe the physics of elementary particles, the vacuum becomes somewhat more complex than previously defined. Even in empty space, matter can appear spontaneously as a result of fluctuations of the vacuum. It may be pointed out, for example, that an electron and a positron, or antielectron, can be created out of the void. Particles created in this way have only a fleeting existence; they are annihilated almost as soon as they appear, and their pressure can never be detected directly. They are called *virtual particles* in order to distinguish them from real particles. Thus, the traditional definition of vacuum (space with no real particles in it) holds. In their excellent paper, the aforementioned authors discuss how, near a superheavy atomic nucleus, empty space may become unstable, with the result that matter and antimatter can be created without any input of energy. The process may soon be observed experimentally.

Even when all matter and heat radiation have been removed from a region of space, the vacuum of classical physics remains filled with a distinctive pattern of electromagnetic fields. The discovery of a connection between thermal radiation and the structure of the classical vacuum reveals an unexpected unity in the laws of physics, but it also complicates the view of what was once considered simply *empty space*. But, even with its pattern of electric and magnetic fields, the vacuum remains the simplest state of nature. Perhaps this statement reflects more on the subtlety of nature than it does on the simplicity of the vacuum.

Vacuum Pumps

Two widely used vacuum pumps are the mechanical rotary oil-sealed pump and the vapor pump. The former provides a medium vacuum and works relative to the atmosphere. The vapor pump, on the other hand, provides a high or very high vacuum and operates relative to a medium

TABLE 1. VARIOUS QUALITIES OF VACUUM AND PRESSURE RANGES

Quality of Vacuum	Pressure Range (torr)	Molecular Density, n (molecules/cubic centimeter)	Mean Free Path, λ (centimeters)
Coarse or rough vacuum	760–1	$2.69 \times 10^{19} - 3.5 \times 10^{16}$	$6.6 \times 10^{-6} - 5 \times 10^{-3}$
Medium vacuum	$1–10^{-3}$	$3.5 \times 10^{16} - 3.5 \times 10^{13}$	$5 \times 10^{-3} - 5$
High vacuum	$10^{-3}–10^{-7}$	$3.5 \times 10^{13} - 3.5 \times 10^{9}$	$5 - 5 \times 10^{4}$
Very high vacuum	$10^{-7}–10^{-9}$	$3.5 \times 10^{9} - 3.5 \times 10^{7}$	$5 \times 10^{4} - 5 \times 10^{6}$
Ultrahigh vacuum	$<10^{-9}$	$<3.5 \times 10^{7}$	$>5 \times 10^{6}$

vacuum provided by a rotary pump, referred to as a backing pump in this connection. Thus, the most widely used high-vacuum system able to establish an ultimate pressure of about 10^{-6} torr or below consists of a vapor pump backed by a rotary pump.

Several patterns of rotary oil-sealed pumps exist, but they have in common the fact that the volume between a rotor (or rotating plunger) and a stator is divided into two crescent-shaped sections, which are isolated from one another as regards the passage of gas. Further, they are furnished with an intake port and a discharge outlet valve to the atmosphere. One revolution of the rotor (speeds of 450 to 700 revolutions per minute are used), gas is swept from the intake port, compressed, and discharged to the atmosphere via the one-way outlet valve. The mechanism is immersed in a low-vapor-pressure oil for sealing and lubrication in a small pump; larger units have a separate oil reservoir and feed device. A spring-loaded vane type of rotary oil-sealed pump is shown in Fig. 1. A single-stage pump of this kind provides an ultimate pressure of about 10^{-2} torr; a two-stage one with two units in cascade will give an ultimate of about 10^{-4} torr. Rotary pumps with speeds from 20 to 20,000 liters/minute are commercially available, the smallest being driven by an 1/8-hp motor, the largest requiring a 40-hp motor.

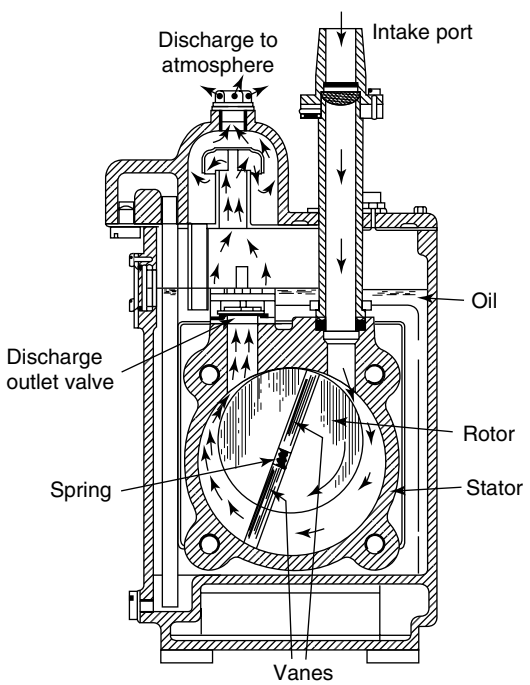

Fig. 1. Spring-loaded vane-type rotary oil-sealed vacuum pump.

These pumps handle permanent gases efficiently. Condensable vapors, e.g., water vapor, are not satisfactorily pumped because they may liquefy during the compression part of the rotation. To prevent this, gas ballast is a common provision whereby air from the atmosphere is admitted to the pump through a simple, adjustable screw valve to the region between the rotor and stator just before the discharge outlet valve. The amount of extra air admitted is readily adjusted to provide a compressed gas-vapor mixture, which opens the discharge valve before vapor condensation occurs. Gas ballasting will clearly increase significantly the ultimate pressure provided by the pump, but this is not important since the gas-ballast valve can be closed after initial pumping has removed most of the water vapor.

Vapor pumps are of two main types: vapor diffusion pumps and vapor ejector pumps. Both employ vapor (of either mercury or a low-vapor-pressure oil) issuing from a jet as a means of driving gas in the direction from the intake port to the discharge outlet, which is maintained at a medium vacuum by a backing rotary pump. In the diffusion pump (a two-stage design utilizing oil as the pump fluid), the vapor issuing from the top, first-stage jet is directed downward towards the backing region. Gas molecules from the intake port diffuse into the streaming vapor. The directed oil molecules collide with the gas molecules to give them velocity components toward the backing region. A large pressure gradient is thereby established in the pump so that the intake pressure may be over 100,000 times less than the backing pressure. The intake pressure may therefore be 10^{-6} torr or lower with a backing pressure of 10^{-1} torr.

In the diffusion pump, the vapor stream is not essentially influenced by the gas pumped. In the vapor ejector pump, however, the vapor stream is enabled by a higher boiler pressure to be denser and of greater speed with a higher intake pressure, so that the gas is entrained by the high-speed vapor. Viscous drag and turbulent mixing now carry the gas at initially supersonic speeds down a pump housing of diminishing cross section. The ejector pump is designed to operate with a maximum pumping speed at an intake pressure of 10^{-1} to 10^{-3} torr and with a backing pressure of 0.5 to 1 torr or more. The diffusion pump, on the other hand, is designed to have a fairly constant speed from 10^{-3} torr down to an ultimate 10^{-6} torr or much lower in a modern, bakeable stainless steel system.

An important mechanical pump, which operates in the same pressure region as the oil ejector, is the Roots pump, capable of very great speeds and requiring backing by a rotary oil-sealed pump.

A vacuum system may consist of a diffusion pump and a backing pump, together with baffles, cold traps and isolation valves. The cold trap is essential if a mercury vapor diffusion pump is used and is best filled with liquid nitrogen ($-196\,^{\circ}C$); otherwise, the system will be exposed to the mercury vapor pressure, which is 10^{-3} torr at $18\,^{\circ}C$.

Ultrahigh-vacuum systems with stainless steel traps and metal sealing gaskets, and bakeable (except for the pumps) for several hours to $450\,^{\circ}C$, may be constructed to provide an ultimate pressure of 10^{-9} to 10^{-10} torr.

Other vacuum pumps include the sorption type based on the high gas take-up of charcoal or molecular sieve material at liquid nitrogen temperatures. Sorption pumps may be used in place of rotary pumps, with a desirable freedom from rotary pump oil vapor, especially in systems where the amount of gas to be handled is limited.

The chief rival to the vapor diffusion pump at present is the getterion pump of the Penning discharge type, sometimes called the sputter-ion pump, with electrodes of titanium metal. The principle of operation is illustrated by Fig. 2 where an egg-box type anode is situated between plane cathodes. The anode-cathode operating potential difference is of the order of 2 to 10 kV, and the magnetic flux density is about 3,000 gauss. The chief pumping action with active gases such as hydrogen, nitrogen and oxygen is to the anode which receives deposited titanium (which has very high gas affinity) sputtered from the cathodes under the action of the positive ion bombardment. Some gas, especially the inert gases like argon, is pumped to the cathodes.

A typical multicell pump of moderate size of this type has a pumping speed of about 250 liters/second. Much larger pumps with speeds of up to 5,000 liters/second are commercially available, as are small single-cell units with speeds of some 2 liters/second.

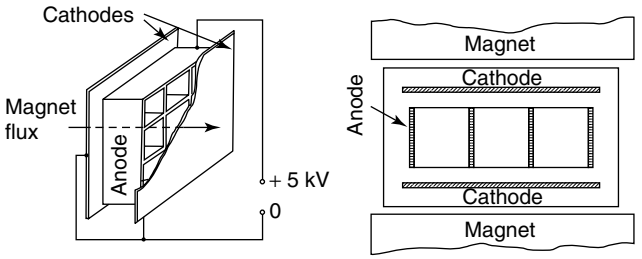

Fig. 2. Sputter-ion vacuum pump.

The sputter-ion pumps provide a vapor-free system giving a so-called dry vacuum, and they are often incorporated in plant with molecular sieve sorption as the backing pump. For medium-size laboratory plant able to provide ultrahigh vacuum they are most attractive. Probably their chief disadvantage is that the life of the pump is only about 40 hours at 10^{-3} torr, but this increases inversely with the pressure, so that it is 40,000 hours at 10^{-6} torr. At present, they are therefore strong rivals to the diffusion pump for plant where moderate amounts of gas are handled in the lower pressure ranges.

In cryogenic pumping, the provision is, within an initially evacuated system, a surface which is at such a low temperature that gas impinging on the surface will be condensed. For example, if the surface is maintained at the temperature of liquid helium (−269 °C), all other gases have insignificantly low vapor pressures at this temperature and molecules of these gases impinging on the surface would remain there. A pumping speed for nitrogen of nearly 12 liters sec^{-1} cm^{-2} of cooled surface is hence theoretically possible. Liquid nitrogen, together with molecular sieve and other sorbent surfaces, and also liquid-hydrogen (−253 °C, at which the vapor pressure of solid nitrogen is 10^{-10} torr) and liquid-helium cooled metallic surfaces, are being actively investigated for the possibility of providing very high pumping speeds (10^6 liters/sec is not out of question) in space simulators and other plants.

Vacuum Measurement

Subatmospheric pressure usually is expressed in reference to perfect vacuum or absolute zero pressure. Like absolute zero temperature (the concept is analogous), absolute zero pressure cannot be achieved, but it does provide a convenient reference datum. Standard atmospheric pressure is 14.695 psi absolute, 30 inches of mercury absolute, or 760 mmHg of density 13.595 g/cm^3 where acceleration due to gravity is $g = 980.665$ cm/s^2. 1 mmHg, which equals 1 torr, is the most commonly used unit of absolute pressure. Derived units, the million or micrometer, representing 1/1000 of 1 mmHg or 1 torr, are also used for subtorr pressures.

In the MKS system of units, standard atmospheric pressure is 750 torr and is expressed as 100,000 Pa (N/m^2) or 100 kPa. This means that 1 Pa is equivalent to 7.5 millitorr (1 torr = 133.3 pascal). Vacuum, usually expressed in inches of mercury, is the depression of pressure below the atmospheric level, with absolute zero pressure corresponding to a vacuum of 30 inches of mercury.

When specifying and using vacuum gages, one must constantly keep in mind that atmospheric pressure is *not* constant and that it also varies with elevation above sea level.

Vacuum gages can be either direct or indirect reading. Those that measure pressure by calculating the force exerted by incident particles of gas are direct reading, while instruments that record pressure by measuring a gas property that changes in a predictable manner with gas density are indirect reading.

The range of operation for these two classes of vacuum instruments is given in Table 2. Since the pressure range of interest in present vacuum technology extends from 760 to 10^{-13} torr (over 16 orders of magnitude), there is no single gage capable of covering such a wide range. The ranges of vacuum where specific types of gages are most applicable are shown in Fig. 3.

TABLE 2. RANGE OF OPERATION OF MAJOR VACUUM GAGES

Principle	Gage type	Range, torr
Direct reading	Force measuring:	
	Bourdon, bellows, manometer (oil and mercury),	$760–10^{-6}$
	McLeod capacitance (diaphragm)	760×10^{-6}
Indirect reading	Thermal conductivity:	
	Thermocouple (thermopile)	$10–10^{-3}$
	Pirani (thermistor)	$10–10^{-4}$
	Molecular friction	$10^{-2}–10^{-7}$
	Ionization:	
	Hot filament	$10–10^{-10}$
	Cold cathode	$10^{-2}–10^{-15}$

The operating principles of some vacuum gages, such as liquid manometers, bourdon, bellows, and diaphragm gages involving elastic members, were described earlier in this article. The remaining vacuum measurement devices include the thermal conductivity (or Pirani and thermocouple-type gages), the hot-filament ionization gage, the cold-cathode ionization gage (Philips), the spinning-rotor friction gage, and the partial-pressure analyzer.

Pirani or Thermocouple Vacuum Gage. Commercial thermal conductivity gages ordinarily should not be considered as precision devices. Within their rather limited but industrially important pressure range, they are outstandingly useful. The virtues of these gages include low cost, electrical indication readily adapted to remote readings, sturdiness, simplicity, and interchangeability of sensing elements. They are well adapted for uses where a single power supply and measuring circuit is used with several

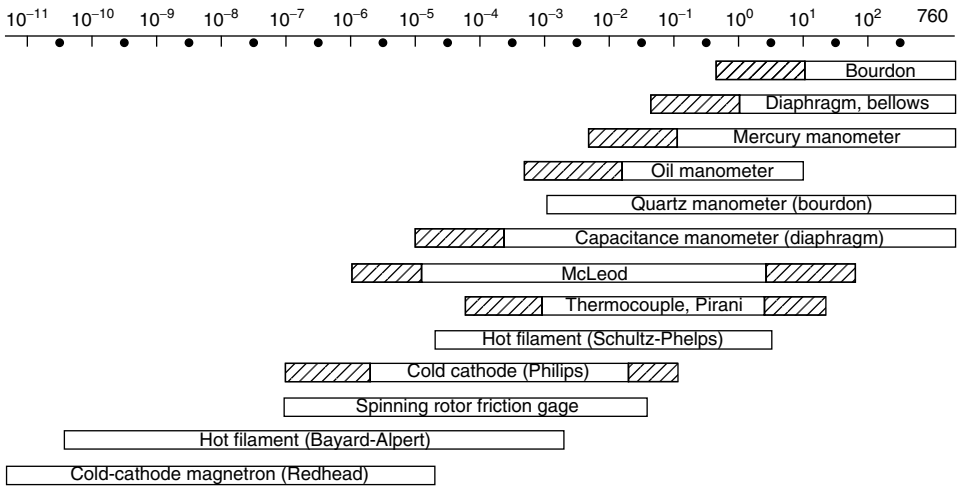

Fig. 3. Vacuum gages versus measurement range.

sensing elements located in different parts of the same vacuum system or in several different systems.

The working element of the gages consists of a metal wire or ribbon exposed to the unknown pressure and heated by an electric current. See Fig. 4. The temperature attained by the heater is such that the total rate of heat loss by radiation, gas convection, as thermal conduction, and thermal conduction through the supporting leads equals the electric power input to the element. Convection is unimportant and can be disregarded, but the heat loss by thermal conduction through the gas is a function of pressure. At pressures of approximately 10 torr and higher, the thermal conductivity of a gas is high and roughly independent of further pressure increases. Below about 1 torr, on the other hand, the thermal conductivity decreases with decreasing pressure, eventually in linear fashion, reaching zero at zero pressure. At pressures above a few torr, the cooling by thermal conduction limits the temperature attained by the heater to a relatively low value. As the pressure is reduced below a few hundred millitorr, the heater temperature rises, and at the lowest pressures, the heater temperature reaches an upper value established by heat radiation and by thermal conduction through the supporting leads.

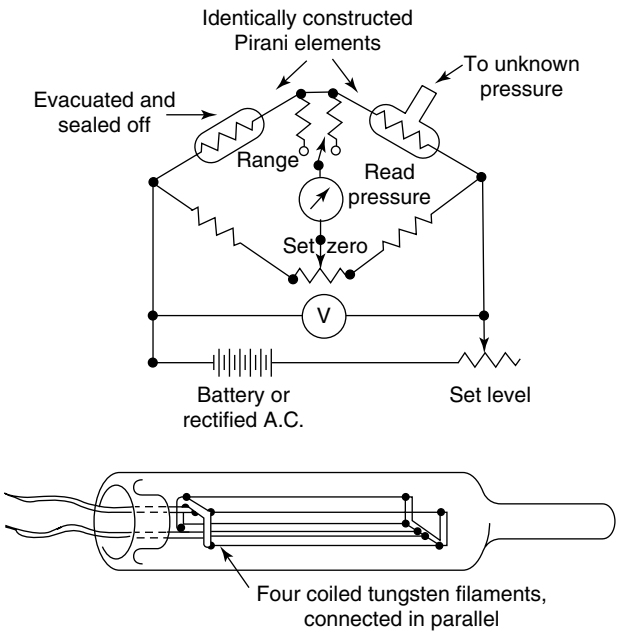

Fig. 4. Pirani gage: (*Top*) Gage in fixed-voltage Wheatstone bridge. (*Bottom*) Sensing element.

Hot-Filament Ionization Vacuum Gage. This gage is the most widely used pressure-measuring device for the region from 10^{-2} to 10^{-11} torr. The operating principle of this gage is illustrated in Fig. 5.

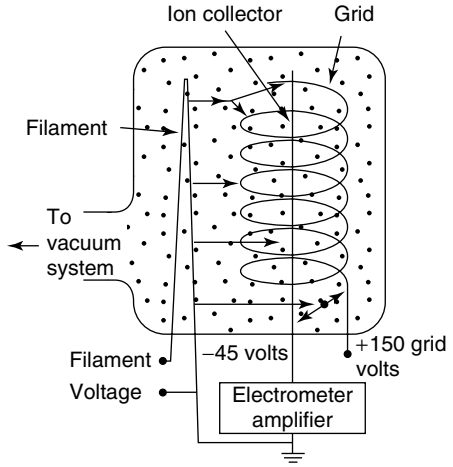

Fig. 5. Hot-filament ionization gage. (*Bayard-Alpert type*.)

A regulated electron current (typically about 10 mA) is emitted from a heated filament. The electrons are attracted to the helical grid by a dc potential of about +150 volts. In their passage from filament to grid, the electrons collide with gas molecules in the gage envelope, causing a fraction of them to be ionized. The gas ions formed by electron collisions are attracted to the central ion collector wire by the negative voltage on the collector (typically −30 volts). Ion currents collected are on the order of 100 mA/torr. This current is amplified and displayed using an electronic amplifier.

This ion current will differ for different gases at the same pressure — that is, a hot-filament ionization gage is composition-dependent. Over a wide range of molecular density, however, the ion current from a gas of constant composition will be directly proportional to the molecular density of the gas in the gage.

Cold-Cathode Ionization Vacuum Gage. This ingenious gage, invented by Penning, possesses many of the advantages of the hot-filament ionization gage without being susceptible to burnout. Ordinarily, an electrical discharge between two electrodes in a gas cannot be sustained below a few millitorr pressure. To simplify a complicated set of relationships, this is because the "birthrate" of new electrons capable of sustaining ionization is smaller than the "death rate" of electrons and ions. In the Philips gage this difficulty is overcome by the use of a collimating magnetic field, which forces the electrons to traverse a tremendously increased path length before they can reach the collecting electrode. In traversing this very long path, they have a correspondingly increased opportunity to encounter and ionize molecules of gas in the interelectrode region, even though this gas may be extremely rarefied. It has been found possible by this use of a magnetic field and appropriately designed electrodes, as indicated in Fig. 6, to maintain an electric discharge at pressures below 10^{-9} torr.

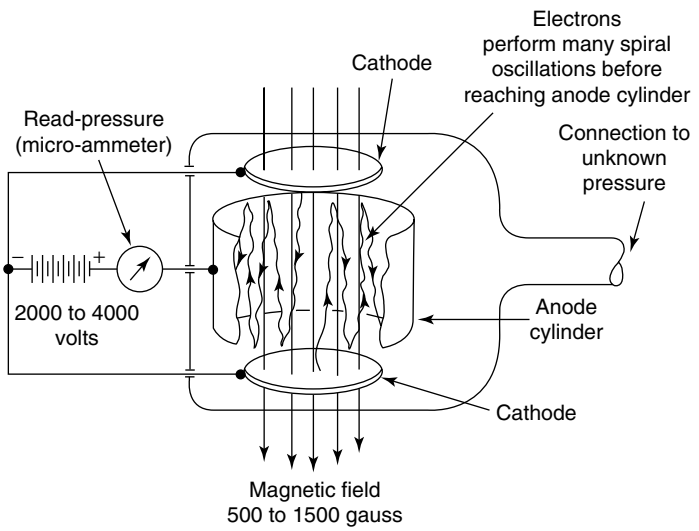

Fig. 6. Philips cold-cathode ionization vacuum gage.

Comparison with the hot-filament ionization gage reveals that, in the hot-filament gage, the source of the inherently linear relationship between gas pressure (more exactly molecular density) and gage reading is the fact that the ionizing current is established and regulated independently of the resulting ion current. In the Philips gage this situation does not hold. Maintenance of the gas discharge current involves a complicated set of interactions in which electrons, positive ions, and photoelectrically effective x-rays all play a significant part. It is thus not surprising that the output current of the Philips gage is not perfectly linear with respect to pressure. Slight discontinuities in the calibration are also sometimes found, since the magnetic fields customarily used are too low to stabilize the gas discharge completely. Despite these objections, a Philips gage is a highly useful device, particularly where accuracy better than 10 or 20% is not required.

The Philips gage is composition-sensitive, but, unlike the situation with the hot-filament ionization gage, the sensitivity relative to some reference

gas, such as air or argon, is not independent of pressure. Leak hunting with a Philips gage and a probe gas or liquid is a useful technique. Unlike the hot-filament ionization gage, the Philips gage does not involve the use of a high-temperature filament and consequently does not subject the gas to thermal stress. The voltages applied in the Philips gage are on the order of a few thousand volts, which is sufficient to cause some sputtering at the high-pressure end of the range. This results in a certain amount of gettering or enforced takeup of the gas by the electrodes and other part of the gage. Various design refinements have been used to facilitate periodic cleaning of the vacuum chamber and electrodes, since polymerized organic molecules are an ever-present contaminant.

The conventional cold-cathode (Philips) gage is used in the range from 10^{-2} to 10^{-7} torr. Redhead has developed a modified cold-cathode gage useful in the 10^{-6} to 10^{-12} torr range. See Fig. 7. The operating voltage is about 5000 volts in a 1-kG magnetic field.

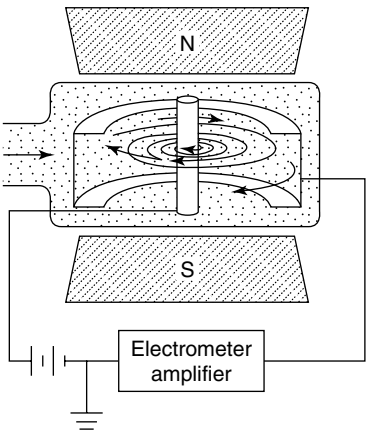

Fig. 7. Inverted magnetron, a cold-cathode gage, produces electrons by applying a high voltage to unheated electrodes. Electrons spiraling in toward the central electrode ionize gas molecules, which are collected on the curved cathode.

Spinning-Rotor Friction Vacuum Gage. Although liquid manometers (U-tube, McLeod) serve as pressure standards for subatmospheric measurements (760 to 10^{-5} torr), and capacitance (also quartz) manometers duplicate this range as useful transfer standards, calibration at lower pressures depends on both volume expansion techniques and presumed linearity of the measuring system. The friction gage allows extension of the calibration range directly down to 10^{-7} torr. It measures pressure in a vacuum system by sensing the deceleration of a rotating steel ball levitating in a magnetic field. See Fig. 8.

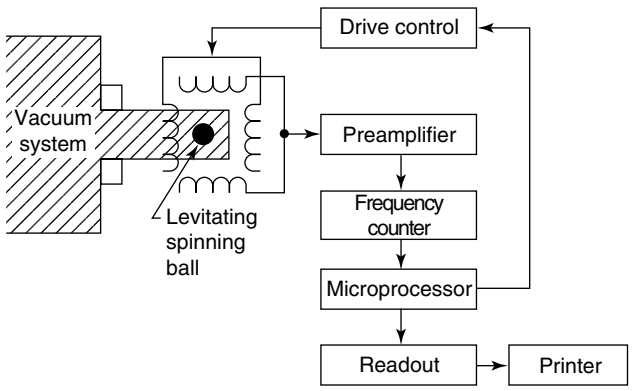

Fig. 8. Schematic diagram of spinning-rotor friction gage.

Partial-Pressure (Residual Gas) Analyzers. Many applications of high-vacuum technology are more concerned with the partial pressure of particular gas species than with total pressure. Also, "total" pressure gages generally give accurate readings only in pure gases. For these reasons partial-pressure analyzers are finding increasing application. These are basically low-resolution, high-sensitivity mass spectrometers that ionize a gas sample in a manner similar to that of a hot-filament ionization gage. The resulting ions are then separated in an analyzer section, depending on the mass-to-charge ratio of each ion. The ion current corresponding to one ion type is then collected, amplified, and displayed. Partial-pressure gages are very valuable diagnostic tools in both research and production work. The major types are listed in Table 3.

TABLE 3. CHARACTERISTICS OF PARTIAL-PRESSURE ANALYZERS

Type	Minimum partial pressure, torr	Resolution,* au	Magnetic field
Magnetic sector	10^{-11}	20–150	Yes
Cycloidal	10^{-11}	100–150	Yes
Quadrupole	10^{-12}	100–300	No
Time of flight	10^{-12}	200	No

*Maximum mass number at which a mass number difference of 1 can be observed.

VACUUM DEPOSITION. The process of coating a base material by evaporating a metal under high vacuum and condensing it on the surface of the material to be coated, which is usually another metal or a plastic. Aluminum is most commonly used for this purpose. The coatings obtained range in thickness from 0.01 to as many as 3 mils. A vacuum of about one-millionth atmosphere is necessary. The process is used for jewelry, electronic components, decorative plastics, etc. Thermally evaporated metals and dielectric coatings can be effectively applied to glass by this method. It is also called vacuum coating and vacuum metallizing.

See also **Thin Films**.

VACUUM DEPOSITION (Thin-Film). See **Thin Films**.

VACUUM DISTILLATION. Distillation at pressure below atmospheric but not so low that it would be classed as molecular distillation. Since lowering the pressure also lowers the boiling point, vacuum distillation is useful for distilling high-boiling and heat-sensitive materials such as heavy distillates in petroleum, fatty acids, vitamins, etc.

See also **Petroleum**.

VACUUM FLUORESCENT DISPLAYS. A vacuum fluorescent display (VFD) is essentially a flat CRT that uses multiple cathodes and a matrix deflection system. The vast majority of VFDs are segmented types; high-resolution dot matrix displays have been developed over a number of years, but they are expensive to manufacture, so market penetration has not occurred. The basic structure of a VFD is shown in Figure 1.

The glass anode substrate holds the connector conductors, the insulation layer, the anode, and the phosphor layer. These structures are formed by thin-film and thick-film processing. The grid structure is positioned over the anode, and the cathode filaments are stretched and held above the grid. The entire structure is then sealed in an evacuated cell.

The cathode filament is heated to about 600 °C (1,100 °F) to facilitate the emission of thermal electrons. An anode voltage of 10 to 50 volts is supplied to the anode, and at the same time the grid voltage is applied to the grid of that selected segment. Electrons from the filament accelerate past the grid and anode, and they collide with the phosphor, resulting in photon emission. The display can be driven in a dynamic or static system. The dynamic system is a type of multiplexing in which a pulse is applied

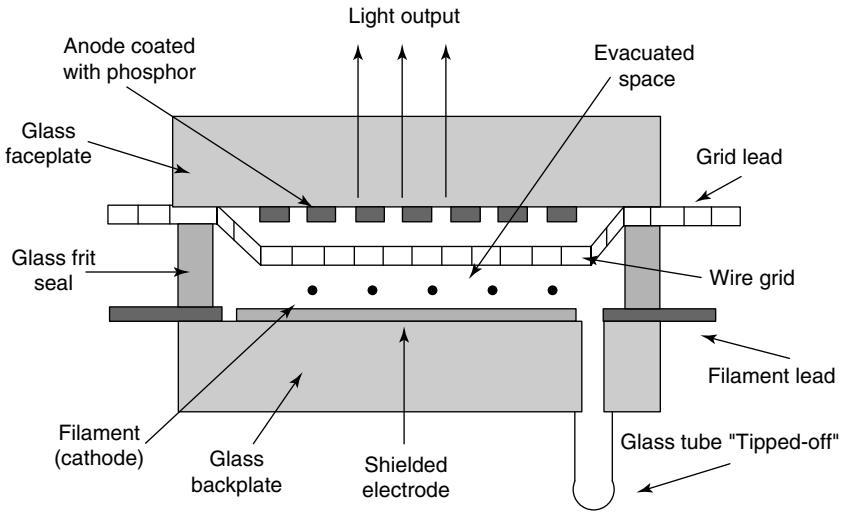

Fig. 1. Cross section of vacuum fluorescent display.

to the grid of each digit or row and to the anode of each selected digit. The multiplexing of very large arrays is not a problem with VFD technology.

The front luminous VFD (FLVFD) is a significant advance that has improved the appearance of the basic structure. This display uses a phosphor deposited on a transparent conductive film of ITO. The emission is observed as one looks through the phosphor, formed as a thin film to increase the amount of light transmitted. Narrow lines of aluminum with wide spacing are deposited on the glass as conductors to help boost the brightness of the phosphor.

The single-matrix VFD is the simplest in construction and lowest in manufacturing costs. The simplicity of the design allows the displays to be made with the highest resolution. The design has a major shortcoming: The increased number of lines leads to a lower duty cycle, requiring a higher anode voltage in order to maintain brightness. As mentioned in previous sections, high-voltage drivers are expensive.

Futaba Corporation (http://www.futaba.com/) has built displays of this type with formats of 320×300 and 640×400 pixels. The firm also demonstrated a 640×400 pixel, graphic VFD with 16 gray levels. The development of a driver IC (32-bit, 64 levels) for the plasma display has allowed the grayscale to be achieved by the pulse-width control method. Using this IC, images with grayscale were displayed on the VFD when NTSC signals were applied. A front luminous VFD was used; it had 640×200 pixels with a pixel pitch of 0.28×0.56 mm. This led to a panel with 640×400 pixels using electrostatic deflection.

Despite the relative simplicity of the character type displays, dot matrix displays with a high pixel count are still very difficult to manufacture, especially at a low cost. Large-area graphic VFDs are not considered competitive with LCDs, PDPs, or TFEL displays and have not been widely used.

Trends in VFD manufacturing include higher brightness, reduced operating voltages, larger sizes, longer life, improved control circuitry, single voltage power source, and a larger selection of colors. Although the majority of the VFDs on the market are blue-green monochrome versions, some dual-color standard models are available, and three-color models can be made on a custom basis. Suppliers are working on full-color (16.77 million colors) versions, but the large dot pitch of VFDs limits the practicality of full-color displays. Most VFDs are custom designed, and good engineering support and customer service are essential in this market segment.

Manufacturers are also trying to improve the brightness and longevity of the three primary colors and reduce the dot pitch to <0.6 mm. Improvements in phosphors, device design, and cathodes are intended to increase the performance of graphic VFDs. Technological development focuses on the following: more colors, higher luminance, larger sizes, and longer life expectancy. Current trends related to display tube manufacturing include rib-grid fluorescent displays, color fluorescent displays, LCD-compatible character modules for easy equipment installation, and integration of memory function on displays.

Rib-grid VFDs use thick-film printed grids instead of metal mesh grids, allowing for greater freedom in pattern design. A VFD in this format has partition walls (ribs) with a width of 0.1 to 0.14 mm. This frees the VFDs from various restrictions required by the metal mesh. Usually, no limitations are placed on the shape and size of rib-grid VFDs. Rib-grid fluorescent display tubes are primarily custom designed because of the ease of laying out display patterns and producing higher resolutions (pixel densities). The higher pixel density can be obtained by printing the grid electrodes. This allows the display to show a large amount of information in a limited space. Because the spacing between VFD segments developed using thick-film printed grids can decrease in size when compared with spacing required for metal mesh grids, the spacing between the adjacent characters narrows. At the same time, the width of each character widens, allowing for designs with easy-to-read displays.

VFDs are increasing in luminance and viewing area, while at the same time using reduced voltages. In cases in which an LCD module does not provide the appropriate brightness or viewing angle, a U-version small character module uses the interface specifications that are virtually the same as those of LCDs. Such VFDs use control codes that are almost the same as those used by LCD controllers. This module is identical in overall thickness to a 2-line $\times$ 20-character LCD with backlighting.

Small character modules capable of displaying 20×2 lines or 24×2 lines of the 5×7 dot fonts are coming to the market. These modules are designed as replacements for LCD modules. Their power consumption is reduced, and a power-saving design is adopted to suspend the converters' operation in the display off state. A 2-line $\times$ 16-character U-version VFD has also been developed. It is compatible with the 2×16 miniature LCD character module. See also **Liquid Crystal Display Technology**.

Color Vacuum Fluorescent Displays

Color VFD tube modules adopt two different luminescent materials, each placed next to one another, with minimal space between them in order to emit three colors. Futaba has shown a system with a green tube that offers 500 cd/m^2 of luminance and a red tube with 250 cd/m^2 of luminance; the company claims lifetimes of 10,000 hours when used as a text display. Blue may be added to the color capability. It may take two years before a blue phosphor is ready for commercial use. These products are a long way from full-color capability.

Chip-Lighting Vacuum Fluorescent Display (CLVFD)

The chip-lighting VFD is a blend of semiconductor technology and conventional VFD technology. The display is a phosphor dot matrix on top of a 5.4×6 mm semiconductor chip that integrates memory function and display driver circuits. The basic structure of this display device is similar to the conventional VFD except for the structure of the anode. In a typical VFD, wiring, insulation, and phosphor layers are fabricated directly on the glass plate and no semiconductor devices are arranged internally. With CLVFD, phosphor matrices are fabricated on a semiconductor chip

and arranged on a glass plate. The chip and outer leads are connected by wire bonding. These types of graphic displays contain semiconductor driver ICs with embedded memory. Claimed benefits of CLVFDs over conventional VFDs include low noise, longer life, higher brightness, and stable operation under varied conditions.

Chip-In-Glass (CIG) Vacuum Fluorescent Display

In chip-in-glass (CIG) technology, slim chips are hidden in the glass envelopes to provide a smaller and more functional display. The main feature of CIG design is the elimination of special external VFD drivers, along with many of the lead pins. Since CIGs do not require chip-mounting space, as do conventional VFDs, they can potentially be made in smaller packages.

Ise Electronics and NEC have used CIG technology to produce dot matrix VFDs. Production costs are lower than for conventional VFDs, and the devices are more compact. Graphic displays for presenting Chinese or Japanese Kanji script have also been developed. The use of static drives allows operation at low voltages (about 10 volts) and lower power consumption, a longer product life, and less noise (compared to dynamic drives) when displaying the same kind of patterns. However, static drive operation has the disadvantage of increasing the number of driver chips with higher segment counts. VALAIS WIND. See **Winds and Air Movement**.

VALENCE. A whole number that represents of denotes the combining power of one element with another. By balancing these integral valence numbers in a given compound, the relative proportions of the elements present can be accounted for. If hydrogen and chlorine both have a valence of 1, oxygen a valence of 2, and nitrogen 3, the valence-balancing principle gives the formulas HCl, H_2, NH_3, Cl_2O, NCl_3, and N_2O_3, which indicate the relative numbers of atoms of these elements in compounds that they form with each other. In inorganic compounds it is necessary to assign either a positive or negative value to each valence number, so that valence balancing will give a zero sum by alegebraic addition. Negative numbers are called polar valence numbers (-1 and -2). The valence of chlorine may be -1, -1, $+3$, $+5$, or $+7$, depending on the type of compound in which it occurs. In organic chemistry only nonpolar valence numbers are used.

VALLEY WIND. See **Winds and Air Movement**.

VALVE (Control). The final control element that directly changes the value of the controlled variable in an automatic control system by varying the rate of flow of some medium, such as steam, water, reactant, etc. The control valve has been defined as a continuously variable orifice in a fluid-flow line. The complete control valve consists of an actuator and a valve body. The actuator provides the power to vary the port opening in the valve body. The valve body assembly consists of a pressure-tight chamber that is screwed, flanged, or welded into a pipeline. Control valves frequently are classified on the basis (1) of the *means of actuation*, notably pneumatically or electrically, although there are also hydraulically operated valves as well as electromechanical, electropneumatic, and electrohydraulic modes of operation; (2) of the style of *valve-body design*, which follows to a large degree the valve body styles of manually operated valves, notably globe valves and rotary-stem valves, as well as the lesser used butterfly valves, slide valves, 3-way valves, angle valves, Saunders patent valves, etc.; and (3) of the *characteristic* of the valve, i.e., the flow behavior as the valve operates through its rated stroke, such as a quick-opening characteristic, an equal-percentage characteristic, a parabolic characteristic, etc. Control valves also may be classified in terms of the service for which they are intended — high temperature, high pressure, cryogenic and vacuum ranges, etc. Valve bodies are obtainable in numerous materials and sizes. Depending upon quality of service, the materials used include carbon steel, alloy steel, stainless steel, bronze, and corrosion-resistant alloys, such as Monel, Hastelloy, Inconel, Duriron, etc.

A diaphragm-actuated (pneumatic) control valve with cage-guided valve plug is shown in Fig. 1. An increasing pneumatic error signal operates in the upper chamber of the valve to push the stem downward against spring pressure. The standard range of pneumatic signals is from 3 to 15 pounds per square inch (0.2 to $\sim$1 atmosphere). In the high-pressure double-port control valve of Fig. 2, a pneumatic piston operator is used instead of a diaphragm-type motor.

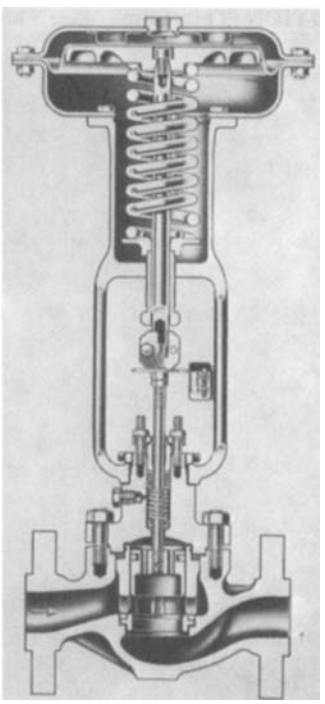

Fig. 1. Section of diaphragm-actuated control valve with cage-guided valve plug.

Electric actuators for control valves fall into two basic categories: (1) inherently two-position actuators, including solenoid and relay actuation; and (2) inherently infinite-position actuators, including reversible electric motor drives, saturable-core reactors, silicon-controlled rectifiers, variable-speed electric motor drives and electropneumatic converters.

For a comprehensive discussion of automatically controlled valves, reference to the "Process/Industrial Instruments and Controls Handbook," Considine, D.M. and G.K. McMillan: 5th Edition, McGraw-Hill Companies, Inc., 1999, is suggested.

VANADINITE. The mineral vanadinite corresponds to the formula $Pb_5(VO_4)_3Cl$, being composed of lead chloride and lead vanadate in the proportion of 90.2% of the former and 9.8% of the latter. It crystallizes in the hexagonal system, is usually prismatic, but the crystals are often skeletal or cavernous; it may be found in crusts. Its fracture is uneven; brittle; hardness, 2.75–3; specific gravity, 6.86; fresh fractures show a resinous luster; color, yellow, yellowish-brown, reddish-brown, and red; streak, white to yellowish; translucent to opaque. Vanadinite, not a common mineral, occurs as an alteration product in lead deposits. It is found in the Ural Mountains, Austria, Spain, Scotland, Morocco, the Transvaal, Argentina, and Mexico. In the United States it occurs in Arizona, New Mexico, and South Dakota. It is used as an ore of vanadium and to some extent of lead as well. It is interesting to note that this mineral was first described as a chromate upon its discovery in Mexico in 1801. It was not until the discovery of the element vanadium in 1830 that the true nature of this compound was known.

VANADIUM. [CAS: 7440-62-2]. Chemical element symbol V, at. no. 23, at. wt. 50.942, periodic table group 5, mp 1,880–2,000 °C (3,416–3,632 °F), bp 3,380 °C (6,116 °F), density 6.10 g/cm^3. Elemental-vanadium has a body-centered cubic crystal structure. Vanadium is a silver-white, very hard (7 on the Mohs scale), oxidizes upon exposure to air, burns upon ignition to form the pentoxide V_2O_5, insoluble in HCl, slowly dissolves in hydrofluoric, HNO_3, or H_2SO_4 (hot, concentrated), or aqua regia. Insoluble in HaOH solution. There are two naturally occurring isotopes ^{50}V (radioactive and with a half-life something greater than 10^{14} years and only present to the extent of 0.24% in natural substances) and ^{51}V (99.76 abundance percentage). Five other radioactive isotopes have been identified ^{46}V through ^{49}V and ^{52}V. ^{49}V has a half-life of 330 days. ^{48}V has a half-life of 16.1 days; the others have half-lives measured in seconds or minutes. First ionization potential 6.74 eV; second, 14.7 eV; third 29.6 eV; fourth 48.3 eV; fifth, 68.64 eV. Oxidation potentials: $V \rightarrow V^{2+} + 2e^-$, 1.5 V, $V^{2+} \rightarrow V^{3+} + e^-$, 0.255 V, $VO^{2+} + H_2O \rightarrow VO_2^+ + 2H^+ + e^-$, −1.00 V. Electronic configuration $1s^2 2s^2 p^6 3s^2 p^6 d^3 4s^2$.

Other important physical characteristics of vanadium are given under **Chemical Elements**.

The element was first reported by Andrés Manuel del Rio in 1801; later and separately reported by Nils Gabriel Sefstr "om in 1830.

Occurrence. Vanadium is widely distributed throughout the earth but in low abundance, ranking 22nd among chemical elements of the Earth's crust. The lithosphere contains ca 0.07 wt % vanadium and few deposits contain more than 1–2 wt %. Vanadium occurs in uranium-bearing minerals of Colorado, in the copper, lead, and zinc vanadates of Africa, and with certain phosphatic shales and phosphate rocks in the western United States. It is a constituent of titaniferous magnetites, which are widely distributed with large deposits in Russia, South Africa, Finland, the People's Republic of China, eastern and western United States, and Australia. At one time, the largest and most important vanadium deposits were the sulfide and vanadate ores from the Peruvian Andes, but these are depleted. Most of the vanadium reserves are in deposits in which the vanadium would be a by-product or coproduct with other minerals, including iron, titanium, phosphate, and petroleum.

Trace amounts of vanadium have been found in meteorites and it has been identified in the spectrum of many stars including the Earth's sun. It is estimated that vanadium occurs in seawater to the extent of about 9.5 tons per cubic mile (2.1 metric tons per cubic kilometer). The occurrence of vanadium in oak and beech trees and some forms of aquatic sea life indicates its biological importance.

There are over 65 known vanadium-bearing minerals, some of the more important are listed in Table 1. Patronite, bravoite, sulvanite, davidite, and roscoelite are classified as primary minerals, whereas all of the others are secondary products which form in the oxidizing zone of the upper lithosphere. The carnotite and roscoelite ores in the sandstones of the Colorado Plateau have been important sources of vanadium as well as of uranium.

The metallic vanadates of lead, copper, and zinc, which occur in Namibia (southwest Africa) and Zambia, are also a large resource of vanadium-bearing ores, as are the phosphatic shales and rocks of the phosphoria formation in Idaho and Wyoming. Vanadium salts are obtained as by-products of the phosphoric acid and fertilizer industries. See also **Fertilizer**. Large reserves of vanadium in Arkansas and Canada and the titaniferous magnetite ores will probably become increasingly significant as sources of production. Certain petroleum crude oils, especially those from South America, contain varying amounts of vanadium compounds. These accrue as fly ash or boiler residues upon combustion of the crude oils and they can be reclaimed

Physical Properties. Important physical properties of some industrial and other selected vanadium compounds are listed in Table 2.

Vanadium is stable in air below 250 °C (482 °F). On prolonged storage the surface becomes bluish-gray to brownish-black, and significant oxidation takes place in air above 300 °C (572 °F). Vanadium absorbs hydrogen in interstitial lattice sites at elevated temperatures (up to 500 °C (932 °F). The metal becomes brittle and can easily be powdered. This hydrogen is liberated on heating to 600–700 °C (1,112–1,292 °F) in vacuum. At low temperature, a hydride phase exists in the V–H system. Vanadium reacts with nitrogen at >800 °C (>1,472 °F) to form vanadium nitrides. It has a high affinity for carbon, forming carbides at 800–1000 °C (1,472–1.832 °F).

In its compounds, vanadium exhibits the oxidation state II, III, IV, or V. It is relatively stable towards dilute sulfuric, hydrochloric, and phosphoric acids, but is dissolved by nitric and hydrofluoric acids. Its corrosion resistance towards tap water is good, and towards seawater moderate to good, but pitting does not occur. Vanadium is resistant to 10 % sodium hydroxide solution, but is attacked by a hot solution of potassium hydroxide. Vanadium and some vanadium alloys have good corrosion resistance towards molten low-melting metals and alloys, especially alkali metals, which are used in nuclear reactors as coolants and heat-exchange media.

Vanadium, a typical transition element, displays well-characterized valence states of 2-5 in solid compounds and in solutions. Valence states of −1 and 0 may occur in solid compounds. In oxidation state 5, vanadium is diamagnetic and forms colorless, pale yellow, or red compounds. In lower oxidation states, the presence of one or more *3d* electrons, usually unpaired, results in paramagnetic and colored compounds. All compounds of vanadium having unpaired electrons are colored, but because the absorption spectra may be complex, a specific color does not necessarily correspond to a particular oxidation state. As an illustration, vanadium(IV)

TABLE 1. IMPORTANT MINERALS OF VANADIUM

Mineral	CAS Registry Number	Color	Formula	Location
patronite	[12188-60-2]	greenish black	$V_2S + nS$	Peru
bravoite	[12172-92-8]	brass	$(Fe,Ni,V)S_2$	Peru
sulvanite	[15117-74-5]	bronze-yellow	$3Cu_2S \cdot V_2S_6$	Australia, United States (Utah)
davidite	[12173-20-5]	black	titanate of Fe, U, V, Cr, and rare earths	Australia
roscoelite	[12271-44-2]	brown	$2K_2O \cdot 2Al_2O_3(Mg,Fe)O \cdot -$ $3V_2O_5 \cdot 10SiO_2 \cdot 4H_2O$	United States (Colorado, Utah)
carnotite	[1318-26-9]	yellow	$K_2O \cdot 2U_2O_3$, $V_2O_5 \cdot 3H_2O$	southwest United States
vanadinite	[1307-08-0]	reddish brown	$Pb_5(VO_4)_3Cl$	Mexico, United States, Argentina
descloizite	[19004-61-6]	cherry-red	$4(Cu,Pb,Zn)O \cdot V_2O_5 \cdot H_2O$	Namibia, Mexico, United States
cuprodescloizite	[12325-36-9]	greenish brown	$5(Cu,Pb)O \cdot (V,As)_2O_5 \cdot 2H_2O$	Namibia
vanadiferous			$Ca_5(PO_4)_3(F,Cl,OH)$; VO_4 ions replace some PO_4 ions	United States (Montana)
titaniferous magnetite			$FeO \cdot TiO_2 - FeO \cdot (Fe,V)O_2$	Russia, People's Republic of China, Finland, Union of South Africa

TABLE 2. PHYSICAL PROPERTIES OF SOME INDUSTRIAL AND OTHER SELECTED VANADIUM COMPOUNDS

Compound	CAS Registry number	Formula	Appearance	Mol wt	Density, g/cm^3	Mp, °C	Bp, °C	Solubility
vanadic acid, meta	[13470-24-1]	HVO_3	yellow scales	99.95				soluble in acid and alkali
ammonium metavanadate	[7803-55-6]	NH_4VO_3	white–yellowish or colorless crystals	116.98	2.326	200 dec		slightly soluble in H_2O
potassium metavanadate	[13769-43-2]	KVO_3	colorless crystals	134.04				soluble in hot H_2O
sodium metavanadate	[13718-26-8]	$NaVO_3$	colorless, monoclinic prisms	121.93		630		soluble in H_2O
sodium orthovanadate	[13721-39-6]	Na_3VO_4	colorless, hexagonal prisms	183.94		850–856		soluble in H_2O
sodium pyrovanadate	[13517-26-5]	$Na_4V_2O_7$	colorless, hexagonal prisms	305.84		632–654		soluble in H_2O
vanadium carbide	[12070-10-9]	VC	black cubic	62.95	5.77	2810	3900	insoluble in H_2O; soluble in HNO_3 with decomposition
vanadium nitride	[24646-85-3]	VN	black cubic	64.95	6.13	2320		soluble in *aqua regia*
vanadium(III) trichloride	[7718-98-1]	VCl_3	pink crystals, deliquescent	157.301	3	dec		soluble (deliquescent) in H_2O; soluble in methanol and ether
vanadium(IV) tetrachloride	[7632-51-1]	VCl_4	red-brown liquid	192.75	1.816	28 ± 2	148.5	soluble (deliquescent) in H_2O; soluble in methanol, ether, and chloroform
vanadium(V) oxytrichloride	[7727-18-6]	$VOCl_3$	yellow liquid	173.3	1.829	−77 ± 2	126.7	soluble (deliquescent) in H_2O; soluble in methanol, ether, acetone, and acid
vanadium(II) oxide	[12035-98-2]	VO	light green crystals	66.95	5.758	ignites		soluble in acid
vanadium(III) oxide	[1314-34-7]	V_2O_3	blue crystals	149.88	4.87	1970		soluble in HNO_3, HF, and alkali in presence of oxide
vanadium(IV) oxide	[12036-21-4]	VO_2	blue crystals	82.94	4.339	1967		soluble in acid and alkali
vanadium(V) oxide	[1314-62-1]	V_2O_5	yellow-red rhombohedra	181.88	3.357	690	1750 dec	slightly soluble in H_2O; soluble in acid and alkali
vanadium(IV) disilicide	[12039-87-1]	VSi_2	metallic prisms	107.11	4.42			soluble in HBr
vanadium(III) acetylacetonate	[13476-99-8]	$V(C_5H_7O_2)_3$	brown crystals	348.27	0.9–1.2	178–190		soluble in methanol, acetone, benzene, and chloroform
biscyclopentadienyl-vanadium chloride	[12083-18-6]	$(C_5H_5)_2VCl_2$	pale green crystals	252.04		250 dec		soluble in methanol and chloroform

oxy salts are generally blue, whereas vanadium(IV) chloride is deep red. Differences over the valence range of 2–5 are shown in Table 3.

Production. The bulk of world vanadium production is derived as a by-product or coproduct in processing iron, titanium, and uranium ores, and, to a lesser extent, from phosphate, bauxite, and chromium ores, spent catalysts and the ash, fume, or coke from burning or refining petroleum. Total world production of V_2O_5 was ~85 t (190×10^6 lb) in 2004.

Essentially no U.S. production, 9 t (20×10^6 lb in 2004), of primary vanadium compounds has been as by-products or coproducts of uranium or of ferrophosphorus derived from smelting Idaho phosphates. However, a uranium/vanadium producer did start up in 2005. Essentially all of the 2004 U.S. production was from processing petroleum residues, and spent catalysts. The only domestic commercially mined ore, for its sole production of vanadium, is Arkansas brookite. It has contributed

TABLE 3. MAGNETISM AND COLOR OF VANADIUM COMPOUNDS

Compound	CAS Registry Number	Vanadium valence	No. of *d* electrons	Magnetic moment, J/T×10^{-23}[a]	Color
$VOCl_3$	[7727-18-6]	5	0	0	yellow
$VOSO_4 \cdot 5H_2O(NH_4)V$	[12439-96-2]	4	1	1.60	blue
$(SO_4)_2 \cdot 12H_2O$	[29932-01-2]	3	2	2.60	blue
$VSO_4 \cdot 7H_2O$	[36907-42-3]	2	3	3.47	violet

[a] To convert J/T to μ_B, divide by 9.274×10^{-24}.

significantly to domestic supply since ~1969, however, it has not been mined since 1992.

Most foreign vanadium is obtained as a coproduct of iron and titanium. South Africa, Norway, and Finland are suppliers. Chile produces slag from an iron operation. Australia had the world's largest vanadium operation, but it shut down in 2003 after only a few years of operation. Russia and the People's Republic of China produce slag and pentoxide from iron–titanium ores.

Uses. Most vanadium produced is consumed as ferrovanadium. Ferrovanadium is made by the aluminum or silicon reduction of the oxide in the presence of iron in an electric-arc furnace. The product contains about 85% vanadium, 12% carbon, and 2% iron. Ductile vanadium metal also is produced in significant quantities, mainly by the calcium reduction of the oxide in a process developed by McKechnie and Seybolt. Pure vanadium oxide, calcium metal, and iodine are charged into a heavy-walled steel cylinder, excluding all moisture. After evacuation, heat is applied to initiate the reaction. Molten droplets of vanadium collect beneath the calcium oxide-calcium iodide slag and there form a single button or regulus. Ductile vanadium metal produced in this manner has an analysis of 99.7% vanadium, 0.10% oxygen, 0.04% nitrogen, 0.008% hydrogen, 0.04% iron, and 0.03% carbon. The metal is soft and ductile, can be hot- and cold-worked easily. Any heating must be done in vacuum or an inert atmosphere because the metal oxidizes readily. With exception of HNO_3, the metal withstands other acids and aerated saltwater better than most stainless steels. It has a comparatively low cross section for neutron capture and is of interest in the nuclear field. The density is 22% less than iron and 28% greater than titanium. The coefficients of thermal and electrical conductivity are higher than those of titanium.

Most vanadium is used by the steel industry. The addition of vanadium to steel causes the formation of vanadium carbide. The carbides are very hard and wear-resistant; they maintain a fine dispersion. The addition of very small quantities (0.02–0.08%) of vanadium enhances strength and toughness of the resulting steel. Many structural, plate, bar, and pipe steels contain vanadium in these amounts. For little additional cost, in comparison with plain carbon steels, there is a marked increase in performance, including higher strength in the as-rolled condition without heat treatment. Often, manganese and copper are added in small quantities along with the vanadium. Some sheet steels that are used for deep-drawing as in auto and home-appliance parts contain vanadium to suppress aging. For such steels, ferrovanadium is added to rimming steels, resulting in a good, nonaging, deep-drawing steel at a smaller cost than for aluminum-killed deep-drawing steel. Some large steel forgings contain vanadium to the extent of 0.5 to 0.15% with the object of improving the mechanical properties of the forgings. Vanadium is particularly effective in raising the strength and ductility of large steel castings and forgings when added in a small percentage. A large number of tool steels contain vanadium to the extent of 0.10 to 5.00%. In these steels, vanadium insures the retention of hardness and cutting ability at the high temperatures resulting from the rapid cutting of metals. The use of vanadium in cast iron controls the size and distribution of graphite flakes and thus improves strength and wear resistance. One of the most popular of the titanium-base alloys contains 4% vanadium and 6% aluminum. The addition ingredient for this titanium alloy, produced in large quantities, is a base 40:60 vanadium-alloy.

The use of certain vanadium compounds as catalysts has been increasing. Vanadium oxytrichloride is a catalyst in making ethylene-propylene rubber. Ammonium metavanadate and vanadium pentoxide are used as oxidation catalysts, particularly in the production of polyamides, such as nylon, in the manufacture of H_2SO_4 by the contact process, in the production of phthalic and maleic anhydrides, and in numerous other oxidation reactions, such as alcohol to acetaldehyde, anthracene to anthraquinone, sugar to oxalic acid, and diphenylamine to carbazole. Vanadium compounds have been used for many years in the ceramics field for enamels and glazes. Colors are produced by various combinations of vanadium oxide and silica, zirconia, zinc, lead, tin, selenium, and cadmium. Vanadium intermediate compounds also are used in the making of aniline black used by the dye industry.

Chemistry and Compounds. The chemistry of vanadium compounds is related to the oxidation state of the vanadium. Thus, V_2O_5 is acidic and weakly basic, VO_2 is basic and weakly acidic, and V_2O_3 and VO are basic. Vanadium in an aqueous solution of vanadate salt occurs as the anion, eg, $(VO_3)^-$ or $(V_3O_9)^{3-}$, but in strongly acid solution, the cation $(VO_2)^+$ prevails. Vanadium(IV) forms both oxyanions $(V_4O_9)^{2-}$ and oxycations $(VO)^{2+}$. Compounds of vanadium(III) and (II) in solution contain the hydrated ions $[V(H_2O)_6]^{3+}$ and $[V(H_2O)_6]^{2+}$, respectively.

Coordination compounds of vanadium are mainly based on six coordination, in which vanadium has a pseudooctahedral structure. Coordination number 4 is typical of many vanadates. Coordination numbers 5 and 8 also are known for vanadium compounds, but numbers <4 have not been reported. See also **Coordination Compounds**.

Aqueous pentavalent vanadium is readily reduced to the tetravalent state by iron powder or by SO_2 gas. A stronger reducing agent, eg, zinc amalgam, is needed to yield divalent vanadium. Divalent and trivalent vanadium compounds are reducing agents and require storage under an inert atmosphere to avoid oxidation by air.

Interstitial and Intermetallic Compounds. In common with certain other metals, eg, Hf, Nb, Ti, Zr, Mo, W, and Ta, vanadium is capable of taking atoms of nonmetals into its lattice. Such uptake is accompanied by a change in the packing pattern to a cubic close-packed structure. Carbides, hydrides, and nitrides so formed are called interstitial compounds. Their composition is determined by geometrical packing arrangements rather than by valence bonding. As all possible vacant lattice sites need not be filled, the compositions display a range of nonmetal content up to the theoretical limit. A range for the vanadium nitride compound is $VN_{0.71-1.00}$. Compounds corresponding to V_2C [CAS: 12012-17-8], VC, and $VH_{1.8}$ [CAS: 12713-06-3] have been formed. Vanadium borides also are known. In VB [CAS: 12045-27-1], the boron atoms form a zigzag chain; whereas, in VB_2 [CAS: 12007-37-3], the interstitial boron atoms are linked in a layer of hexagons.

Large-atomed nonmetals, eg, Si, Ge, P, As, Se, and Te, form compounds with vanadium that are intermediate between being interstitial and intermetallic. The interstitial and intermetallic vanadium compounds are very hard crystalline solids (9–10 on Mohs' scale), have high melting points (2,000–3,000 °C (3,632–5,432 °F), and generally are resistant to attack by mineral acids. Except for carbides that are used in impure form, eg, in making alloy steels, this group of compounds is little used. Vanadium disilicide, VSi_2, which is made by the reaction of vanadium pentoxide with silicon metal at ~1,200 °C (~2,192 °F), has limited use as a refractory material. See also **Refractories**.

Vanadium Oxides. Vanadium pentoxide [CAS: 1314-62-1] (V_2O_5) is intermediate in behavior and stability between the highest oxides of titanium, ie, TiO_2 [CAS: 13463-67-7], and of chromium, ie, CrO_3 [CAS: 1333-82-0]. It is thus less stable to heat than TiO_2 and more heat-stable than CrO_3. Also, V_2O_5 is more acidic and a stronger oxidant than TiO_2, but less so than CrO_3. An excess of aluminum is capable of reducing V_2O_5

to a V — Al alloy, but only calcium can reduce the oxide to vanadium metal. Solubility in water is 0.1–0.8 g/100 g H_2O and is lowest for crystals solidified from the molten state. The pentoxide readily dissolves in both acids and alkalies. In strongly alkaline solutions (pH >13), simple mononuclear vanadate ions are present. In strongly acid solutions, the main species is the dioxyvanadium(V) cation $(VO_2)^+$. More complex ions are present in solutions of intermediate strength alkali or acid; these include $(VO_3)^-$, $(HVO_4)^{2-}$, $(V_3O_9)^{3-}$, $(V_4O_{12})^{4-}$, $(V_{10}O_{28})^{6-}$, and others.

Vanadium(IV) Oxide (vanadium dioxide, VO_2) [CAS: 12036-21-4] is a blue-black solid, having a distorted rutile (TiO_2) structure. It can be prepared from the reaction of V_2O_5 at the melting point with sulfur or carbonaceous reductants such as sugar or oxalic acid. The dioxide slowly oxidizes in air. Vanadium dioxide dissolves in acids to give the stable $(VO)^{2+}$ ions and in hot alkalies to yield vanadate(IV) species, eg, $(HV_2O_5)^-$.

Vanadium(III) oxide (vanadium sesquioxide, V_2O_3) [CAS: 1314-34-7] is a black solid, having the corundum (Al_2O_3) structure. It can be prepared by reduction of the pentoxide or ammonium metavanadate by natural gas, hydrogen or carbon. Air oxidation proceeds slowly at ambient temperatures, but oxidation by chlorine at elevated temperatures to give $VOCl_3$ and V_2O_5 is rapid.

Vanadium(II) oxide is a nonstoichiometric material with a gray-black color, metallic luster, and metallic-type electrical conductivity. Metal — metal bonding increases as the oxygen content decreases, until an essentially metal phase containing dissolved oxygen is obtained.

Vanadates. Ammonium metavanadate and, to a lesser extent, potassium and sodium metavanadates, are the main vanadates of commercial interest. The pure compounds are colorless crystals. Vanadates(V) are identified as the meta (MVO_3), ortho (M_3VO_4), and pyro ($M_4V_2O_7$) compounds, and the nomenclature commonly used is that applied to the phosphates (M is univalent). Orthovanadates contain discrete tetrahedral $(VO_4)^{3-}$ anions. The pyrovanadates also contain discrete ions $(V_2O_7)^{4-}$ and have two VO_4 tetrahedra sharing a corner. The metavanadate structure is different for the anhydrous and hydrated salts. In the anhydrous salts KVO_3 and NH_4VO_3, the vanadium atoms are four-coordinate, with VO_4 tetrahedra linking through two oxygen atoms. In the hydrated form, $KVO_3 \cdot H_2O$, the vanadium atoms are five coordinate, with three shared oxygen atoms per vanadium and two terminal oxygen atoms.

Vanadium Halides and Oxyhalides. Known halides and oxyhalides of vanadium, their valences, and their colors are listed in Table 4. Only vanadium(V) oxytrichloride ($VOCl_3$) and the tetrachloride (VCl_4) have appreciable commercial importance. The trichloride (VCl_3) is of minor commercial interest. The absence of pentavalent vanadium halides, other than the fluoride, is attributed to the relative weakness of the fluoride–fluoride bond compared with analogous bonds in other halides. Even VCl_4 is somewhat unstable, and VBr_4 decomposes at −23 °C (−9.4 °F).

Vanadium(V) oxytrichloride [CAS: 7727-18-6] ($VOCl_3$) is readily hydrolyzed and forms coordination compounds with simple donor molecules, eg, ethers, but is reduced by reaction with sulfur-containing ligands and molecules. It is completely miscible with many hydrocarbons and nonpolar metal halides, eg, $TiCl_4$, and it dissolves sulfur.

Vanadium(IV) chloride (vanadium tetrachloride, VCl_4) [CAS: 7632-51-1] is a red-brown liquid, is readily hydrolyzed, forms addition compounds with donor solvents, eg, pyridine, and is reduced by such molecules to trivalent vanadium compounds. Vanadium tetrachloride dissociates slowly at room temperature and rapidly at higher temperatures, yielding VCl_3 and Cl_2. Decomposition also is induced catalytically and photochemically. This instability reflects the difficulty in storing and transporting it for industrial use.

Vanadium(III) chloride (vanadium trichloride, VCl_3) [CAS: 7718-98-1] is a pink-violet solid, is readily hydrolyzed, and is insoluble in nonpolar solvents but dissolves in donor solvents, eg, acetonitrile, to form coordination compounds. Chemical behavior of the tribromide (VBr_3) is similar to that of VCl_3.

Vanadium Sulfates. Sulfate solutions derived from sulfuric acid leaching of vanadium ores are industrially important in the recovery of vanadium from its raw materials. Vanadium in tetravalent form may be solvent-extracted from leach solutions as the oxycation complex $(VO)^{2+}$. Alternatively, the vanadium can be oxidized to the pentavalent form and solvent extracted as an oxyanion, eg, $(V_3O_9)^{3-}$. Pentavalent vanadium does not form simple sulfate salts.

TABLE 4. VANADIUM HALIDES AND OXYHALIDES

Vanadium valence	Formula	CAS Registry Number	Appearance[a]
		Halides	
V	VF_5	[7783-72-4]	white
IV	VF_4	[10049-16-8]	green
	VCl_4	[7632-51-1]	red-brown liquid
	VBr_4[b]	[13595-30-7]	magenta
III	VF_3	[10049-12-4]	green
	VCl_3	[7718-98-1]	red-violet
	VBr_3	[13470-26-3]	gray
	VI_3	[15513-94-7]	dark brown
II	VF_2	[13842-80-3]	blue
	VCl_2	[10580-52-6]	pale green
	VBr_2	[14890-41-6]	orange-brown

	$VOBr_2$	[13520-89-3]	yellow-brown
III	VOCl	[13520-87-1]	brown
	VOBr	[13520-88-2]	violet

[a] At room temperature; solid unless identified as liquid.
[b] Decomposes at −23 °C.

Vanadium(IV) oxysulfate pentahydrate (vanadyl sulfate), $(VOSO_4 \cdot 5H_2O)$ is an ethereal blue solid and is readily soluble in water. It forms from the reduction of V_2O_5 by SO_2 in sulfuric acid solution. Vanadium(III) sulfate [CAS: 13701-70-7] $[V_2(SO_4)_3]$ is a powerful reducing agent and has been prepared in both hydrated and anhydrous forms. The anhydrous form is insoluble in either water or sulfuric acid. Vanadium(II) sulfate heptahydrate ($VSO_4 \cdot 7H_2O$) is a light red-violet crystalline powder that can be prepared by electrolytic reduction of $VOSO_4$. The powder is oxidized by air and dissolves in water to give a red-violet solution.

Health, Safety, and Environmental Considerations. Although most foods contain low concentrations of vanadium (<1 ng/g), food is the major source of exposure to vanadium for the general population. High air concentrations of vanadium occur in the occupation setting during boiler-cleaning operations as a result of the presence of vanadium oxides in the dust. The lungs absorb soluble vanadium compounds V_2O_5 well, but the absorption of vanadium salts from the gastrointestinal tract is poor. The excretion of vanadium by the kidneys is rapid with a biological half-life of 20-40 hours in the urine. Vanadium is probably an essential trace element, but a vanadium-deficiency disease has not been identified in humans. The estimated daily intake of the US population ranges from 10-60 micrograms V. Vanadyl sulfate is a common supplement used to enhance weight training in athletes at doses up to 60 mg/d. In vitro and animal studies indicate that vanadate and other vanadium compounds increase glucose transport activity and improve glucose metabolism. In general, the toxicity of vanadium compounds is low. Pentavalent compounds are the most toxic and the toxicity of vanadium compounds usually increases as the valence increases.

Most of the toxic effects of vanadium compounds result from local irritation of the eyes and upper respiratory tract rather than systemic toxicity. The only clearly documented effect of exposure to vanadium dust is upper respiratory tract irritation characterized by rhinitis, wheezing, nasal hemorrhage, conjunctivitis, cough, sore throat, and chest pain. Case studies have described the onset of asthma after heavy exposure to vanadium compounds, but clinical studies to date have not detected an increased prevalence of asthma in workers exposed to vanadium.

VAN ALLEN, JAMES (1914–1994). Van Allen was an American physicist who earned his Ph.D. in physics from the State University of Iowa. Between the years of 1939 and 1942, he researched at the Carnegie Institution's Department of Terrestrial Magnetism. In 1942, he began weapons research for the U.S. Navy at Johns Hopkins University. He is known for developing the radio proximity fuse that increased missile efficiency.

In 1946, Van Allen became the administrator and coordinator of the U.S. Army's V-2 research program and designed payloads to be sent into the atmosphere. In 1951, he returned to the State University of Iowa and became head of the department of physics and astronomy. During this research time, he discovered high-altitude radiation belts. This discovery is now named the Van Allen radiation belts.

See also **Van Allen Radiation Belts**.

J. M. I.

VAN ALLEN RADIATION BELTS. These are belts of charged particles (electrons and protons) that are trapped by the Earth's external magnetic field and which circle the Earth at altitudes of approximately 1000 to 6000 kilometers. The paths of the particles are determined by the direction of the external lines of force of the Earth's magnetic field. The particles migrate from the region above the Earth's equator toward the North Pole, then toward the South Pole, and then return to the region above the equator. This is a definition essentially developed by the IEEE Communications Committee.

Although the belts were predicted a quarter-century earlier by James Van Allen, they were not confirmed until 1958 by instruments aboard the U.S. Explorer 1 satellite. The Van Allen belts are well known for single-event upsets that occur when a single, heavy ion shoots through a satellite-based semiconductor, causing a memory bit to change. Radhardening of electronic devices for Van Allen radiation sources as well as other radiation found in outer space (or in the terrestrial atmosphere as the result of a nuclear event) is extremely important to military and aerospace equipment. See also **Radiation Hardening (Electronics)**.

VAN DE GRAAF GENERATOR. See Particles (Subatomic).

VANDENBERG AIR FORCE BASE. See **Spaceports U.S**.

VAN DER WAALS EQUATION. A form of the equation of state, relating the pressure, volume, and temperature of a gas, and the gas constant. Van der Waals applied corrections for the reduction of total pressure by the attraction of molecules (effective at boundary surfaces) and for the effect of reduction of total volume by the volume of the molecules (but not the actual molecular volume). The equation takes the form

$$\left(P + \frac{a}{V^2}\right)(V - b) = RT$$

in which P is the pressure of the gas, V is the volume, T is the absolute temperature, R is the gas constant, and a and b are correction terms which have been evaluated and reported for many gases. See also **Characteristic Equation**.

VAN DER WAALS FORCES. Interatomic or intermolecular forces of attraction due to the interaction between fluctuating dipole moments associated with molecules not possessing permanent dipole moments. These dipoles result from momentary dissymmetry in the positive and negative charges of the atom or molecule, and on neighboring atoms or molecules. These dipoles tend to align in antiparallel direction and thus result in a net attractive force. This force varies inversely as the seventh power of the distance between ions.

VAN DER WAALS, JOHANNES DIDERIK (1837–1923). Van der Waals was a Dutch physicist, he was a professor of physics at the University of Amsterdam from 1877 to 1907. He was especially interested in thermodynamics and he won the 1910 Nobel Laureate in Physics for his work on gases and liquids, his most well known expressed as Van der Waals Equation. He also studied the attractive forces, which hold the atoms of molecules together and is named now Van der Waals forces. Van der Waals bonding, a crystalline structure with the weakest bonding, is also named in his honor.

See also **Characteristic Equation**; **Chemical Elements**; **Van Der Waals Equation**; and **Van Der Waals Forces**.

J. M. I.

VANE. 1. A thin and more-or-less flat object intended to align itself with a stream or flow in a manner similar to that of the common weathercock, as: (a) a device that project ahead of an aircraft to sense gusts or other actions of the air so as to create impulses or signals that are transmitted to the control system to stabilize the aircraft; (b) a fixed or movable surface used to control or give stability to a rocket.

2. A blade or paddlelike object, often fashioned like an airfoil and usually one of several, that rotates about an axis, either being moved by a flow or creating a flow itself, such as the blade of a turbine, of a fan, of a rotary pump or air compressor, etc.

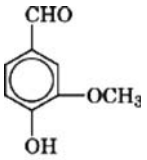
3. Any of certain stationary blades, plates, or the like that serve to guide or direct a flow, or to create a special kind of flow, as: (a) any of the blades in the nozzle ring of a gas-turbine engine; (b) any of the plates or slatlike objects that guide the flow in a wind tunnel; (c) a plate or fence projecting from a wing to prevent spanwise flow.

VANILLA BEAN. See **Bean**.

VANILLIN. [CAS: 121–35–5]. Vanillin is an organic compound with the molecular formula $C_8H_8O_3$. Vanillin, a natural product, can be found as a glucoside (glucovanillin) in vanilla beans, at concentrations of about 2%. It can be extracted with water, alcohol, or other organic solvents. Approximately 250 by-products have been identified in natural vanilla, out of which 26 are present at levels in excess of 1 ppm. The balance of all these products contributes to the subtle taste of vanilla beans. The vanilla bean contains about 2% vanillin, but the 10% extract prepared from beans has several times the strength of a solution of 2% vanillin. The best known natural source of vanillin is the vanilla plant, *Vanilla planifolia* A., which belongs to the orchid family. It is cultivated mainly in Mexico, Madagascar, Reunion, Java, and Tahiti.

The long and expensive process of extracting vanillin from vanilla beans yields a product that has an inconsistent quality. The demand for this universally popular flavoring cannot be satisfied by vanilla beans alone. The consumption of naturally occurring vanilla has gradually given way to synthetic vanillin. Synthetic vanillin is identical to that contained in the pod, but differs in smell and flavor from natural vanillin as a result of the various compounds in the natural extract that do not exist in artificial

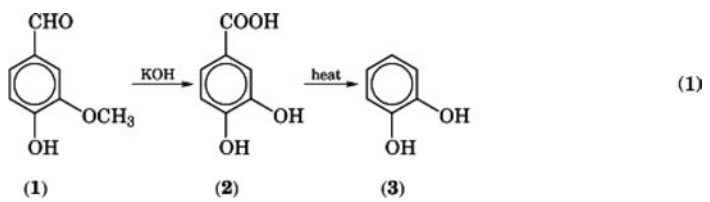
vanillin. These other compounds represent only 2% of the extract; the remaining 98% is vanillin. Vanillin is the common name for 3-methoxy-4-hydroxybenzaldehyde [CAS: 121-33-5] (**1**).



(1)

Production. Vanillin was observed long before it was reported in chemical literature, as it crystallizes on the surface of vanilla beans after harvesting, processing, and storage. The first report in the literature was probably made by Bucholtz in 1816. Some years later, Bley referred to vanillin as vanilla camphor. In 1858, Gobley crystallized out vanillin from alcoholic solutions of vanilla bean extract and succeeded in obtaining it in a relatively pure form. He reported its composition to be $C_{10}H_6O_2$. Its correct analysis, $C_8H_8O_2$, was established in 1872 by Carles, who also gave its correct melting point, 81 °C (177.8 °F).

In 1874, Tiemann and Haarmann examined the structure of vanillin and reported it to be 3-methoxy-4-hydroxybenzaldehyde. This was not a difficult task because, on treatment with potassium hydroxide, vanillin (**1**) gave protocatechaic acid [CAS: 99-50-3] (**2**), which, in turn, was decarboxylated to catechol [CAS: 120-80-9] (**3**) by dry distillation (eq. **1**). As both compounds were known at that time, the position of the substituent groups in vanillin was established. Finally, Reimer synthesized vanillin from guaiacol [CAS: 90-05-1] and thus proved the identity of its structure. In 1894 Rhône-Poulenc began producing vanillin on an industrial scale. Since then, many other producers have entered into vanillin production, often only to leave it behind.

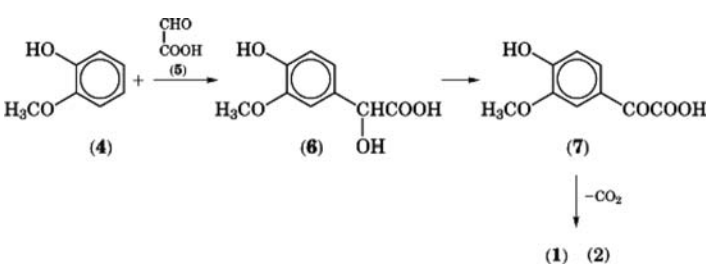


(1)

(1) (2) (3)

The manufacture of vanillin shows the progress made in the chemistry and chemical engineering of the substance. Most commercial vanillin is synthesized from guaiacol; the remainder is obtained by processing waste sulfite liquors. Preparation by oxidation of isoeugenol is of historical interest only.

Preparation from Guaiacol and Glyoxylic Acid. Several methods can be used to introduce an aldehyde group into an aromatic ring. Condensation of guaiacol (**4**) with glyoxylic acid (**5**), followed by oxidation of the resulting mandelic acid (**6**) to the corresponding phenylglyoxylic acid (**7**) and decarboxylation continues to be a competitive industrial process for vanillin synthesis (eq 2).



(4) (6) (7)

(1) (2)

Preparation from Waste Sulfite Liquors. The starting material for vanillin production can also be the lignin present in sulfite wastes from the cellulose industry. See also **Lignin**. The concentrated mother liquors are treated with alkali at elevated temperature and pressure in the presence of oxidants. The vanillin formed is separated from the by-products, particularly acetovanillone, 4-hydroxy-3-methoxyacetophenone, by extraction, distillation, and crystallization. In contrast to vanillin from lignin, the principal impurity found in vanillin from guaiacol is 5-methyl vanillin, typically present at levels of about 100 ppm, although levels as high as 3000 ppm have been found. This impurity is completely odorless.

No residual guaiacol can be found in vanillin produced by the guaiacol process. In contrast to vanillin from lignin, vanillin from guaiacol is extremely consistent in quality owing to the consistency of the supply source, and shows no variation in taste, odor, or color.

Properties. Solubility in water is less than 2%; the solubility in ethanol, is given by the ratio one part vanillin to two parts alcohol. Certain manufacturing processes require that the product be in liquid form.

Particle size, crystal shape, and distribution of vanillin are important and greatly affect parameters such as taste, flavor, solubility, ease of dispersion in solvent, flowability of the powder, caking effect, and production of dust.

The taste effect is generally sweet, but depends strongly on the base of preparation. For tasting purposes, vanillin is often evaluated in ice-cold milk with about 12% sugar. A concentration of 50 ppm in this medium is clearly perceptible. Vanilla is undoubtedly one of the most popular flavors; its consumption in the form of either vanilla extracts or vanillin is almost universal.

The food flavor industry is the largest user of vanillin, an indispensable ingredient in chocolate, candy, bakery products, and ice cream. Commercial vanilla extracts are made by macerating one part of vanilla beans with ten parts of 40–50% alcohol. Although vanillin is the primary active ingredient of vanilla beans, the full flavor of vanilla extract is the result of the presence of not only vanillin but also other ingredients, especially little-known resinous materials which contribute greatly to the quality of the flavor.

It is easy to smell a difference in the quality of vanillins from different origins, but it is normally difficult to taste the same difference, provided the various samples are of good quality. Vanillin is sensitive to contamination with other crystalline odor chemicals. Adherent or absorbed odor on the crystals perceptibly affects the odor of vanillin from a fiber-drum or other large containers.

Available Grades. Rhovanil Extra Pure is the trade name of the food-grade vanillin of Rhodia, worldwide leader in the diphenols area. The following grades are commercially available: Rhovanil Extra Pure crystallized, Rhovanil Fine Mesh, Rhovanil Free Flow, and Rhovanil Liquid.

Rhovanil Extra Pure is the standard mesh, multipurpose quality of food-grade extra pure vanillin. Rhovanil Fine Mesh, a specially calibrated extra pure vanillin that avoids demixing with other very fine dry ingredients such as sucrose, flour, and dextrose, provides a faster dissolution rate at lower stirring, at lower temperature, in low acidity medium, or in viscous liquids.

Rhovanil Free Flow is obtained by adding an anticaking agent (0.5% max) to the extra pure vanillin. The flowability is increased, making it particularly suitable for self-dispensing equipment (instant beverage), while both mixability and dispersion/dissolution ratios remain as good as the standard Rhovanil Extra Pure vanillin.

Applications. In flavor formulations, vanillin is used widely either as a sweetener or as a flavor enhancer, not only in imitation vanilla flavor, but also in butter, chocolate, and all types of fruit flavors, root beer, cream soda, etc. It is widely acceptable at different concentrations; 50–1000 ppm is quite normal in these types of finished products. Concentrations up to 20,000 ppm, i.e., one part in fifty parts of finished goods, are also used for direct consumption such as toppings and icings. Ice cream and chocolate are among the largest outlets for vanillin in the food and confectionery industries, and their consumption is many times greater than that of the perfume and fragrance industry.

When vanillin is not used as a single flavoring ingredient, it is a key part of flavor compounding. At least 30% of food-grade vanillin consumed in the world is through flavoring compounds.

In the industrial production of dry cookies, cakes, and pastries, the vanillin content ranges between 20 and 50 g per 100 kg of dough. Often, vanillin is added at the dry stage of dough preparation as the flour and

sugar are being mixed. In fat-free recipes, it is possible to add and mix vanillin powder with eggs.

Vanillin is added, in powder form during the manufacturing process of chocolate, in average amounts of 20 g per 100 kg of the finished product. However, this amount varies according to the quality of the chocolate being made.

Main applications in confections are sugared almonds, caramel, nougat, and sweets. For sugared almonds and caramel, vanillin is mixed into the sugar in the dry phase of the recipe. For nougat, Vanillin is added during the liquid phase of manufacturing. In sweets, vanillin is added in the form of a 10% ethanol solution. Vanillin is used in flavored milk, desserts, yogurts, sorbets, and ice cream.

Vanillin sugar is prepared by dry mixing or impregnating the sugar with a vanillin alcohol solution and evaporating the alcohol. Vanillin confers a pleasant note to liqueur flavoring and improves the flavor of fortified wines by giving them a greatly enhanced bouquet. Vanillin is used as a palatability enhancer to make animal feed more appetizing by flavor-masking minerals with off-taste. Vanillin, a crystal, is the main constituent of the vanilla bean. Its importance can be illustrated by the fact that human preferences in fragrances and in flavors, as determined by various studies, comprise three main smells or tastes: rose, vanilla, and strawberry. Vanillin is used in perfumes and cosmetics as a fragrance and as a washing deodorant.

A flaked technical-grade vanillin, Vaniltek, to be used in pharmaceutical applications. The single largest use for vanillin is as a starting material for the manufacture of an antihypertensive drug having the chemical name of Methyldopa or L-3(3,4-dihydroxyphenyl)-2-methylalanine. Other drugs made from vanillin include L-Dopa, Trimethoprim Mebeverine, and Verazide for example.

Vanillin itself has some bacteriostatic properties and therefore has been used in formulations to treat dermatitis. Hydrazones of vanillin have been shown to have a herbicidal action similar to that of 2,4-D, and the zinc salts of dithiovanillic acid. A new potential use for vanillin is as a ripening agent to increase the yield of sucrose in sugarcane by the treatment of the cane crop a few weeks before harvest.

The antiultraviolet protection properties of vanillin have been patented and look promising for the plastics and cosmetics (suncreams) industries.

Health and Safety Factors. Vanillin is listed in the *Code of Federal Regulations* by the FDA as a Generally Recognized As Safe (GRAS) substance. The Council of Europe and the FAO/WHO Joint Expert Committee on Food Additives have both given vanillin an unconditional Acceptable Daily Intake (ADI) of 10 mg/kg.

Vanillin has a low potential for acute and chronic toxicity. Vanillin is known to cause allergic reactions in people previously sensitized to balsam of Peru, benzoic acid, orange peel, cinnamon, and clove, but vanillin itself is not an allergic sensitizer. Vanillin has been reported to be a bioantimutagen, demonstrating the ability to protect against mutagenic effects by enhancement of an error-free post-replication repair pathway.

VAN SLYKE REACTION. See **Amino Acids**.

V ANTENNA. A V-shaped arrangement of conductors, balanced-fed at the apex, and with included angle, length, and elevation proportioned to give the desired directivity.

VAN'T HOFF EQUATION. A relationship representing the variation with temperature (at constant pressure) of the equilibrium constant of a gaseous reaction in terms of the change in heat content, i.e., of the heat of reaction (at constant pressure). It has the form:

$$\frac{d \ln K_p}{dT} = \frac{\Delta H}{RT^2}$$

in which K_p is the equilibrium constant at constant pressure, T is absolute temperature, R is the gas constant, and ΔH is the standard change in heat content, or, for ideal gases, the change in heat content.

VAN'T HOFF LAW. A dissolved substance has the same osmotic pressure as the gas pressure it would exert in the form of an ideal gas occupying the same volume as that of the solution.

VANT'T HOFF, JACOBUS HENDRICUS (1852–1911). Van't Hoff was born in Rotterdam, the Netherlands. In 1869 he entered the Polytechnic School at Delft and obtained his technology diploma in 1871. His decision to follow a purely scientific career, however, came soon afterwards during vacation–work at a sugar factory when he anticipated for himself a dreary profession as a technologist. After having spent a year at Leyden, mainly for mathematics, he went to Bonn to work with A.F. Kekulé from autumn 1872 to spring 1873. This period was followed by another in Paris with A. Wurtz, when he attended a large part of the curriculum for 1873–1874. He returned to Holland in 1874 and received his Ph.D. from the University of Utrecht under E. Mulder. He did research on chemical dynamics and equilibrium. He was awarded the first Nobel Prize in Chemistry in 1901.

In his later years, Van't Hoff spent his research time trying to understand the action of enzymes as biological catalysts.

J. M. I.

VAPOR. Vapor (US English) or vapour (British English). A substance in the gaseous state, but below its critical temperature, is called a vapor. If a pure liquid partly filling a closed container is allowed to stand, the space above it becomes filled with the vapor of the liquid, which then develops a pressure. This vapor pressure increases up to a certain limit, depending upon the temperature, where it becomes constant, and the space is then said to be saturated.

Such a body of vapor is not subject to all of the laws of gases. If the space occupied by it is diminished without change of temperature, there is no increase in pressure, but instead part of the vapor condenses. And if the temperature is raised, the pressure goes up not at a uniform but at an increasing rate, because of both the expansion of the liquid and the further evaporation from it. The relation of vapor to liquid takes on a curious aspect as the critical state is approached, in which the vapor and the liquid have equal density.

See also **Boiler (Steam Generator)**; **Boiling**; **Boiling Point**; and **Supersaturated Vapor**.

VAPOR-ABSORPTION REFRIGERATION. See **Refrigeration**.

VAPOR DENSITY. The density of a gas referred to the density of hydrogen or air as unity. If the density of hydrogen is taken as 2, the vapor density is approximately the molecular weight; if it is taken as one, the vapor density equals about half the molecular weight.

VAPOR-FILLED THERMOMETER. See **Thermometer (Filled-System)**.

VAPORIZATION. The change of a substance from the liquid or solid state to the gaseous state.

VAPORIZATION (Heat of). The evaporation of a given mass of any liquid requires a definite quantity of heat, dependent upon the liquid and upon the temperature at which it evaporates. The quantity required per unit mass at a fixed temperature is called the heat of vaporization of the substance at that temperature. It may be measured by allowing the vapor to condense in a suitable calorimeter, the heat thus evolved, corrected for fall of temperature before and after condensation, being observed. (The

heat evolved in condensing is equal to that absorbed when the liquid evaporates.) The result is often surprising. For example, the evaporation of water at the boiling point requires about 540 calories per gram, or more than five times the heat required to raise its temperature from freezing to boiling. The explanation is the large amount of energy necessary to separate the molecules against their cohesion, and the much smaller amount (about 7.4% of the whole) which is used in expanding the vapor against atmospheric pressure. At lower temperatures the value is still greater, because the cohesion is then more effective; with water, for each degree below the normal boiling point, about 0.6 calorie per gram must be added to the heat of vaporization. Trouton found that the heat of vaporization per mole for different liquids bears a nearly constant ratio to the absolute temperature of the boiling point.

A number of methods have been developed for measuring the heat of vaporization. In the Awberg and Griffith's method, the flow is continuous; the heat of evaporation of the liquid under investigation is transmitted to a stream of water flowing at constant rate and its increase in temperature is measured.

VAPOR LOCK. Volatility of a fuel such as gasoline makes for easier starting of an engine using it, but creates one undesirable feature, namely, vapor lock. This phenomenon is associated with the fuel supply to internal combustion engines. It occurs mainly in the fuel lines conveying a volatile fuel. If the fuel line from supply tank to engine has many bends and fittings, if it is exposed to engine heat, or if parts of it are under vacuum, bubbles of fuel vapor may form in the lines, causing irregular engine operation, or even stoppage. See also **Petroleum**.

VAPOR PRESSURE. The vapor pressure of a substance (solid or liquid) is the pressure exerted by its vapor when in equilibrium with the substance. For pure substances it depends only on the temperature. The simplest way to measure the vapor pressure of a substance is to introduce a small amount of it into the closed end of a barometer tube and note the decrease in the height of the barometer.

The vapor pressure of a solvent is lowered on dissolving the solute in it. This lowering for dilute solutions is proportional to the mole fraction of the solute (Raoult's Law). The lowering of the vapor pressure of the solution can be related to the lowering of the freezing point and the elevation of the boiling point. These phenomena serve as a basis for molecular weight determinations. If both components of the solution are volatile, each lowers the vapor pressure of the other and the ratios of the two substances in the liquid and vapor phase are not necessarily the same. Use is made of this fact to separate the two substances by distillation.

Equilibrium vapor pressure is the vapor pressure of a system in which two or more phases or a substance coexist in equilibrium. In meteorology, the reference is to water substance, unless otherwise specified. If the system consists of moist air in equilibrium with a plane surface of pure water or ice, the more specialized term *saturation vapor pressure* is usually employed, in which case, the vapor pressure is a function of temperature only. In the atmosphere, the system is complicated by the presence of impurities in liquid or solid water substance (see also **Raoult's Law**), drops or ice crystals or both, existing as aerosols; and, in general, the problem becomes one of nucleation. For example, the difference in vapor pressure over supercooled water drops and ice crystals is the basis for the Bergeron-Findeisen theory of precipitation formation.

VAPOR-TYPE VACUUM PUMP. See **Vacuum**.

VARACTOR. See **Semiconductor**.

VARDAR. See **Winds and Air Movement**.

VARIABLE-AREA FLOWMETER. See **Flow Measurement**.

VARIABLE-FOCUS LENS. A lens system, part of which is movable, and so designed as to have correction for lens aberrations, continual sharp focusing of the image on the receiving film and constant value in the F/System as the focal length is changed. Such a lens gives the effect of moving the camera towards or away from the object. Variable focus lenses are used in motion picture and television cameras; commonly called Zoomar lenses.

VARIABLE (Process). The quantity or characteristic that is the object of measurement in an instrumentation or automatic control system. Other terms used include measurement variable, instrumentation variable, and process variable. The latter term is commonly used in the manufacturing industries. Numerous ways to classify variables have been proposed — by methods of measurement, by end-measurement objectives, and so on. One of the most convenient and meaningful classifications is the physical and/or chemical nature of the variable, as follows:

Thermal Variables. These variables relate to the condition or character of a material dependent upon its thermal energy. Variables included are: *temperature, specific heat, thermal-energy variables* (enthalpy, entropy, etc.), and calorific value.

Radiation Variables. These variables relate to the emission, propagation, and absorption of energy through space or through a material in the form of waves; and by extension, corpuscular emission, propagation, and absorption. Variables included are: *nuclear radiation*; *electromagnetic radiation* (radiant heat, infrared, visible, and ultraviolet light; x- and cosmic rays; gamma radiation).

Force Variables. Force variables include *total force, moment or torque*, and *force per unit area*, such as pressure, vacuum, and unit stress.

Rate Variables. These variables are concerned with the rate at which a body is moving toward or away from a fixed point. Time always is a component of a rate variable. Variables included are: *flow, speed, velocity*, and *acceleration*.

Quantity Variables. These variables relate to the total quantity of material that exists within specific boundaries. Variables include: *mass* and *weight*.

Physical Property Variables. These variables are concerned with the physical properties of materials with the exception of those properties which are related to chemical composition and direct mass and weight. Variables included are: *density* and *specific gravity, humidity, moisture content, viscosity, consistency*, and *structural characteristics*, such as hardness, ductility, and lattice structure.

Chemical-Composition Variables. These variables relate to the chemical properties and analysis of substances. A very abridged list of analysis variables would include: Identification and concentration of carbon dioxide, carbon monoxide, hydrogen, nitrogen, oxygen, water, hydrogen sulfide, nitrogen oxides, sulfur oxides, methane, ethylene, alcohol, and so on. Also included in this category is measurement of pH (hydrogen ion concentration) and redox measurements. See also **Analysis (Chemical)**.

Electrical Variables. Included here are those variables which are measured as the "product" of a process, as in the case of measuring the current and voltage of a generator, and also as part of an instrumentation system. Numerous transducers, of course, yield electrical signals that represent by inference some other variable quantity, such as a temperature or pressure. Variables in this class include: *electromotive force, electric current, resistance, conductance, inductance, capacitance*, and *impedance*.

Geometric Variables. These variables are related to position or dimension and relate to the fundamental standard of length. Variables include: *position, dimension, contour*, and *level* (as of a material in a tank or bin).

See also **Control System**.

VARIABLE SAMPLING FRACTION. See **Sampling (Statistics)**.

VARIABLE STAR. Any star whose brightness changes, for whatever reason, is designated a *variable star*. Although oriental records indicate that novae and supernovae were recorded as early as the fourth century A.D., the first systematic observations of variability date from the late sixteenth century, with the discovery of Mira (*o* Ceti) by Fabricius. The first periodic variable to be well studied, Algol, was identified by Goodricke in the late eighteenth century, and modeled as an eclipsing variable by Goodricke and soon afterwards by Herschel. At the time, all periodic variability was assumed to be due to a dark companion producing eclipses of the visible

star. By the beginning of the 20th century, it was recognized that this model would not explain the range of behavior attributed to these stars. The pulsation mechanism, developed primarily by Eddington and Rosseland, was eventually adopted as an alternative source of periodic fluctuation. This has lead to the separation of variable stars into two broad categories: (1) those which are eclipsing binaries and (2) those which are intrinsic variables. In addition there are cataclysmic variables, which are discussed in the entry on **Nova and Supernova**; and the dMe or *flare stars*. See also **Flare Stars**.

VARIANCE. In statistics, the variance of a population is the second moment about the mean, that is to say, the average of the square of deviations from the mean. It is the most commonly used measure of dispersion. In mechanics, the term refers to the number of degrees of freedom of a system. In physics and chemistry, the variance is the number of degrees of freedom of a system, or the degrees of freedom themselves.

VARIANCE (Analysis of). See **Analysis of Variance**.

VARIATE. See **Random Variable**.

VARIATE DIFFERENCE METHOD. If the nonrandom part of a time-series can be represented locally by a polynomial, this part can be removed by taking successive differences of the series. If the variances of the successive difference series are calculated, and the rth variance divided by $(2r)!/(r!)^2$, the resulting numbers should decrease until the trend has been eliminated and then remain at a roughly constant value which estimates the variance of the random part of the original series. A similar technique can be used to estimate the correlation between the random parts of two series.

VARIATION (Coefficient of). The coefficient of variation of a distribution, V, is defined as the standard deviation divided by the mean,

$$V = \frac{\sigma_x}{\overline{x}}$$

Some authors define it as

$$V = 100\frac{\sigma_x}{\overline{x}}$$

in order to avoid decimals.

VARIATION (Mathematics). If two variables x and y are related by the power function relationship $y = kx^n$, where k and n are constants, we say that y varies as x^n, or y varies as the nth power of the x, or that y is proportional to x^n. The factor k is called the constant of variation, or the constant of proportionality, or the proportionality factor. For another use in mathematics, see also **Variations (Calculus of)**.

VARIATIONS (Calculus of). The problem of the calculus of variations is to determine functions in such a way that a definite integral depending upon them and their derivatives may assume an extreme value. In the simplest case the problem is to minimize the value of the integral

$$I[y] = \int_a^b F(x, y, y')\,dx$$

with given a, b, $y(a)$, $y(b)$. Thus, if $y = f(x)$ is the desired minimizing function and if we consider neighboring functions $y + \varepsilon\eta(x)$, where $\eta(x)$ is any fixed function of x with $\eta(a) = \eta(b) = 0$ and ε is a real number, we may regard $I[y + \varepsilon\eta]$ as a function of ε alone with a minimum at $\varepsilon = 0$, so that

$$\left.\frac{dI}{d\varepsilon}\right|_{\varepsilon=0} = 0$$

But

$$\frac{dI}{d\varepsilon} = \int_a^b \left(\frac{\partial F}{\partial y}\eta + \frac{\partial F}{\partial y'}\eta'\right)$$

so that, by integration by parts,

$$\int_a^b \eta\left\{\frac{\partial F}{\partial y} - \frac{d}{dx}\left(\frac{\partial F}{\partial y'}\right)\right\} = 0$$

and from the fundamental lemma (see definition below).

$$\frac{\partial F}{\partial y} - \frac{d}{dx}\left(\frac{\partial F}{\partial y'}\right) = 0$$

which is called the Euler-Lagrange equation of the original problem. It represents a necessary condition for an extreme value of the definite integral.

The fundamental lemma referred to above may be stated thus. If $\phi(x)$ is continuous in the closed interval $[a, b]$ and $\int_a^b \eta(x)\phi(x)dx = 0$ for all $\eta(x)$ with continuous first derivatives and such that $\eta(a) = \eta(b) = 0$, then $\phi(x)$ is identically zero.

The above remarks can be generalized directly to deal with integrands involving derivatives of higher than first order and with the case where the integrand depends upon more than one function. The function $\varepsilon\eta(x)$ is called the variation of y, and $\varepsilon(dI/d\varepsilon)$ is the variation of I. (Compare the definition of the differential of a dependent variable.)

VARICELLA. See **Chickenpox**.

VARICOCELE. See **Arteries and Veins**.

VARIOLA. See **Smallpox**.

VARIOLITE. Variolites (*varius*, "speckled, variegated") are a group of dark green basic igneous rocks that, especially on weathered surfaces, exhibit pale colored spots, or spherules, that give them a pockmarked appearance. In some conditions these spots weather out prominently; they are grey, pale green, violet or yellowish, while the matrix of the rock is usually dark green.

The variolites are related most closely to the basalts or diabases. They are nearly always much decomposed, and, since they are also fine-grained rocks, their original composition may be much obscured by secondary changes. The variolitic spots are rounded in outline and are often about a quarter-inch in diameter, but may exceed this size. They have a radiate structure and are sometimes, though not generally, zoned with concentric circles of different appearance and composition.

Other variolites are glassy or partly crystalline facies of olivine-free dolerites, occurring as thin dikes or intrusions or at the margins of dolerite masses. In these the feldspars are well crystallized as thin rods with square or forked ends radiating outwards from a center. They are commonly oligoclase, and sometimes assume branching or feathery forms.

Another group of variolites includes the most famous rock of this type, which comes from the Durance, in France. Pebbles of this were well known to collectors for a long time before they were traced to their source at Mont Genvre. They were proved to belong to a diabasic rock that shows well-marked pillow-structure or spheroidal jointing. Each pillow has a marginal portion which is variolitic, but towards the center of the block-shaped masses the structure becomes coarse and groups of radiate feldspars make their appearance. It is doubtful whether the variolite is an intrusive rock or a lava flow. Many of these pillow lavas (or spilites) occur in the Devonian rocks of Germany, and they often have variolitic facies which seem to belong to the same group as the rock of the Durance. Their spherulites are very often oligoclase feldspar or decomposition products after a felspathic mineral. In other cases they consist of chlorite or pale green amphibole, both of which may be secondary after pyroxene. The ground mass is very fine grained and is filled with chlorite, epidote, leucoxene, and other secondary minerals. There is much reason to believe that it was originally in large measure vitreous, but has suffered devitrifaction. Sometimes little steam cavities occur and may serve as a nucleus from which the variolite has grown. The radiate structure of the varioles is often nearly obliterated in these much-decomposed rocks, in fact it may never have been very perfect. Variolites are found also in several parts of the Swiss Alps at Jatluga on Lake Onega, in Anglesey, the Lleyn district and Fishguard in Wales, in Cornwall, and in more than one place in Ireland.

VARIOMETER. An instrument for comparing magnetic forces, especially of the earth's magnetic field.

VARLEY BRIDGE. See **Bridge Circuits (Electrical/Electronic)**.

VARMUS, HAROLD ELLIOT (1939–). Harold Varmus was an American virologist and 14th Director of the National Institutes of Health, whose discoveries helped establish the mechanisms underlying the development of viral-induced tumors.

Born and raised in Freeport, Long Island, Varmus alternated his interests between literature and medicine, obtaining a bachelor's degree in the former from Amherst College in 1961, and spending one year as a graduate student at Harvard University, before transferring to Columbia College of Physicians and Surgeons to obtain his medical degree (1966). Upon completing his residency, he took up a research fellowship at the National Institutes of Health in Bethesda and then a postdoctoral position in the laboratory of Michael Bishop at the University of California, San Francisco, in 1969. After two decades of research there, during which time he rose through the ranks to the position of full professor, Varmus was appointed as the Director of the National Institutes of Health (NIH) in 1993. He stepped down from this position in December 1999 to assume the Directorship of the Memorial Sloan-Kettering Cancer Center in New York City. See also **Bishop, J. Michael (1936–Present)**.

Varmus' main contributions have been in the area of tumor virology. While investigating the genetics of the *Rous sarcoma virus*, which causes tumors in chickens, Varmus and Bishop discovered that a version of the viral gene responsible for inducing the tumor was actually present in the normal (noncancerous) cells of the birds. Subsequent work revealed that this gene — the proto-oncogene — was picked by the virus and mutated, and that the introduction of this mutated gene into the normal cells was responsible for the development of tumors. This work garnered Varmus and Bishop the Nobel Prize for Physiology or Medicine in 1989. After moving to NIH, Varmus redirected his research interests to other problems related to retroviruses, including the biochemistry of the *Human immunodeficiency virus* (HIV) and the development of mammary tumors in mice. See also **Oncogenes**.

NEERAJA SANKARAN, Yale University, New Haven, CT

VARNISH. (1) An organic protective coating similar to paint except that it does not contain colorant. It may be composed of a vegetable oil (linseed), tung, etc.), and solvent or of a synthetic or natural resin and solvent. In the first case the formation of the film is due to polymerization of the oil and in the second to evaporation of the solvent. "Long-oil" varnishes such as spar varnish have a high proportion of drying oil; "short-oil" types have a lower proportion, i.e., furniture varnishes. Spirit varnishes contain such solvents as methanol, toluene, ketones, etc. and often also thinners such as naphtha or other light hydrocarbon.

(2) A hard, tightly adherent deposit on the metal surfaces of automobile engines resulting from resinous oxidation products of gasoline and lubricating oils.

See also **Paints and Coatings**.

VARVES. The annual layers of sediment deposited in lakes and fiords by meltwater from glaciers. Each layer consists of two parts deposited at different seasons and differing in color and texture so that the layers can be measured and counted. If the series is complete, the number of layers gives the date on which the ground was vacated by the retreating ice. Varves were discovered by G. de Geer at Lake Ragunda in Sweden in 1905, and have since been found in many other regions. They differ in thickness from year to year. These differences were attributed by de Geer to variations of solar radiation and hence are supposed to be similar in all parts of the world. It was proposed that in this way dates of varve series could be determined even if the upper layers were missing, but this method of dating has been doubted. See also **Lakes**.

VASCULAR HEADACHE. See **Headache**.

VASCULAR SYSTEM (Plants). A complex system of cells and tissues called xylem and phloem, serving to conduct water, mineral salts, and food through the plant. The vascular system also gives strength and support to the plant. It composes the bulk of the tissues of roots and stems of woody plants.

VASCULAR TISSUE. Blood, lymph, and related fluids of the body. These liquids are regarded as tissues because they consist of characteristic cells lying in an intercellular substance. The liquid condition of the intercellular substance is responsible for their fluidity.

VAS DEFERENS. See **Gonads**.

VASOMOTOR NERVES. See **Arteries and Veins**.

VASOPRESSIN. See **Central and Peripheral Nervous Systems**.

VAST GALAXY DRIFT. Two astronomers have discovered that our own Milky Way Galaxy and most of its neighboring galaxies contained within a huge volume of the universe, one billion light years in diameter, are drifting with respect to the more distant universe. This startling result may imply that the universe is "lumpier" on much larger scales than can be readily explained by any current theory. The new observations thus challenge our understanding of how the universe evolved.

This surprising conclusion comes from the deepest systematic survey of galaxy distances to date, conducted by Dr. Tod R. Lauer of National Optical Astronomy Observations (NOAO) in Tucson, Arizona, and Dr. Marc Postman of the Space Telescope Science Institute (STScI) in Baltimore, Maryland. The two astronomers used NOAO telescopes at Kit Peak National Observatory, new Tucson, Arizona, and at Cerro Tololo Inter-American Observatory, near La Serena, Chile, to study galaxy motions over the entire sky out to a distance of over 500 million light years, thus exploring a volume of space about thirty times larger than has been surveyed by the National Astronomy Observatories, Tucson, AZ.

The expansion of the universe causes all galaxies to be moving away from us. Galaxies at the far edge of the volume surveyed by Lauer and Postman are receding from us at 5 percent of the speed of light. The large flow that the astronomers discovered comes from looking at the galaxy motions "left over" once the expansion of the universe has been taken into account. This flow means that the nearby universe appears to be drifting in a particular direction with respect to the move distant universe, as well as expanding.

Lauer and Postman have measured the drift of the Milky Way with respect to 119 clusters of galaxies located all over the sky at distances as far as 500 million light years. The galaxy clusters are at a variety of distances from us, and galaxies in the distant clusters appear dimmer than the ones in nearby clusters. However, once the various distances are accounted for, the brightest galaxy in each cluster is always found to give off roughly the same amount of light. Astronomers refer to such objects as "standard candles." In a uniformly expanding universe, the distances to the clusters are estimated by how fast they are moving away from us. If the Milky Way Galaxy is drifting, however, its motion makes measurement of the expansion speed depend on the direction we are looking, and the "standard candles" galaxies will appear to vary slightly in brightness in a smooth pattern across the sky. Lauer and Postman used images of the cluster galaxies to detect this pattern and determine the motion of our own galaxy.

If the motion of the Milky Way is caused by galaxies closer in than the set of clusters, its motion with respect to the distant clusters should be essentially identical to that with respect to the microwave back ground radiation. But the motion of the Milky Way that Postman and Lauer measured from the distant clusters is in a completely different direction from the inferred from the microwave background. The most likely solution

to this dilemma is that the clusters themselves are moving with respect to the microwave background with an average velocity of 425 miles per second toward that direction of the constellation of Virgo. Because of the enormous size of the volume containing the clusters, however, this result would imply the existence of even more distant and massive concentrations of matter if the motions are caused by gravitational force.

See **Cosmology**.

V-BAND. A frequency band used in radar extending approximately from 46 to 56 gigacycles per second.

V CENTER. One of the simple types of color centers, originally considered to be a positive ion vacancy with a bound positive hole. In the alkali halides the absorption band occurs in the ultraviolet part of the spectrum.

VECTOR. 1. An element of a *linear* or *vector space*. See also **Linear Space**. 2. A directed line segment in Euclidean n-space. If $(\lambda_1, \lambda_2, \ldots, \lambda_n)$ is a point in Euclidean n-space, then the line segment from the origin $(0, 0, \ldots, 0)$ to $(\lambda_1, \lambda_2, \ldots, \lambda_n)$ is the directed line segment associated with the vector $(\lambda_1, \lambda_2, \ldots, \lambda_n)$.

A vector is often indicated graphically by means of an arrow (technically called a *stroke*). The length of the arrow is proportional to the scalar magnitude of the vector, and the direction in which the arrow points is the direction of the vector. The tail or initial point of the arrow is its *origin*; the head or final point is its *terminus*.

A vector of unit length, drawn in the positive direction and tangential to a coordinate system, is a unit vector. It is not necessary that the system be orthogonal. In the common case, a rectangular Cartesian coordinate system is used and the unit vectors along OX, OY, OZ axes are called **i**, **j**, **k**, respectively.

For an arbitrary vector, scalar quantities called the components are required to determine it numerically. In three dimensions, they are directed lines, parallel to the axes of a coordinate system. Thus, if a rectangular Cartesian system is used, with unit vectors **i**, **j**, **k**, any vector may be written as $\mathbf{A} = \mathbf{i}Ax + \mathbf{j}Ay + \mathbf{k}Az$, where (Ax, Ay, Az) are its three components. In the more general case of an n-dimensional vector the components of the vector are the n matrix elements of a column or row matrix. If, in a rectangular coordinate system, a point has coordinates (x, y, z) then its *position vector* is one drawn from the coordinate origin to the point. It may be written as $\mathbf{R} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$. In polar coordinates or in spherical polar coordinates, a vector drawn from the origin of the coordinate system to a point is a *radius vector*.

As previously seen, a vector is commonly indicated by a boldface letter such as **A**, which stand for its three scalar components (A_1, A_2, A_3) referred to some coordinate system. In the Gibbs notation, scalar and vector products (see also **Vector Multiplication**) are shown with dots and crosses, respectively. Thus, if C is a scalar and **V**, **A**, **B** are vectors, then $C = \mathbf{A} \cdot \mathbf{B}$ and $\mathbf{V} = \mathbf{A} \times \mathbf{B}$. Less commonly used symbols have been proposed by Hamilton, Grassmann, Heaviside, and others. They include: $T\mathbf{A}$ (T for tensor), $|\mathbf{A}|$ for the magnitude of a vector; $S\mathbf{AB}$, $(\mathbf{AB})$ for the scalar product; $V\mathbf{AB}$, $\mathbf{A}V\mathbf{B}$, and $[\mathbf{AB}]$ for the vector product.

A more precise definition of a vector is often required. Suppose that a point located in a rectangular coordinate system has components (x_1, x_2, x_3). The same point, however, could also be described in other coordinate systems, obtained from the first one by translation of the origin and rotations about the coordinate axes. If the components of the point in the second system are (x_1', x_2', x_3'), assumed for convenience to have the same origin as that of the first system, then the relation between the components, called a linear transformation, is

$$x_i' = \sum_{j=1}^{3} c_{ij} x_j'. \quad i = 1, 2, 3$$

where the c_{ij} are the nine direction cosines between the various coordinate-axis pairs. Matrix notation may also be used to write $\mathbf{x}' = \mathbf{R}\mathbf{x}$, where x' and x are column vectors; **R** is the orthogonal matrix of the direction cosines. If this transformation law holds, one speaks of a *polar, proper*, or *localized vector*; if the law does not hold, a pseudovector or *axial vector*.

The concept of vector may be generalized extensively. A *four-vector* has four components. One type is called a quaternion, another, used principally in relativity theory, has for its components (x, y, z, ict), where x, y, z are positional coordinates, $i = sqrt{-1}$, c is the velocity of light, and t is the time. The components of such a vector in one coordinate system are related to the components in another system by a *Lorentz transformation*. See also **Tensor**.

If (x', y', z') are functions of (x, y, z), then the vector $\mathbf{V}' = \mathbf{i}x' + \mathbf{j}y' + \mathbf{k}z'$ is a vector function of the vector $\mathbf{V} = \mathbf{i}x + \mathbf{j}y + \mathbf{k}z$, where $(\mathbf{i}, \mathbf{j}, \mathbf{k})$ are unit vectors. The function is a linear vector function if $f(\mathbf{A} + \mathbf{B}) = f(\mathbf{A} + f(\mathbf{B}))$, for all vectors **A**, **B** and $f(k\mathbf{V}) = kf(\mathbf{V})$, where k is a scalar. More generally, suppose the components of **V** and **V**′ are (V_1, V_2, V_3) and (V_1', V_2', V_3') respectively and that the relation between the two vectors in matrix form is $\mathbf{V} = \mathbf{M}\mathbf{V}'$, where **M** is a (3×3)-matrix with elements M_{ij}. Then the function is a linear vector function, for $f(k\mathbf{V}) = kf(\mathbf{V})$ and $f(\mathbf{V} + \mathbf{V}') = f(\mathbf{V}) + f(\mathbf{V}')$, as before.

The vector **V** can be written as the sum of a symmetric and an antisymmetric linear vector function, $\mathbf{V} = \mathbf{S} + \mathbf{A}$. If $\mathbf{S} + \mathbf{QV}'$, then $Q_{ii} + M_{ii}Q_{ij} + Q_{ji} + (M_{ij} + M_{ji})/2$, $i \neq j$. Similarly, $\mathbf{A} = \mathbf{TV}'$, $T_{ii} = 0$, $T_{ij} + (M_{ij} - M_{ji})/2$. The antisymmetric function can also be written as a vector product, $\mathbf{A} + \mathbf{T} \times \mathbf{V}'$.

See also **Dyadic**.

VECTOR ADDITION. If **A**, **B** are vectors with components A_x, A_y, A_z and B_x, B_y, B_z, respectively, their sum is a new vector $\mathbf{C} = \mathbf{A} + \mathbf{B}$, with components $A_x + B_x$, $A_y + B_y$, $A_z + B_z$. Vector addition obeys the commutative and associative laws of algebra: $\mathbf{A} + \mathbf{B} = \mathbf{B} + \mathbf{A}$; $(\mathbf{A} + \mathbf{B}) + \mathbf{C} = \mathbf{A} + (\mathbf{B} + \mathbf{C})$. To subtract a vector **B** from a vector **A**, take the negative of **B** and add $-\mathbf{B}$ to **A**.

VECTOR DERIVATIVE. If a vector **R** is a function of a single scalar variable t, there are three possible ways in which **R** may vary with t, for if $\mathbf{R}_1$ and $\mathbf{R}_2$ refer to t_1 and t_2, respectively, then $\mathbf{R}_2$ may differ from $\mathbf{R}_1$: in magnitude only; in direction only; in both magnitude and direction. Since even the general case is relatively simple, assume that a curve is traced by the terminus of the continuously varying vector **R**, the origin of the vector being kept fixed at the origin of a coordinate system. Let A and B be two neighboring points on this curve and let $\mathbf{R}_1$ and $\mathbf{R}_2$ be their position vectors, then the vector $\Delta\mathbf{R} = \mathbf{R}_2 - \mathbf{R}_1$ has the direction of the secant AB, which approaches the tangent to the curve at A as $\Delta t = t_2 - t_1$ approaches zero. The quotient $\Delta\mathbf{R}/\Delta t$ is the average rate of change of **R** in the interval between t_1 and t_2. The derivative is defined as

$$\lim_{t \to 0} \Delta\mathbf{R}/\Delta t = d\mathbf{R}/dt$$

In terms of unit vectors, and with the use of primes for differentiation, $\mathbf{R} = \mathbf{i}R_x + \mathbf{j}R_y + \mathbf{k}R_z$, $\mathbf{R}' = \mathbf{i}R_x' + \mathbf{j}R_y' + \mathbf{k}R_z'$, $\mathbf{R}'' = \mathbf{i}R_x'' + \mathbf{j}R_v'' + \mathbf{k}R_z''$. For a composite function of two or more vectors, each depending on a single scalar t, the usual rules of differentiation hold, except that the order of the vectors must be retained if vector products are involved.

There are also several differential vector operators. See also **Curl**; **Del**; **Divergence (Mathematics)**; **Gradient (Mathematics)**; and **Laplacian**.

VECTOR FIELD. An assignment of a vector to each point of region of space. Thus, in three dimensions, the vector assigned to each point is described by three quantities, the components of the vector along the coordinate axes. Examples are wind velocities in the atmosphere, electrostatic or electromagnetic field. See also **Scalar Field**.

VECTOR INTEGRAL. A kind of inverse operation to differentiation. Corresponding to ordinary definite integrals (see also **Multiple Integral**) there are *line integrals, surface integrals*, and *volume integrals* of vector functions.

(a) *Line integral*. Suppose $\mathbf{r} = \mathbf{r}(t)$ determines a curve C in space and that $d\mathbf{r}$ is an infinitesimal line element of this curve. Three different line integrals may then be formed, using a scalar ϕ or a vector **V**:

$$(1) \quad \int_C \phi \, d\mathbf{r}; \quad (2) \quad \int_C \mathbf{V} \cdot d\mathbf{r}; \quad (3) \quad \int_C \mathbf{V} \times d\mathbf{r}$$

The results of integration are a vector, a scalar, a vector, respectively.

In each case, the line integral may be reduced to a sum of definite integrals and evaluated by the usual methods of integral calculus. The line integral may be generalized for the complex variable and the result is a contour integral.

(b) *Surface integral*. There are three possible cases:

$$(1)\quad \int_S \phi\, d\mathbf{S};\quad (2)\quad \int_S \mathbf{V}\cdot d\mathbf{S};\quad (3)\quad \int_S \mathbf{V}\times d\mathbf{S}$$

which give a vector, a scalar, a vector. It is convenient to write only one integral sign, in general, and to understand by the symbol S, attached to the integral sign, that the limits of integration are suitably chosen. The surface element $d\mathbf{S} = d\mathbf{x}\times d\mathbf{y}$.

In case (2), if $\mathbf{V}$ is the product of density and velocity of a fluid (or electric, magnetic, gravitational force; heat, etc.), the integral is the *flux* of $\mathbf{V}$ through the surface. See also **Area**.

(c) *Volume integral*. In vector notation, the element of volume $d\tau = dx\,dy\,dz$ is a scalar. There are thus two possible volume integrals:

$$(1)\quad \int \phi\, d\tau,\quad (2)\quad \int_\tau \mathbf{V} d\tau$$

The integrals are, respectively, a scalar and a vector. As is frequently the custom, only one integral sign is used, and the symbol τ is a reminder that the integration is triple and that appropriate limits of integration are to be supplied. See also **Volume (Geometry)**.

A circulatory integral is a vector function

$$\int \mathbf{V}\cdot d\mathbf{r}$$

over a closed contour. It is a measure of the tendency of lines of force to close up. If $\mathbf{V}$ refers to a fluid, then this integral is a measure of the flow around the path chosen. When the vector field has a potential, this integral is zero and the field is said to be irrotational, thus its curl must vanish.

If $\mathbf{V}$ describes a vector field, for example, the velocity of an incompressible fluid, then the total flux through a surface S in the field is given by

$$\int_S \mathbf{V}\cdot d\mathbf{S}$$

The vector $\mathbf{V}$ may refer to electric, magnetic, or gravitational force; heat or a fluid, etc. The surface integral may be converted to a volume integral by Gauss's theorem.

For other relations between vector integrals see also **Green Function**; and **Stokes Theorem**.

VECTOR MULTIPLICATION. There are two distinct kinds of products of two vectors: the scalar product and the vector product (see also **Pseudovector**). They are also sometimes called inner and outer products but these terms more commonly refer to tensor products. There are also several possibilities for the product of three or four vectors, as the subsequent discussion will show.

1. *Scalar Product*. If $\mathbf{A}$ and $\mathbf{B}$ are two vectors, of magnitude A, B, respectively, their scalar product is $\mathbf{A}\cdot\mathbf{B} = AB\cos\theta$, where θ is the angle between the two vectors. This product, which is a scalar quantity, is also known as the dot product. If the vectors are complex, the result of multiplication is the Hermitian scalar product (see also **Linear Space**).

The scalar product of two vectors obeys the commutative and distributive laws: $\mathbf{A}\cdot\mathbf{B} = \mathbf{B}\cdot\mathbf{A}$; $\mathbf{A}\cdot(\mathbf{B}+\mathbf{C}) = \mathbf{A}\cdot\mathbf{B} + \mathbf{A}\cdot\mathbf{C}$. If $\mathbf{A}$ is perpendicular to $\mathbf{B}$, then $\mathbf{A}\cdot\mathbf{B} = 0$, and consequently if $\mathbf{A}\cdot\mathbf{B} = 0$, then $\mathbf{A}$ is perpendicular to $\mathbf{B}$ and the two vectors are said to be orthogonal. If $\mathbf{A}$ is parallel to $\mathbf{B}$, then $\mathbf{A}\cdot\mathbf{B} = \mathbf{AB}$. Consequently, $\mathbf{A}\cdot\mathbf{A} = A^2$, the square of the length of $\mathbf{A}$.

2. *Vector Product*. The vector product of $\mathbf{A}$ and $\mathbf{B}$ (also called skew or cross product) is of length $C = AB\sin\theta$ and its direction is perpendicular to the plane determined by $\mathbf{A}$ and $\mathbf{B}$. In Cartesian coordinates, with unit vectors i, j, k, one has

$$\mathbf{C} = \mathbf{A}\times\mathbf{B} = (A_yA_z - A_zB_z)\mathbf{i} + (A_zB_z - A_zB_z)\mathbf{j} + (A_xB_y - A_yB_x)\mathbf{k} = \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ A_x & A_y & A_z \\ B_x & B_y & B_z \end{vmatrix}$$

Vector multiplication is not commutative, in this case, for $\mathbf{A}\times\mathbf{B} = -\mathbf{B}\times\mathbf{A}$ but the distributive law of multiplication still holds.

3. *Products of Unit Vectors*. For the two kinds of vector multiplication described in (1) and (2), the results for unit vectors are: $\mathbf{i}\cdot\mathbf{j} = \mathbf{j}\cdot\mathbf{i} = \mathbf{i}\cdot\mathbf{k} = \mathbf{k}\cdot\mathbf{i} = \mathbf{j}\cdot\mathbf{k} = \mathbf{k}\cdot\mathbf{j} = 0$; $\mathbf{i}\cdot\mathbf{i} = \mathbf{j}\cdot\mathbf{j} = \mathbf{k}\cdot\mathbf{k} = i^2 = j^2 = k^2 = 1$; $\mathbf{i}\times\mathbf{j} = -\mathbf{j}\times\mathbf{i} = \mathbf{k}$; $\mathbf{j}\times\mathbf{k} = -\mathbf{k}\times\mathbf{j} = \mathbf{i}$; $\mathbf{k}\times\mathbf{i} = -\mathbf{i}\times\mathbf{k} = \mathbf{j}$; $\mathbf{i}\times\mathbf{i} = \mathbf{j}\times\mathbf{j} = \mathbf{k}\times\mathbf{k} = 0$.

4. *Triple Products of Vectors*. Three vectors $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ may be combined to form products with meaning in several ways: (a) $\mathbf{A}(\mathbf{B}\cdot\mathbf{C})$, a vector with the same direction as $\mathbf{A}$ and magnitude ABC $\cos\theta$, where θ is the angle between $\mathbf{B}$ and $\mathbf{C}$. (b) $\mathbf{A}\cdot(\mathbf{B}\times\mathbf{C})$, the scalar triple product, giving the volume of a parallelepiped with edges **A, B, C**. It is frequently indicated by the symbol $[\mathbf{ABC}]$ and if the three vectors all lie in the same plane $[\mathbf{ABC}] = 0$. It may be written in terms of its components as a determinant

$$[\mathbf{ABC}] = \begin{vmatrix} A_x & A_y & A_z \\ B_x & B_y & B_z \\ C_x & C_y & C_z \end{vmatrix}$$

Its properties include $[\mathbf{ABC}] = [\mathbf{BCA}] = [\mathbf{CAB}] = -[\mathbf{ACB}] = -[\mathbf{BAC}] = -[\mathbf{CBA}]$. (c) The vector triple product, $\mathbf{V} = \mathbf{A}\times(\mathbf{B}\times\mathbf{C})$ is perpendicular to both $\mathbf{A}$ and the vector $(\mathbf{B}\times\mathbf{C})$. It therefore lies in the plane determined by $\mathbf{B}$ and $\mathbf{C}$. Its properties include:

$$\mathbf{A}\times(\mathbf{B}\times\mathbf{C}) = \mathbf{B}(\mathbf{A}\cdot\mathbf{C}) - \mathbf{C}(\mathbf{A}\cdot\mathbf{B}) = -\mathbf{A}\times(\mathbf{C}\times\mathbf{B}) = (\mathbf{C}\times\mathbf{B})\times\mathbf{A} = -(\mathbf{B}\times\mathbf{C})\times\mathbf{A}.$$

5. *Quadruple Products of Vectors*. If $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$, $\mathbf{D}$ are any four vectors, two types of quadruple products can occur:

(a) $(\mathbf{A}\times\mathbf{B})\cdot(\mathbf{C}\times\mathbf{D}) = (\mathbf{A}\cdot\mathbf{C})(\mathbf{B}\cdot\mathbf{D}) - (\mathbf{A}\cdot\mathbf{D})(\mathbf{B}\cdot\mathbf{C})$;
(b) $(\mathbf{A}\times\mathbf{B})\times(\mathbf{C}\times\mathbf{D}) = (\mathbf{A}\cdot\mathbf{C}\times\mathbf{D})\mathbf{B} - (\mathbf{B}\cdot\mathbf{C}\times\mathbf{D})\mathbf{A}$.

The latter equation is also conveniently written in the equivalent form $[\mathbf{ABC}]\mathbf{B} - [\mathbf{BCD}]\mathbf{A} = [\mathbf{ABD}]\mathbf{C} - [\mathbf{ABC}]\mathbf{D}$, where the bracket signifies the scalar triple product. See also **Reciprocal Vector System**.

Products of more than four vectors can always be reduced to combinations of one or more of the preceding types.

VECTOR SPACE. See **Linear Space (Vector Space)**.

VEERING WIND. See **Winds and Air Movement**.

VEERY. See **Thrush**.

VEGA (α Lyrae). Ranking fifth in apparent brightness among the stars, Vega has a true brightness value of 55 as compared with unity for the sun. Vega is a white, spectral type A star and is located in the constellation Lyra north of the ecliptic. Estimated distance from the Earth is 27 light years. In the northern latitudes, Vega is visible during some portion of every night throughout the year, and dominates the summer skies. Because of its distinctly bluish tinge, it is one of the most beautiful stars of the northern skies, and references to it are found in ancient literature. At one time, Vega was the pole star, and because of precession, the pole will be close to Vega about 11,500 years hence.

VEGETABLE OILS (Edible). Vegetable oils are prepared from at least ten major oilseeds, plus a few other sources that may develop into high volume at some future date. There are both edible and nonedible vegetable oils. Technical and industrial vegetable oils, such as castorseed and tung oils, are used in nonfood applications. Some oils, such as linseed (flaxseed) and olive oil, depending upon the manner in which they have been treated and refined, find both food and nonfood applications. Other oils, such as soybean, sunflower, rapeseed, sesame, and safflower oils, are used predominantly in food processing and in the production of feedstuffs.

Usually, in considering edible vegetable oils, the availability of animal fats, such as butterfat, lard, tallow, etc., and of fish and other marine oils, is noted because there is surprising versatility among all oils and fats, allowing significant substitutions in the same end-product. Perhaps this is best illustrated by the fact that coconut oil, corn (maize) oil, cottonseed oil, palm oil, groundnut (peanut) oil, safflower oil, and soybean oil all are or have been used in commercial margarines for the retail market. The processor of a given brand of margarine will select the oil or a combination of oils, considering price and availability, as well as desirable end-product characteristics (stick or brick; soft tub; diet or imitation; etc.), among other factors. The pressed cakes and meals remaining after extraction of oil from beans and seeds finds wide use in animal feedstuffs.

The consumption of fats and oils by persons in the United States has increased steadily since the early 1960s. In 1963, 46.3 pounds (21 kilograms) were consumed per capita per year, rising to 54.4 pounds (24.7 kilograms) in the late 1970s. During this period, butter dropped from 13.9% of total fats and oils to 7.7%; lard dropped from 12.9% to 4%; margarine increased from 19.4% to 20.2%; shortenings of various kinds increased from 27.2% to 30.6%; and salad and cooking oils increased markedly from 26.6% to 37.5%.

On a worldwide basis, as of the early 1980s, the various sources of edible oils, in terms of volume of production, rank as follows: Soybeans, 50.3%; cottonseed, 16.2%; groundnuts (peanuts), 11.4%; sunflower seeds, 7.9%; rapeseed, 6.9%; copra (coconut), 2.9%; flaxseed (linseed), 1.8%; sesame seed, 1.1%; palm kernel, 0.9%; and safflower seed, 0.6%. See also **Diet**.

Principal edible uses of these oils are found in cooking and salad oils; frying oils; margarine, mayonnaise, and salad dressings; bakery, cake mix, and pie shortenings; and whipped topping and other nondairy products, such as coffee creamers.

Definitions

Some of the common terms used in describing edible oils and fats are:

Saturated — the state in which all available valence bonds of an atom, especially carbon, are attached to other atoms. The straight-chain alkyls (paraffins) are typical saturated compounds. Several fatty acids found in oils and fats are listed in Table 1. Where no double- or triple-bonds are available, such compounds cannot be hydrogenated because there are no places for attaching additional hydrogen atoms.

Monosaturated — the state where one double bond is present in the compound. Under proper conditions of hydrogenation, an additional hydrogen atom can be added, thus resulting in a saturated compound.

Polyunsaturated — the state where two or more double bonds are present in the compound. Again, under proper conditions of hydrogenation, one or more additional hydrogen atoms can be added, thus resulting in a compound that is less unsaturated or that is saturated, depending upon the number of double bonds originally available and the degree of hydrogenation effected.

Hydrogenation — any reaction of hydrogen with an organic compound. In the case of fats and oils, this is the direct addition of hydrogen to double bonds of unsaturated molecules, resulting in a partially or a fully saturated product.

Hydrogenation can be accomplished with gaseous hydrogen under pressure in the presence of a catalyst (nickel, platinum, or palladium). The degree of saturation of an oil or its fatty acid substituents affects its fluidity (melting or softening point), density, refractive index, and general reactivity. Frequently, the degree of hydrogenation of an oil will be determined by measuring its refractive index. Vegetable and fish oils can be hardened or solidified by catalytic hydrogenation. Partial hydrogenation clarifies some oils and makes them odorless. Fatty oils, such as oleic acid, are converted into stearic acid by hydrogenation. Coconut oil, groundnut (peanut) oil, and cottonseed oils can be made to appear, taste, and smell like lard; or they can be made to resemble tallow. Sometimes, hydrogenated oils are referred to as synthetic shortenings. Generally, hydrogenated oils have higher melting points and lower iodine values than the natural, untreated oils.

For many years, hydrogenation was a batch operation, but in recent years, continuous hydrogenation processes have been displacing the batch methods, especially in large-scale facilities. Hydrogenation pressures vary as well as temperatures, but the latter are usually in the 93–135 °C range. It is not uncommon to mix two or more oils prior to hydrogenation. Considerably more detail on the hydrogenation process is given in the entry on **Hydrogenation**.

Deodorizing — crude oils tend to have undesirable odors and tastes. These are due to the presence of various volatile components. These are removed by passing steam through the heated oil under diminished pressure.

Winterizing — because of widespread use of refrigeration, salad oils and other end-products prepared from vegetable oils must not become cloudy or solidify at relatively low storage temperatures. Thus, most salad oils differ from cooking oils, in that the latter, if stored under refrigeration, may slowly solidify and be difficult to pour from a container. To prevent cloudiness and solidification at low temperatures, the oils are "winterized." This involves subjecting the oils to low temperatures in stages, during which time crystals of high-melting-point fat are formed. A final low temperature of about 5.5 °C is reached in the process, at which temperature the oil is allowed to stand for a considerable time, during which considerable crystallization occurs. Slow cooling and gentle agitation ensure maximum removal of the high-melting-point fats. The crystalline material remaining after filtration is essentially stearine, with traces of wax, gums, and soaps. Improvements in the winterizing process during the past several years have reduced the time required from 3 to 6 days down to about 5 hours. The more recent processes involve solvent extraction and centrifugation.

Iodine Value (or Number) — the percentage of iodine that will be absorbed by a chemically unsaturated substance, such as vegetable oil, in a given time under specified conditions. The iodine value is a measure of degree of unsaturation. Two methods are described in the "Food Chemicals Codex:" the Hanus method and the Wijs method.

TABLE 1. CHARACTERISTICS OF VEGETABLE OIL FATTY ACIDS

Principal Fatty Acid	Formula Weight	Number of Double Bonds	Position Of Bonds	Number of Carbon Atoms	Formula
SATURATED COMPOUNDS					
Caproic	116.09	0	—	6	$C_5H_{11}COOH$
Caprylic	144.21	0	—	8	$C_7H_{15}COOH$
Capric	172.26	0	—	10	$C_9H_{19}COOH$
Lauric	200.31	0	—	12	$C_{11}H_{23}COOH$
Myristic	228.36	0	—	14	$C_{13}H_{27}COOH$
Palmitic	256.42	0	—	16	$C_{15}H_{31}COOH$
Stearic	258.47	0	—	20	$C_{19}H_{39}COOH$
UNSATURATED COMPOUNDS					
Palmitolenic	254.42	1		16	$C_{15}H_{29}COOH$
Linolenic	278.42	3	cis-9, cis-12, cis-15	18	$C_{17}H_{29}COOH$
Linoleic	180.44	2	cis-9, cis-12	18	$C_{17}H_{31}COOH$
Oleic	282.45	1	cis-9	18	$C_{17}H_{33}COOH$

TABLE 2. CHARACTERISTICS AND PROPERTIES OF MAJOR VEGETABLE OILS

Property	Coconut Oil	Cottonseed Oil	Groundnut (Peanut) Oil	Pal Oil	Rapeseed Oil
Color	White	Pale-yellow or yellowish-brown to dark ruby-red, or black-red.	Yellow to greenish-yellow	Yellow-brown	Brown (raw); yellow (refined)
State (at room temperature)	Semisolid (nondrying oil)	Liquid (semidrying oil)	Liquid (nondrying)	Solid (buttery)	Liquid (viscous)
Odor	Slight	Slight (when refined)	Nutlike	Agreeable	Characteristic
Melting point	77°–90 °F; 25°–32 °C	Slightly below 32 °F; 0 °C[#] (before winterizing process)	23°–37 °F; −5°–+3 °C[@]	86 °F; 30 °C	328 °F; 0 °C[$]
Specific gravity	0.92	0.915–0.921	0.912–0.920	0.952	0.913–0.916
Saponification value	250–264	190–198	186–194	247.6	174
Iodine value	7–10	109–116	88–98	13.5	100.3
Principal constituents	Glycerides of fatty acids of approximate composition: Lauric acid 45–48% Myristic acid 17–20% Capric acid 6–8% Palmitic acid 5–9% Caprylic acid 5–7% Oleic acid 4–8% Stearic acid 2–5% Arachidic acid 1%± Palmitoleic acid 0.4%± Unsaturated acids 8% Saturated acids 92% (Approximate)	Glycerides of fatty acids of approximate composition: Linoleic acid 47–50% Palmitic acid 26–27% Oleic acid 18–19% Stearic acid 2%+ Palmitoleic acid 1%± Myristic acid 1%− Capric acid 0.5% Linolenic acid 0.4%± Lauric acid 0.4% Arachidic acid 0.2%± Unsaturated acids 73%	Glycerides of fatty acids of approximate composition: Oleic acid 40–52% Linoleic acid 25–37% Palmitic acid 8.5–10.5% Behenic acid 2.5%± Lignoceric acid 1.5%± Stearic acid 1.5–3.0% Arachidic acid 1.5–2.5% Myristic 0.2%± Unsaturated acids 82% Saturated acids 18% (Approximate) Saturated acids 27% (Approximate)	Triglycerides of fatty acids of approximate composition: Palmitic acid 37–47% Oleic acid 31–44% Lauric acid 4–8% Stearic acid 2.5–5.5% Myristic acid 0.8–1.5% Linoleic acid 1–3% Palmitoleic acid 0.2–0.4% Arachidic acid 0.2–0.4% Unsaturated acids 50% Saturated acids 50% (Approximate) There are some significant differences in composition of palm oil (from fleshy fruit pulp) and palm kernel oil.[∅]	High in unsaturated acids, especially oleic, linoleic, and erucic acids, the latter being 40% in older varieties, but more recent varieties have a lower erucic acid content.

Soluble in	Alcohol, carbon disulfide, chloroform, ether. immiscible in water.	Benzene, carbon disulfide, chloroform, ether. Slightlyform, soluble in alcohol.	Carbon disulfide, chloroform, ether, petroleum ether. Insoluble in alkalies, but saponified by alkali hydroxides with formation of soaps. Slightly soluble in alcohol. Insoluble in water.	Alcohol, carbon disulfide. chloroform, ether. Insoluble in water.	
Grades	Crude, refined, Ceylon, Manila	Crude, refined, prime summer yellow, bleachable, USP.	Crude, refined, edible, USP.	Crude, refined	
Derivation	Hydraulic press or expeller extraction from coconut meat, followed by alkali-refining, and bleaching.	From cotton seeds by hot-pressing or solvent extraction.	By pressing ground groundnut (peanut) meats or by extraction with hot or cold solvents. Purified by bleaching with fuller's earth or carbon. Hot-pressed oil may be allowed to stand to deposit stearin, prior to filtering.	Separation of fat from palm fruits by expression or centrifugation.	
Food uses	Margarine, hydrogenated shortenings, synthetic cocoa dietary supplements.	Margarine, shortening, salad oils and dressings, stabilizers.	Salad oils, mayonnaise, margarine Sometimes a substitute for olive oil. Cooking oil.	Food shortenings, margarines, competes with soybean oil.	Salad dressings, margarine, substitute for soybean oil.
Special notations	See also entry on **Coconut**.	#Solidification range is 88°–95 °F (31°–35 °C) Flashpoint is 486 °F (252 °C) See also entry on **Cottonseed**.	@Flash point is 540 °F (282 °C) See also **Groundnut (Peanut)**.	⊘Approximate composition of palm kernel oil is: 50% lauric acid, 15% myristic acid, 16% oleic acid, 7% palmitic acid with lesser amounts of capric and caprylic acids. See also **Palm Oil**.	$Flash point is 325 °F (617 °F) Autoignition temperature is 836 °F (447 °C).

Soluble in		Benzene, carbon disulfide, chloroform, ether. Slightly soluble in alcohol.	Alcohol, carbon disulfide, chloroform, ether	Alcohol, carbon disulfide, chloroform, ether
Grades	Crude, refined	Edible should contain less than free fatty acids. Semi-refined, coast, USP.	Coast, refined (salad), crude, foots (for soapstock), clarified.	Crude, refined
Derivation	Hydraulic press or solvent extraction of seeds.	Pressing of seeds.	Oil for edible purposes is bleached with fuller's earth.	Expression from seeds.
Food uses	Dietetic foods, margarine, hydrogenated shortenings	Shortenings, salad oil, margarine	High-protein foods, margarine, salad dressings	Margarine, shortening
Special notations	Considered by some authorities as the most natural, nutritionally sound vegetable oil. See also **Safflower Seed Oil**.	≠Solidifying point is 23 °F (−5 °C) See also **Sesame Seed Oil**.	See also **Soybean Processing**.	See also **Safflower Seed Oil**.

Saponification Number — the number of milligrams of potassium hydroxide required to hydrolyze one gram of sample of an ester (glyceride, fat) or mixture. This test is also described in the "Food Chemicals Codex."

Margarines

Regular margarines (by government regulations) contain at least 80% fat. The remaining content is ~16% water and small amounts (about 4%) of skim or nonfat dry milk and salt. There are several unsalted margarines available. Small amounts of emulsifying agents consisting of lecithin and/or monoglycerides and diglycerides are contained in a number of commercially available margarines. The preservatives most commonly used include sodium benzoate, potassium sorbate, calcium disodium EDTA, isopropyl citrate, and citric acid. Most margarines in the United States are fortified with about 15,000 USP units of vitamin A and a few margarines also contain up to 2000 USP units of vitamin D.

Margarines produced in the United States resemble butter in their proximate composition. The great majority of margarines provide more polyunsaturated fatty acids than an equivalent weight of butter. Diet and imitation margarines were introduced about a decade ago and contain less than 80% fat. The fat content of light blends is about 60% and that of diet imitation margarines is about 40%. Lower fat content in these products is compensated for by higher water content.

A survey of some 40 margarines made in the United States in the late 1970s showed that stick margarines made from partially hydrogenated soybean and cottonseed oil were by far the largest category. Stick margarines made from corn (maize) oil and partially hydrogenated corn oil, and from partially hydrogenated soybean oil and liquid cottonseed oil ranked second and third, respectively. The survey showed that margarines with formulations that included liquid cottonseed oil or liquid and/or partially-hardened palm oil usually contained higher amounts of palmitic acid than did other margarines of the same type. The stearic acid content was reasonably constant for most hard and soft margarines. Margarines made with coconut oil were extremely saturated and contained large amounts of lauric and myristic acids.

Properties of Major Edible Vegetable Oils

The major properties of nine of the principal edible vegetable oils are summarized in Table 2. For descriptions of the constituent acids, see also **Arachidic Acid**; **Caproic Acid**; **Capric Acid**; **Lauric Acid**; **Linoleic Acid**; **Linolenic Acid**; **Myristic Acid**; **Oleic Acid**; **Palmitic Acid**; and **Stearic Acid and Stearates**.

Unconventional Sources of Oils and Proteins

Research efforts continue to find new sources of both food and nonfood oils. Some investigators have reported on the prospects of various gourds indigenous to western North America. Such cucurbits are vigorous and highly drought resistant and produce large quantities of foliage and fruit containing seeds rich in protein and oil, with an extensive system of large, fleshy storage roots which contain starch. Varieties studied have included *Cucurbita foetidissima* and *C. digitata*. Also studied have been varieties of hibiscus (okra). As pointed out by the researchers, the non-conventional protein sources as well as oils would be welcome in a time of protein deficits.

Investigators also have described the potential of the *jojoba plant*, a native of the Sonoran desert of Mexico, Arizona, and California. The desert shrub produces seeds about the size of groundnuts (peanuts) which contain a liquid wax, frequently called *jojoba oil*. The oil is similar to sperm whale oil in its suitability for a number of industrial applications. Sperm whale was placed on the endangered species list by a number of countries, including the United States, in 1971. Prospects of an edible oil from jojoba are undetermined, but the meal remaining after pressing jojoba seeds contains 30–35% protein, and may have potential as a livestock feed. A new jojoba industry would mean a new, renewable resource that has not been exploited before and would offer economic relief to the people of the Sonoran desert region. Other researchers have recently shown a renewed interest in the lupine as a source of edible oils and proteins.

VEIN (Geology). A small or large fissure that has been filled with mineral matter by deposition from aqueous solutions, including "liquors" and gaseous emanations from magmas. Lode means essentially the same thing, the latter being an old Cornish mining term referring to the formations that would "lead" or direct the miner to the desired minerals.

VELA. A southern constellation which once, with Carina and Puppis, was part of a superconstellation known as Argo Navis.

VELOCIMETER. A continuous-wave reflection Doppler system used to measure the radial velocity of an object.

VELOCITY AND SPEED MEASUREMENT. Velocity and speed are considered to be rate variables. See also **Variable (Process)**.

Velocity

Velocity is the time rate of change of position. (Unless angular velocity is specified, this term is understood to refer to linear motion, which may be emphasized by the expression "linear velocity.") Strictly, the velocity of a moving point must specify both the speed and the direction of the motion, and is therefore a vector; though the term is sometimes more loosely used as merely synonymous with speed. The velocity of a point is the time rate of the distance s from a fixed origin O, expressed as the vector derivative of s with respect to the time, ds/dt (Fig. 1); while the speed is the magnitude of the velocity and is not a vector. If the direction of motion is constant, so that the motion is in a straight line (but not necessarily with constant speed), and if the line of motion is clearly understood, it is convenient to treat the distance s and the velocity ds/dt as scalars with respect to some zero point on that line and with appropriate algebraic signs (Fig. 2); otherwise they must be regarded as vectors. If the velocity is variable, account must be taken of the acceleration. Examples of both curved and rectilinear motion are treated under kinematics.

Angular Velocity. A quantity relating to rotational motion. While the use of the term "angular velocity" may be extended to any motion of a point with respect to any axis, it is commonly applied to cases of rotation. Its instantaneous value is defined as the vector, whose magnitude is the time rate of change of the angle θ rotated through, for example, $d\theta/dt$, and whose direction is arbitrarily defined as that direction of the rotation axis for which the rotation is clockwise. The usual symbol is ω or Ω.

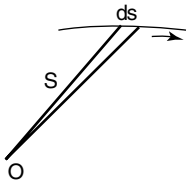

Fig. 1. Velocity expressed as a vector derivative.

The concept of angular velocity is most useful in the case of rigid body motion. If a rigid body rotates about a fixed axis and the position vector of any point P with respect to any point on the axis as origin is $\mathbf{r}$, the velocity $d\mathbf{r}/dt$ of P relative to this origin is $d\mathbf{r}/dt = \boldsymbol{\omega} \times \mathbf{r}$, where $\boldsymbol{\omega}$ is the instantaneous vector angular velocity. This indeed may serve as a definition of $\boldsymbol{\omega}$.

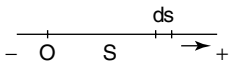

Fig. 2. Treatment of distance and velocity as scalars.

The average angular velocity may be defined as the ratio of the angular displacement divided by the time. In general, however, this is not a vector, since a finite angular displacement is not a vector. The instantaneous angular velocity is more widely used.

Angular velocities, like linear velocities, are vectorially added, for example, if a top is spinning about an axis which is simultaneously being tipped over toward the table, the resultant angular velocity is the vector sum of the angular velocities of spin and of tipping. This enters into the theory of precession. The derivatives of the Eulerian angles are sometimes very useful in describing the angular motion of a rigid body which has components of angular velocity about all its principal axes.

Speed

Speed is a scalar quantity equal to the magnitude of velocity. Velocity is a vector quantity denoting both the direction and the speed of a linear motion, or denoting the direction of rotation and the angular speed in the case of rotation. Industrially, linear speeds are frequently inferred from rotational measurements simply because of the manner in which most machines are designed — with rotating shafts, wheels, and gears to which speed transducers can be conveniently attached.

As with most other areas of industrial instrumentation, analog-type sensors of speed no longer exclusively predominate the technology. Commencing on a small scale in the mid-1950s, digital speed sensors have been developed and, for many applications, digital sensors are preferred because of the ease with which they can be integrated into overall digital control systems. However, it should be stressed that analog-type tachometers are still widely used. The word *tachometer*, which once denoted the conventional direct-current and alternating-current tachometers, has been extended in interpretation to include numerous methodologies, including analog and digital types.

Direct-Current Tachometers. These instruments operate on the principle of the voltage generated when a magnet is rotated with reference to a conductor (as shown in Fig. 3) or vice versa. Polarity of voltage and thus the direction of current flow will depend upon the polarity of the field and the direction of the conductor motion. A dc tachometer system is comprised of a simple dc generator and a dc indicator or recorder. Generator speeds range from 100 to 5000 revolutions per minute (rpm).

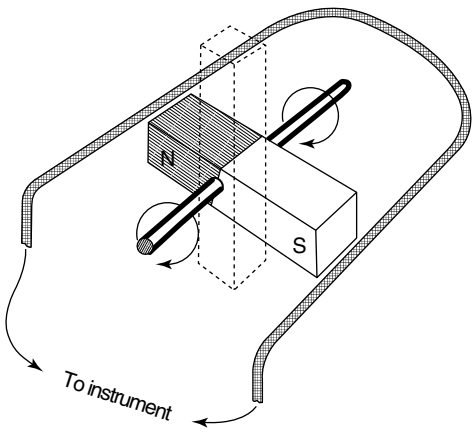

Fig. 3. Rotating magnet within fixed conductor generates voltage in direct-current-type tachometer.

DC tachometers are of two basic types: (1) brush type; and (2) brushless type. Advantages of either type include linear output through zero speed, acceptable accuracy, and refinement of design as the result of many years of experience. Generally, the characteristics of the tachometer can be matched to the equipment whose speed is being determined by employing suitable gearing for effecting speed reduction or multiplication. Brush-type tachometers use either (1) an iron core, or (2) a moving coil. In essence, the iron core type is a simple dc motor that is used as an electrical generator. The moving-coil brush-type dc tachometer uses a winding in the form of a shell or cup. Because of problems with brushes in certain kinds of environments, the brushless dc tachometer is frequently specified. In this design, the positions of the winding and magnet are reversed — with the magnet rotating, while the winding is stationary. Thus, there are no electrical connections required to the rotating member. Additional electrical circuitry is required to sense the position of the rotor and provide appropriate switching. These features add significantly to the cost of the tachometer.

Alternating-Current Tachometers. Fundamentally, an ac tachometer is a three phase electric generator with a three-phase rectifier on the output. There are two principal formats. In the *voltage-responsive tachometer system*, an ac generator and a rectifier-type indicator are used. These instruments can be used where the generator speed for full scale is not less than 500 nor greater than 5000 rpm. With adequate attention to bearings, conventional ac generators may be used at speeds up to 10,000 rpm. The ac tachometer generator embodies a stator surrounding a rotating Alnico permanent magnet. The output of the generator for voltage-responsive systems is temperature compensated and is proportional to speed. In the *frequency-responsive tachometer system*, the system consists of a dc indicator or recorder, a frequency-responsive network which may be contained in a recorder or separate transformer box, and an ac tachometer generator of either the conventional or bearing-less form.

Bearingless tachometer generators are ac generators of the most basic form consisting only of a permanent magnet rotor and a stator. The devices have no bearing or brushes. They are designed to be impervious to oil, grease, and relatively high temperatures and, consequently, may be installed in inaccessible areas, such as gearboxes, which permit saving of space. They have very low torque burdens of less than one ounce-inch and are capable of speeds up to 100,000 rpm.

In general, when a bearingless generator is used, the frequency-responsive approach is used. Since the system is solely dependent upon the frequency output of the generator, voltage variations caused by reductions in the magnetic strength of the rotor due to handling, poor alignment of stator and rotor, or axial travel of the rotor with respect to the stator will not affect the overall accuracy.

Capacitor-Type Tachometer. In the instrument shown in (Fig. 4), the charging current of a capacitor is utilized. The pickup head usually contains a reversing switch, operated from a spindle, which reverses twice with each revolution. Thus, battery potential is applied to the capacitor in each direction, and, with each impulse, a current is passed through the milliammeter. The indicator responds to the average value of these impulses. Therefore, the indications are proportional to the rates of the pulses, which, in turn, are proportional to the rates of the spindle revolutions. No current is drawn from the battery when the spindle is not revolving. A high-accuracy instrument is available wherein the capacitor and reversing switch are connected to one leg of a bridge circuit. The pulse from the periodically charging capacitor upset the balance of the bridge and thus cause an indication by the milliammeter.

Eddy-Current Tachometer. For many years, this type of instrument has been used for automobile speedometers, in which case a flexible shaft arrangement is utilized, but it also finds extensive industrial use. In its basic form, shown in (Fig. 5), the drag-type instrument uses a permanent magnet which is revolved by the source being measured. Close to the revolving magnet is an aluminum disk, pivoted so as to turn against a spring. A pointer attached to the pivoted disk is associated with a calibrated scale. As the permanent magnet is revolved, eddy currents are set up in the disk. The magnetic fields caused by these eddy currents produce a torque which acts in a direction to resist this action and turns the disk against the spring. The disk turns in the direction of the rotating magnetic field and will turn (or be dragged) until the torque developed equals that of the spring. This torque is proportional to the speed of the rotating magnet. The instrument has a uniform scale. This instrument has been highly refined over the years and is available in a number of formats. Remote indication, for example, is obtainable with one form of this tachometer. A three-phase generator is driven from the shaft whose speed is to be measured. The generator output is connected to a three-phase synchronous motor, attached to the

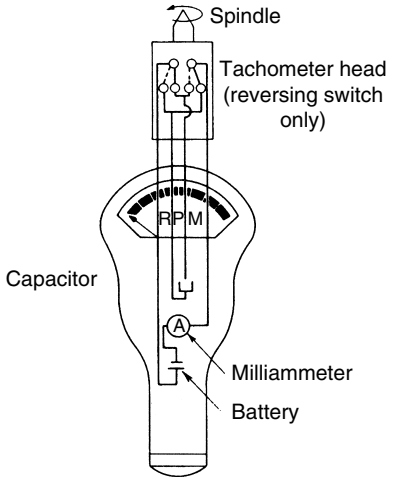

Fig. 4. Capacity-type impulse tachometer.

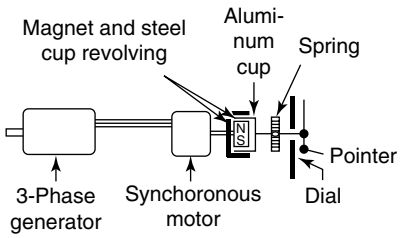

Fig. 5. Drag-type eddy-current tachometer.

indicator, which rotates the magnetic field. Several indicators, each with its own synchronous motor, may be connected to the three-phase generator and will indicate in proportion to the speed of the generator.

Since the indications of this type of instrument are dependent on the frequency of the three-phase generator and not upon its voltage, a high degree of accuracy is attained. These instruments are considered accurate to 10 rpm in a full-scale range of 3000 rpm. The indicator pointer may be revolved through as much as 1080°, in which case a secondary pointer indicates the number of revolutions of the main pointer.

Photoelectric Tachometers. In one instrument of this type, designed to measure speeds up to 3 million rpm, the movable part subject to measurement is arranged to provide reflecting and absorbing areas. The interrupted reflected light produces, by means of a photocell, electric impulses which are applied to a frequency meter which generates a square wave from the pulse voltage and applies it to a discriminating circuit. A fixed current pulse at each half cycle is produced. These pulses are rectified and applied to a dc milliammeter which indicates the average value. Thus, the meter readings are proportional to the number of pulses per second, or the frequency.

In a recent *laser velocimeter* developed for measuring linear velocity, as of a jet engine exhaust, where no contact can be permitted, a laser, mirror, beam splitter, and lens system, and phototube sensor take advantage of the Doppler effect in producing interference fringes which are a measure of the velocity.

Variable-Reluctance Tachometer. In this type of electronic tachometer, pulses produced by the pickup are proportional to speed and are amplified, rectified, and control the direct current to a milliammeter. This type of instrument is rated at 10,000 to 50,000 rpm, with an accuracy of ±1/2% of full-scale reading. The pickup is rated to withstand ambient temperatures from −51 to +160 °C.

Vibrating-Reed Tachometer. Vibrating reeds provide a natural means of measuring the frequency of vibrating or revolving equipment. The reeds are of various lengths, in accordance with their natural period of vibration. They are mounted on a base with a reference scale so that observation of the reed that is vibrating forms a means of measuring the frequency of vibration. Purely electrical frequency is measured by using a solenoid valve associated with the reeds. The frequency of the output of a generator may be measured by simply touching the generator housing with the case of the indicator. Mechanical frequencies, oscillations, and rotations may be measured by bringing the member to be measured in mechanical contact with the instrument by touching it to the bearing support, case, or frame of the rotating device. Once the reeds are correctly adjusted and aged, they retain adjustment for long periods. Individual reeds are adjusted to ±0.3%. A change in temperature of ±25 °C may result in an error of about 0.5%. See Fig. 6.

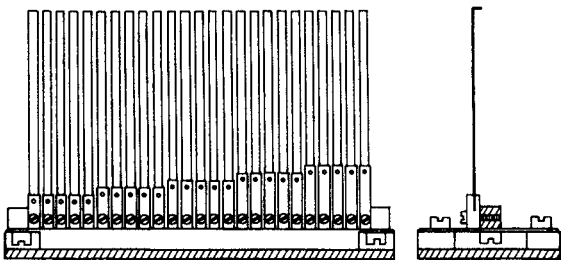

Fig. 6. Vibrating-reed tachometer.

Pneumatic Tachometer. Applicable to speed determinations from 0 to 6500 rpm with accuracies rated at ±0.5% of span, this instrument operates on the force-balance principle with magnetic actuation of a standard pneumatic circuit. See also **Pneumatic Controller**. The input shaft carries an eight-pole permanent magnet. A nonmagnetic alloy disk is held in position by flexture mounts between the keeper plate and the poles of the magnet. As the input shaft rotates the magnet, the magnetomotive pull, due to eddy currents generated in the disk, tends to turn it in the same direction. As reported by the manufacturer (Foxboro), this pull positions the force bar attached to the disk in relation to the nozzle, thereby causing an increase in the back pressure in the air flow through the nozzle. This back pressure is amplified by a relay which produces an output pressure proportional to speed.

Optical Shaft Encoders. Used mainly to sense the exact position of a machine member, optical shaft encoders (digital) can also be used for the measurement of speed.

Other Methods. The measurement of wind and air velocities is described in the entry on **Wind and Air Velocity Measurement**. Governors used for controlling the speed of large rotating equipment are described under **Governor**. Stroboscopes can be used as tachometers provided they have their own flashing-rate control circuits and calibration display. See also **Stroboscope**. Doppler radars are commonly used for measuring linear speeds in auto traffic control. See also **Radar**.

VELOCITY CURVE (Stellar). A plot of radial velocity of a star as ordinates against time as abscissae is known as the velocity curve for the star. The method of formation of a mean velocity curve is similar to that described for the determination of a mean light curve. For the use of the velocity curve in determining the orbit of a spectroscopic binary, see also **Spectroscopic Binaries**.

VELOCITY LIMITING CONTROL. In an automatic control system, control action in which the rate of change of a specified variable will not exceed a predetermined limit.

VELOCITY METER. See **Accelerometer**.

VELOCITY MODULATION. This is a form of electron modulation in which the electrons passing through a resonant cavity in a tube such as the klystron are acted upon by a modulating field in such a manner that their velocities cause them to pass through the collector cavity in groups.

VELOCITY POTENTIAL. A scalar function with its gradient equal to the velocity vector **u** of an irrotational flow.

If $\chi(x, y, z)$ is the velocity potential,

$$\mathbf{u} = -\nabla\chi.$$

If the flow is also nondivergent, the velocity potential satisfies the Laplace equation

$$\nabla^2\chi = 0.$$

The velocity is everywhere normal to the surfaces of constant velocity potential. If a velocity potential exists, it is simpler to describe the motion by means of the potential rather than the vector velocity, since the former is a single scalar function whereas the latter is a set of three scalar functions.

AMS

VELOCITY PROFILE. The graphical representation of the variation with displacement normal to the general direction of flow of the mean flow velocity in a shear flow. For example, the velocity profile of laminar flow through a circular tube is parabolic.

VELVET ANT *(Insecta, Hymenoptera).* A wasp of the family *Multillidae*. The females of these insects are wingless and consequently are antlike in form, but they differ in the absence of the dorsal prominence on the slender waist that characterizes the ants. They are densely hairy insects, usually brightly banded with some shade of red or yellow, black, and sometimes white. The males differ in other details than the presence of wings, hence it is difficult to associate the sexes unless they are taken together. Velvet ants are parasitic in the nests of other insects and some have been reported as parasites on the tsetse fly.

VENA CONTRACTA. A term frequently used in connection with orifice-type flowmeters. As the flow passes through an orifice plate, the flow achieves its narrowest cross section somewhat downstream of the plane of the plate. This location is called the vena contracta, meaning the narrowest jet cross section. See also **Flow Measurement (Liquids and Gases)**; and **Orifice**.

VENEER. See **Wood**.

VENN DIAGRAM. See **Information Theory**.

VENN, JOHN (1834–1923). Venn was a British mathematician who developed Boole's mathematical logic and is especially remembered for Venn diagrams. He taught logic and probability theory at Cambridge University. He wrote *Logic of Chance, Symbolic Logic*, and *The Principles of Empirical Logic*, all of which influenced the development of the theory of statistics and mathematical logic.

Venn also had an interest in history and compiled a history of Cambridge University, which was published in 1922.

J. M. I.

VENOMS. Animal venoms are complex aqueous mixtures of proteins, peptides, carbohydrates, nucleosides, biogenic amines, metallic cations, such as sodium, calcium and zinc, and very low levels of free amino acids and lipids. Proteins and peptides comprise 90–95% of the dry weight of the venom. Among the proteins are enzymes with many diverse activities, including phospholipases, phosphodiesterases, phosphomonoesterase, l-amino acid oxidase, acetylcholinesterase, proteolytic enzymes of the serine proteinase and metalloproteinase classes, arginine esterase, 5′ nucleotidase, hyaluronidase and nicotinamide-adenine dinucleotide nucleosidase. Many potent toxins are included among the peptides, such as presynaptic, postsynaptic and potassium channel-binding neurotoxins, cytotoxins, myotoxins and cardiotoxins. The venom is produced by an apparatus composed of modified exocrine glands and is excreted and injected into the prey or victim through bristles, sticks or fangs. Their effects vary from negligible or moderate local symptoms to severe systemic reactions, death sometimes being the outcome. See also **Mycotoxins**.

Clinical evaluation of the patients and experimental work has permitted the elucidation of a number of biochemical, pharmacological and pathophysiological mechanisms that are involved in the mode of action of animal venoms. In experimental work, purified or recombinant components are now being used as a substitute for crude venoms. Their actions are analyzed, both *in vitro* and *in vivo* and by standardized methods using mainly experimental animals or, exceptionally, natural prey.

Mortality is usually measured by determining the dose that kills 50% of a group of animals (LD_{50}). The most common animal used for analysis is the white mouse, into which the venom or isolated components are intravenously, intraperitoneally or subcutaneously administered. The overall toxicity of venom is the consequence of its various components and the response of the envenomed animal. In order to estimate the 50% endpoint of venom toxicity, a simple method of calculation, developed by Reed and Muench in 1938, may be used.

Although much is known about the effect of venoms and their control, envenoming by venomous animals is still a serious public health problem in tropical and subtropical countries. In addition, antivenom serotherapy, discovered simultaneously by Albert Calmette and by Césaire Auguste Phisalix and Gabriel Bertrand, in France, continues to be an effective measure of treating human victims of animal envenoming.

Insects

There are numerous species of toxic insects. The most frequent incidents of envenomation are caused by Hymenoptera and Lepidoptera species. See also **Insect**.

Hymenoptera. Their venom, produced and stored in their venom glands, contain phospholipases A_2 and B, hyaluronidase, and small peptides such as melitin and mast cell-disrupting peptides, amino acids and histamine. Stings caused by Hymenoptera of all species of wasps, bees, hornets, and ants are symptomatic, with pain at the site of dart penetration. Multiple stings cause massive histamine release, inducing, in addition to the local acute inflammation reaction, a systemic reaction characterized by arterial hypertension (270×150 mmHg), respiratory and kidney failure, and intense intravascular hemolysis. Death may be the outcome, depending on the number of stings and/or the susceptibility of the victim.

Lepidoptera. Contact of human skin with caterpillars from various Lepidoptera species results in local inflammation. The presumptive venom components are probably secreted by epithelial cells stored inside their bristles, and excreted during the contact of the bristles with their predators or victims. Caterpillar bristles contain fibrinolytic, urokinase, kallikrein, factor Xa and tissue plasminogen activator-like activities (*L. achelous*) [Arocha-Piñango, ref.], procoagulant activity [Kelen, et al.:], complement system activator factor(s) and a phospholipase A_2 activity (*L. obliqua*). The immediate local signals of envenoming are burning pain, erythema, oedema and heat, followed by subcutaneous hemorrhages, lymphangitis and proximal adenopathy. Principal symptoms include alterations of the clotting mechanism, characterized by high thrombin activity and low levels of prothrombin, fibrinogen, factor V, factor XIII and plasminogen that last for days [Duarte, et al.:]. See also **Blood Clotting: General Pathway**; and **Blood Coagulation**.

Spiders

Spiders are ubiquitous venomous arachnids common in all inhabited regions. The spider's body is divided into a cephalothorax and an abdomen, linked by a short pedicel. The cephalothorax contains the fangs set on forward-facing chelicerae, the pedipalps and legs; the abdomen contains the book lungs and spinnerets. The venom produced by the venomous glands is injected into the prey through the fangs. See also **Arachnida**; **Mite (Arachnida, Acarina)**; **Spider (Arachnida, Araneida)**; and **Tick (Arachnida, Acarina)**.

Spiders are grouped into "primitive mygalomorphs" (orthognaths) and "modern araneomorphs" (labidognaths), distinguished mainly by the position of the fangs.

The mygalomorph spiders have robust bodies and legs, small eyes and large paraxially set fangs. The genera *Atrax* and *Hadronyche* (Australian funnel-web spiders), specifically the species *A. robustus* and *H. formidabilis*, are potentially dangerous to humans.

The araneomorph spiders vary in size, with a wide spectrum of body shapes and leg lengths, and their fangs are small to moderate in size.

This group includes most of the medically important spiders: the genus *Phoneutria* (armed spider, banana spider) is found in southeast Brazil, Colombia and Costa Rica; the genus *Scaptocosa* (tarantula, licosa), with two species, the genus *Loxosceles* (brown spiders, recluse spiders), with several species, and the genus *Latrodectus* (widow spiders) are found in the Americas, Africa, southern Europe and western Asia or are distributed worldwide, respectively.

A. robustus and *H. formidabilis* and other species from these genera may cause severe envenoming in humans, characterized by local pain and systemic symptoms such as perioral tingling, tongue fasciculation, profuse lacrimation and salivation, dyspnoea, pulmonary oedema and tachycardia, followed by death.

Phoneutria spp: bites from *P. nigriventer* are characterized by a local burning sensation followed by swelling, erythema and sweating. Systemic symptoms include nausea, vomiting, priapism, tachycardia or bradycardia, hypertension or hypotension, and occasionally cardiac arrhythmia. Shock and pulmonary oedema may occur. More than 25 basic neurotoxic proteins of 2–16 kDa, expressing distinct chemical and pharmacological properties, have been isolated and their amino acids sequenced and aligned at the Cys residues. The primary sequence of nine of these proteins showed homology with other neurotoxins [Cordeiro, et al.:].

The venom from the *Scaptocosa* spiders contains some proteolytic enzymes and probably a neurotoxin active on sodium channels. The local symptoms, of pain, oedema and erythema, are not severe; there are generally no systemic signals.

Loxosceles spiders are found either in North America (*L. reclusa*), in the desert areas of the Middle East (*L. deserta*), or in South America (*L. gaucho, L. laeta, L. intermedia*). Envenoming is characterized by local dermonecrosis preceded by intense inflammation. Systemic effects, such as fever, malaise, pruritus, exanthema, intravascular hemolysis, coagulation, thrombocytopenia and renal failure, are restricted to approximately 16% of the victims. The venoms from *L. gaucho, L. laeta*, and *L. intermedia* contain a 35-kDa toxin endowed with sphyngolmyelinase activity and with the property of transforming human erythrocytes into activators of an autologous complement alternative pathway, thus inducing dermonecrosis and an endotoxemic-like shock in mice [Tambourgi, et al.:].

Scorpions

Scorpions are terrestrial arthropods, viviparous with a long gestation period. Their evolutionary history dates back to approximately 425–450 million years ago (middle Silurian) and they have a wide geographical distribution, living on all major land masses except the Antarctic. See also **Arachnida**; and **Scorpion (Scorpionida)**.

The scorpion body is divided into the cephalothorax, or prosoma, and the abdomen, or opisthosoma. The prosoma is covered dorsally by the carapace and bears some sensory organs. It consists of seven visible somites, III–IX. The two chelicerae, two pedipalps and the four pairs of legs are the appendages of somites III, IV and V–VIII, respectively. The opisthosoma is subdivided into a broad anterior mesosoma and a narrow tail-like metasoma. The mesosoma consists of the somites X–XVI and is covered dorsally by a sclerotized plate, or tergum. The metasoma comprises somites XVII–XXI and a telson or "sting." This latter structure, which is not a true somite, is composed of the vesicle and the aculeus.

The venom is produced by a pair of glands found in the vesicle of the telson. Formed by a single layer of epithelial cells, the venom cells exhibit the following secretory-phase cycle of apocrine glands: a resting phase, in which the cells contain homogeneous cytoplasm; an elaboration phase, in which they contain fine uniform granules; an accumulation phase, in which larger granules are seen; and, an expulsion phase, in which the venom granules and a portion of the cell cytoplasm are extruded into the lumen of the gland. The glands are invested mesially and dorsally with the compressor muscle. Each gland is provided with an exit duct that communicates to the exterior via two apertures in the aculeus. During the sting the compressor muscle presses the gland against the cuticle along its exterior lateral and ventral surfaces to excrete the venom.

The order Scorpiones includes thirteen living families: *Bothriuridae* (with 14 genera and 128 species. Members of this family are found in small burrows, under stones, in cracks and crevices, and in self-made burrows); *Buthidae* (with 80 genera (one extinct) and 747 species, this family is the largest of the scorpion families); *Caraboctonidae* (with 4 genera and 18 species, previously included in the family *Iuridae*); *Chactidae* (with 12 genera and 149 species); *Chaerilidae* (with 1 genus with 22 species. They can be found under stones, under fallen trees, etc., in humid (mesic) habitats); *Euscorpidae* (with 11 genera and 75 species); *Hemiscorpiidae* (this family has previously been known as *Ischnuridae*, with 12 genera and 79 species); *Iuridae* (with 2 genera and 2 species); *Microcharmidae* (with 2 genera and 15 species); *Pseudochactidae* (a brand new family, with one genus and one species thus far discovered); (*Scorpionidae* (with 16 genera and 243 species, 2 genera and 2 species are extinct; some of the world's largest scorpions belong to this family); *Superstitioniidae* (with 5 genera and 10 species) and *Vaejovidae* (with 11 genera and 151 species). They include over1, 630 species, but only the venoms of about 25 species are capable of causing human envenoming.

'Scorpionism' is the human accidents caused by the stings of scorpions. Gross statistical estimates of scorpionism vary from a few to hundreds of thousands of stings per year, with around 1% of deaths. Local symptoms of stings are sensations of burning pain, pruritus and hyperesthesia, followed sometimes by inflammation. The onset of clinical symptoms is rapid (within 5–30 min) after the sting. Respiratory failure and cardiovascular manifestations are the usual causes of death. Among the general symptoms are: hypertension, lacrimation, mydriasis, photophobia, nystagmus, nasal secretion, a characteristic sensation of hair in the throat, with dysphonia, cough and dysphagia, hyperesthesia, hyperexcitability, excessive salivation and vomiting.

Scorpion venoms are rich in neurotoxins, proteins that represent some of the most potent toxins known. The neurotoxin I from *Androctonus australis*, for instance, with an LD_{50} (2.5×10^{-9} moles per kg) approximately 10^5 times more toxic than cyanide ($LD_{50} = 1.5 \times 10^{-4}$ moles per kg), is considered a powerful poison. Scorpion toxins constitute a family of small basic proteins of 60–70 amino acid residues crosslinked by four disulfide bridges. According to their toxicity spectrum, scorpion toxins are classified as mammal toxins, insect toxins or crustacean toxins. Mammal toxins, according to their ability to bind to two different sites on the sodium channel, are subdivided into a and b toxins with consequently different pharmacological effects. The a toxins have been found in the venoms of east and North African and middle Eastern scorpions [De Lima and Martin-Eauclaire, ref.].

The principal molecular targets of the scorpion toxins are the voltage-dependent Na^+ and K^+ channels that are found in many excitable tissues and are responsible for the action potential in nerves. They are classified into three general classes according to how they exert their actions: class I, acts on the process of Na^+ inactivation; class II, acts on the process of Na^+ activation; and, class III acts by reducing the passage of Na^+ inward or K^+ outward. Among the class I toxins are those first described in venom from *L. q. quinquestriatus* and later in venoms from other scorpion species, such as the Old World species *Androctonus australis, Mesobutus tamulus* and *M. eupeus*, and the New World specie *Centruroides exilicauda*. These toxins inactivate the Na^+ channels, resulting in prolongation of the action potential to many times its normal duration. Class II includes toxins from the venoms of New World scorpions, such as *C. exilicauda*, *C. suffusus suffusus* and *Tityus serrulatus*, and the Old World *L. quinquestriatus*. They induce a transient, depolarization-induced shift in the voltage-dependent activation. Class III includes toxins that simply reduce the ionic currents, with no changes in the kinetics or voltage dependence of activation or inactivation. Toxin I from *A. australis*, normally considered as belonging to class I, exhibits only a simple blocking effect when tested in the giant axon of *Sepia*. Similarly, toxin II from *C. s. suffusus* and toxin γ from *T. serrulatus*, which shifts the voltage dependence of activation in both frog node and neuroblastoma cells, respectively, causes only a simple blockade of Na^+ currents in skeletal muscles [Simard and Watt, ref.]. The tityustoxin mimics many effects of electrical stimulation by causing cell depolarization, with an increase in the uptake of Na^+ and Ca^{2+} ions and release of acetylcholine. The process is inhibited by tetrodotoxin and blocked by w-agatoxin, an antagonist of the P-type calcium channel [Gomez, et al.:].

The similarities, both in structure and in amino acid sequence, detected among the scorpion toxins suggest that the scorpion toxin genes have evolved by duplication of a common ancestral gene, the resulting genes evolving independently. Such independent evolution of each duplicate gene after insertions, deletions and mutations may explain the variability of the

scorpion toxins in terms of either amino acid sequence or specificity of action. Scorpion venoms from the New World scorpions, *T. stigmurus, T. bahiensis, T. serrulatus, T. costatus, T. cambridgei, Rhopalurus agamemnon* and *Brotheas amazonicus*, demonstrated several protein bands by electrophoresis, most of them crossreacting in immunoblotting with horse anti-*T. serrulatus*, anti-*T. bahensis*, anti-*T. serrulatus* + *T. bahiensis* sera probes. The antibodies present in these antivenoms combine with venom components as measured *in vitro* by enzyme-linked immunosorbent assay (ELISA), and neutralize their lethal effects *in vivo*. These results indicate that the scorpion toxins, besides sharing common functional molecular domains, also share similar antigenic epitopes [Nishikawa, et al.:]. See also **Epitopes**.

Snakes

Snakes (class Reptilia, order Squamata) arose during the Cretaceous, approximately 100–120 million years ago. The poisonous forms, however, are more recent, evolving possibly during the Miocene, 30 million years ago. The snake systematic has not yet been solved: different names apply to the same forms, the same name to different forms, and there is a lack of agreement in the recognition of subspecies, which these are just some, of the factors complicating their classification. See also **Snakes**.

The features commonly used in snake systematic are maxillary dentition, the characteristics of the hemipenis, the presence or extension of the anterior trunk vertebrae bearing ventral processes known as hypapophyses, the form and disposition of scales and the presence of pits and tubercles. Within the higher snakes, *Chaenophydia*, there are four types defined by maxillary dentition. (1) The *aglypha*, with solid maxillary teeth of equal size, sometimes graded with the largest posteriorly or evenly with the posterior teeth abruptly enlarged and fang-like; only a few of these are known to be venomous. (2) The *opistoglypha* have two, three or four posterior teeth in series grooved for the conduction of venom; all *opistoglypha* snakes are venomous. (3) The *proterpglypha* have anterior maxillary teeth that are deeply grooved, usually with the edges fused to enclose the canal; a few *proteroglypha* species "spit" their venom through the tip of the fangs in the form of fine droplets. (4) The *solenoglypha* have fangs in which the groove is completely fused. All these forms are venomous. The hemipenis characteristics used in snake systematics are characterized by the degree by which it is divided or not in individual lobes by the sulcus spermaticus. The hypapophyses is clearly present in many snakes; in other groups these processes partially disappear at the heart, or are even absent. The arrangement of scales on the head and the body, their form and the presence of some sense organs, such as the pits (presumably the thermoreceptors) and the tactile tubercles, are also characteristic.

The 500 species of venomous snakes are distributed into five families:

- *Elapidae* (the kraits, cobras, mambas and coral snakes) are found in the Americas, Africa and Australasia. Members have a small head with short fixed fangs mounted at the front of the jaw (proteroglyphous).
- *Hydrophiidae* comprises the sea snakes found in the coastal waters of Asia and Australasia, with a number of features designed to allow marine existence: the nostrils are mounted dorsally on the head and equipped with a closing mechanism; the tail is flattened laterally; and the tongue is reduced.
- *Viperidae*, the true vipers, is the most widespread family of venomous snakes, present in Europe, Africa, Asia and the Americas but absent in Australasia. Their large, flattened triangular head is equipped with venom fangs, often grooved rather than truly hollow and mounted on the mobile maxillary bone. The fangs are accommodated within the mouth by folding them flat against the upper jaw. When they are to be used, the jaw is opened and the fangs erected.
- *Crotalidae* comprises snakes similar to those of the family Viperidae, except that they possess heat-sensitive pits, situated on the head between the nostril and eye. The family includes snakes found in the Americas and parts of southeast Asia; they are absent from Australasia and Europe, except for *Agkistrodon halys*, which may be found in the Caspian region of Eurasia.
- *Colubridae* is the dominant family of snake in all parts of world, except Australasia. In the venomous species the venom fangs are typically grooved and mounted at the rear of the upper jaws (opisthoglyphous) rather than at the front, as in all other venomous forms.

These families include over 2340 species of snakes.

The snake venom glands are, in general, composed of epithelial cells at different secretory stages enclosed in a tough capsule of connective tissue. The gland may be divided into a posterior main gland and an accessory mucous gland. The main gland is organized into many contiguous tubules converging toward the center and opening into a small lumen. The primary excretory ducts converge to a secondary duct that leads to the fang sheath. Although the main gland cells produce most of the venom components, the cells of the accessory gland are thought to produce sialomucins and other, similar substances. Early general symptoms of snakebite are local pain and bleeding from the fang punctures, followed by pain, tenderness, swelling, bruising, and lymphangitis extending up the limb, and tender enlargement of regional lymph nodes. These are followed by more specific symptoms, which vary according to the group to which the snake belongs. More characteristic symptoms can however be observed, according to the group to which the attributed snake belongs:

- *Vipera, Daboia russelii, Bothrops* spp., Australian elapids, Atractaspididae and Colubridae, such as *Rhabdophis tigrinus*: syncope, vomiting, colic, diarrhea, angio-oedema and wheezing may occur as soon as 5–20 min after bites.
- Colubridae (boomslang: *Dispholidus typus*, bird tree, twig or wine snake), *Thelotornis* spp. (Asian keelbacks: *Rhabdphis* spp., South American *Philodryas* spp.): local swelling, intense bleeding from the fang lesions, and syncope may be followed by repeated vomiting, colicky abdominal pain and headache, widespread systemic bleeding with extensive ecchymoses, incoagulable blood, intravascular hemolysis and renal failure. Death may occur days or weeks later, attributable to hemorrhage or renal failure.
- Atractaspididae (burrowing asps: *Atractaspis* spp., Natal black snake: *Macrelaps microlepdotus*): pain, swelling, blistering and necrosis may develop at the site of the bite, with tender enlargement of local lymph nodes. *A. engadensis, A. irregularis* and *A. microlepidota* may cause severe or fatal envenoming.
- Elapidae (cobras, kraits, mambas, coral snakes and Australian snakes), such as *Dendroaspis, Micrurus* and some *Naja*: tender local swelling, blistering and superficial necrosis are observed. The most impressive feature in envenoming caused by elapids is neurotoxicity. Vomiting, heaviness of the eyelids, blurred vision, fasciculation, parenthesize around the mouth, hyperacusis, headache, dizziness, vertigo, hypersalivation, congested conjunctivae and gooseflesh. Ptosis and external ophthalmoplegia may appear early. This paralysis extends later to the face, palate, jaws, tongue, vocal cords and neck muscles. The respiratory muscles also become paralyzed. Although death may be the outcome, these neurotoxic effects are completely reversible by antivenom or anticholinesterases.
- Hydrophiidae (sea snakes and seakraits): bites may pass unnoticed. In some cases, however, early symptoms, such as headache, a thick feeling in the tongue, thirst, sweating and vomiting may occur. These symptoms may be complicated by myoglobinuria, parenthesize, descending flaccid paralysis with ptosis and ophthalmoplegia.
- Viperidae (vipers, adders, rattlesnakes, lance-head vipers, moccasins and pit vipers): the local effects of these venoms are very severe. Swelling and bruising start early at the site of the bite. Swelling spreads through the bitten limb and trunk. Bruising extending around lymphatics may produce bruising over the regional lymph nodes, which become painful, tender and enlarged. Local and extensive necrosis commonly develops, leaving the tissue susceptible to bacterial infection. Among the general symptoms, extensive haemostatic alterations are the more consistent abnormalities. In consequence, spontaneous systemic hemorrhage manifested by epistaxis, hematemesis, cutaneous ecchymosis, petechiae, discoidal ecchymosis and subconjunctival, retroperitoneal, subarachnoid and intracranial hemorrhages may occur. Hypotension, shock and renal failure are responsible for most cases of fatal envenoming. Envenoming by some species such as *Bitis atropos, D. russelii pulchella, Crotalus d. terrificus* and *Crotalus d. collineatus* may cause neurotoxicity, occasionally with rhabdomyolisis.

These symptoms and lesions are obviously caused by venom components endowed with different toxic properties.

Postsynaptic Neurotoxins. These neurotoxins or α toxins bind to the nicotinic acetylcholine receptor in the postsynaptic membranes of skeletal muscles. They prevent the binding of the chemical neurotransmitter, acetylcholine, thereby blocking the excitation of the muscle. This blockage at the neuromuscular junction leads to flaccid paralysis. Such pharmacological action is similar to that of curare (tubocurarine), an alkaloid poison used by South American Indians in their arrows. Over 100 curaremimetic toxins from a large number of snakes have been isolated and their amino acid sequence determined. According to the number of amino acids, they are classified into short and long neurotoxins. Short neurotoxins contain 60–62 amino acid residues and four disulfide bonds in common positions, between Cys3 and Cys24, Cys17 and Cys45, Cys49 and Cys60, and Cys61 and Cys66. Most of the long neurotoxins consist of 70–74 amino acid residues and have the fifth disulfide bridge between Cys30 and Cys34 [Endo and Tamiya, ref.].

Cytotoxins. These toxins are present in the venom of *Naja m. mossambica, N. nigricollis* and *N. h. annulifera*. Systolic contractions, hemolysis, cytolysis and muscle depolarization are included among their effects. They are basic proteins with 60–63 amino acid residues. They have little affinity for the nicotinic acetylcholine receptor but act on cell membranes, causing persistent depolarization. Despite their different modes of pharmacological action, neurotoxins and cardiotoxins share a high degree of homology in their amino acid sequences.

Presynaptic Neurotoxins. These venom toxins inhibit nerve–muscle transmission by specifically blocking the release, synthesis, storage or turnover of the acetylcholine transmitter. They can be active at the neuromuscular junction, both in the autonomic and in the central nervous systems.

Phospholipases A_2. (PLA_2s). PLA_2s (EC 3.1.1.4, http://www.expasy.ch/cgibin/nicezyme.pl?3.1.1.4), hydrolyze the 2-acylester bond of 3-*sn*-phospholipids. These enzymes are involved in phospholipid digestion and metabolism, signal transduction, fertilization and inflammatory reactions. They are classified into two groups, secretory and cytosolic, according to their localization. Secretory PLA_2s have a mass of about 14 kDa and are further classified into groups I and II on the basis of their primary structure [Denis; and Fujii, et al.:]. They are abundant in snake venoms, and require Ca^{2+} for their enzymatic action. Apart from their catalytic function, snake venom PLA_2s often display additional toxic activities. Presynaptic and postsynaptic neurotoxicity, myotoxicity, hemorrhagic, hemolytic, oedema formation, hypotensive, cardiotoxic, platelet aggregation and convulsive activities have been reported. Not all these effects are exerted by all the enzymes. The presence on target cells of specific receptors and of toxic sites on the PLA_2 molecules is suggested.

Based on comparative analysis of sequences of presynaptic PLA_2 neurotoxins, it has been suggested that their toxicity is associated with a cluster of basic amino acid residues at positions 58–77 and 93–94, with closely located hydrophobic regions 1–7, 68–85 and 93–105 and with the amino acids at positions 6–8, 76–81 and 119–125. Myotoxicity, however, may depend on the existence of a Lys-rich region around residues 85–93 in neurotoxic and myotoxic PLA_2s.

PLA_2s bind to receptors such as the β-bungarotoxin and OS_2 (*O. scutellatus* PLA_2) receptors; a class of voltage-dependent K^+ channels, and block them. Snake venom PLA_2s are distributed into four groups: (1) PLA_2 from sea snakes and Australian elapids; (2) PLA_2 from African and Asian elapids; (3) PLA_2 from *Bungarus* spp.; and (4) PLA_2 from vipers and crotalids.

Crotoxin, present in *C. d. terrificus* snake venom, is a β-neurotoxin that blocks neuromuscular transmission. It consists of the noncovalent association of a basic and weakly toxic PLA_2 subunit with a nontoxic, nonenzymatic crotapotin subunit. Upon association of the two subunits, crotapotin enhances the toxic action of PLA_2.

Nonneurotoxic Toxins. Snake venoms contain a number of nonneurological acting components, particularly in venoms from crotalid and viperid snakes. Among these components are included factors responsible for hemorrhage, myonecrosis, coagulopathy, complement system activation and release of mediators of inflammation.

Hemorrhagins. Hemorrhagic toxins are 20–100-kDa glycoproteins, with one or more polypeptide subunits, capable of selectively hydrolyzing some substrates, their enzymatic activity being cation-dependent. They are present in several snake venoms, especially in crotalid and viperid venoms. Despite differences in molecular weight, they appear to constitute a related family of proteins, the metalloproteinases, arising from a single ancestral gene. They exhibit the ability proteolytically to degrade major components of the basal lamina and extracellular matrix, such as laminin, fibronectin and collagen type IV.

Myotoxins. Some PLA_2-dependent toxins also exhibit myotoxicity characterized by disruption of sarcomeres, disintegration of the myofibril into myofilaments, swelling and loss of the mitochondrial cristae. After these changes, flocculation and pyknosis of myonuclei and breakdown of skeletal muscle fibers into myofilaments occur. Myotoxic components have been described in several snake venoms belonging to the genera *Agkistrodon, Bitis, Bothrops, Calloselasma, Crotalus, Sistrurus, Naja* and *Vipera*.

Components Active on the Hemostatic System. The human hemostatic system is based on sets of interactions involving plasma proteins, platelets, endothelial cells and subendothelial structures. Components with procoagulant, anticoagulant, fibrinolytic, vessel wall interactive, platelet active and plasma protein inactivators have been detected, singly or in association, in venoms of over 100 different snake venoms, particularly from the pit viper and elapid families [Markland, ref.]. See also **Blood Coagulation**.

Releasers of Mediators of Inflammation. Some snake venoms contain components able to release mediators of inflammation. Venom of members of the genus *Naja* contains a fragment of snake complement C3 molecule named cobra venom factor (CVF). Once in contact with mammalian serum, it interacts with factor B. The resulting complex CVFB acquires a C3 convertase activity resistant to the inactivating action of the complement regulatory proteins, but capable of cleaving molecules of C3, thereby releasing C3a, a mediator of inflammation. Other venom components can also induce the production of proinflammatory mediators and cytokines [Cavinato, et al.; Tambourgi, et al.; and Dias da Silva, et al.:]. See also **Cytokines**.

Venomous Marine Animals. Marine animals may cause death and morbidity by introducing their venoms into tissues of their prey or victim. Venoms are injected by a puncturing or traumatizing apparatus, which may be teeth, spines, barbs or miniature "harpoons," such as nematocytes or sting cells.

Toxins from marine animals are grouped into two classes. The first class includes those inducing generally local effects, such as pain, oedema, necrosis, regional lymphadenitis, eventually accompanied by mild systemic reactions such as nausea and vomiting, but rarely by death. These toxins are usually proteins and are found mostly in Cnidaria, Mollusca and fish. The phylum Cnidaria includes the classes Scyphozoa (jellyfish), Hydrozoa (hydra) and Anthozoa (corals and sea anemones). Toxins from *Cnidaria* are found both in specialized toxin-producing cells, called *cnidocytes*, and in nonspecialized cells. Tentacles of all jellyfish contain millions of cnidocytes with tiny stings that are armed with specialized miniharpoon-like structures, nematocytes. When stimulated, they are ejected from cnidocytes at a median velocity of 2 m s^{-1}, and an acceleration constant of 40 000**g**, penetrating the integument of the prey or victim and injecting multiple small amounts of venom. The toxins are polypeptides or proteins exhibiting inflammatory, cytolytical, hemolytic and neurological properties. The sea anemone *Rhodactis howesi*, found in Australian seas, induces severe and generalized immobilization. Use for suicide purposes by Samoan islanders has been reported. See also **Coelenterata**; **Hydratuba (Jellyfish)**; **Medusa (or Hydromedusa)**; **Mollusca**; **Mollusks**; and **Scphozoa**.

The second class of toxins includes a large group of neurotoxins. Tetrodotoxin and saxitoxin have been identified in red seaweeds (*Jania rubens* and *Arthrocardia gardneri*), crabs (*Mithrax hispidus*), tunicates (*Phallusia nigra*) and *Pseudomonas* spp. and in some fishes. These toxins are also produced by some marine algae and bacteria (*Vibrio* spp.). Envenoming by these neurotoxins is classified into five groups: (1) paralytic shellfish poisoning, saxitoxin being the principal toxin involved–burning sensation on the lips, tongue, face, neck, arms and legs, sometimes culminating in fatal paralysis; (2) gut envenoming, characterized by diarrhea; (3) food envenoming, characterized by respiratory distress; (4) amnesic envenoming induced by ingestion of some venomous diatoms, which produce domoic acid which interacts with glutaminergic receptors, inducing mental disturbances such as loss of memory, unconsciousness and sometimes

death; and (5) ciguatera envenoming, caused by ciguatoxin, a neurotoxin produced by dinoflagellates and ingested and accumulated by some fish. It induces mild to moderate, but rarely severe neurotoxic effects. Two other potent tedroxins are presently known, the first okadaic acid, is a potent phosphatase inhibitor earlier isolated from the sponge *Halichondri okadai* and later from two species of dinophlagelates, *Prorocentrum lima* and *Dinophisis sp*. The second, batzellin A, was isolated from the sponge *Batzella*. See also **Diatom**; **Dinoflagellata**; and **Foodborne Diseases (Shellfish Poisoning)**.

VENTIFACT. A stone whose form has been modified by the sand-blasting effect of wind-carried sediments. See also **Dreikanter**.

VENTILATING FAN. See **Fan**.

VENTILATION. 1. In the equation for the time constant of a thermometer, a quantity equal to the product of wind speed and air density. The time constant varies inversely with ventilation. The concentration of an air pollutant is inversely proportional to the ventilation, the mass flux of "clean air" moving past the observer. Stagnation, a condition caused by the lack of ventilation, is historically associated with major air pollution episodes. It occurs due to the lack of horizontal wind speed and the lack of vertical wind speed, for example, caused by an inversion.

2. The exchange of properties with the surface layer such that property concentrations are brought closer to equilibrium values with the atmosphere. Such exchange may occur without water mass formation.

3. In weather-observing terminology, the process of causing "representative" air to be in contact with the sensing elements of observing instruments; especially applied to producing a flow of air past the bulb of a wet-bulb thermometer.

VENTRICLE (Brain). A cavity of the vertebrate brain. The first and second ventricles are in the cerebral hemispheres. The third is formed of the persisting median cavity of the first primitive brain vesicle. The fourth ventricle is the cavity of the third primary vesicle, and all other remnants of the original cavities become narrowed passages. The ventricular system contains cerebrospinal fluid. See also **Central and Peripheral Nervous Systems**.

VENTURI EFFECT. See **Winds and Air Movement**.

VENTURI FLOWMETER. See **Flow Measurement**.

VENUS. The second planet from the sun, traveling in an orbit between that of Mercury and the Earth. The mean distance of Venus from the sun is 108.21 million kilometers (67.24 million miles). Venus comes closer to the Earth than other neighboring planets. At inferior conjunction, when Venus lies between the Earth and the sun, it is about 40 million kilometers (25 million miles) distant. Because only a crescent of the planet is viewed from the Earth at inferior conjunction, the planet does not appear brighter than when the full disk is viewed at the time of superior conjunction, a distance of some 259 million kilometers (161 million miles), when the planet lies behind the sun. A full cycle of phases, as seen from the Earth, requires 584 days (the synodic period). Venus makes one complete revolution around the sun in 225 days. The axis of rotation of the planet is nearly perpendicular to the plane of its orbit. In past years, the period of rotation of the planet about its own axis has been variously estimated. One accepted value is 243.09 ± 0.18 earth days. Observations have indicated that Venus rotates in a retrograde sense with respect to the behavior of all other planets excepting Uranus. The diameter of the planet is estimated at 12,102.8 kilometers (7521 miles) at the equator. The orbit of Venus around the sun is nearly a perfect circle (eccentricity $= 0.0068$). Its orbital velocity is estimated at about 35 kilometers (21.8 miles) per second. The density is estimated at 5.431 grams per cubic centimeter. There are no known satellites.

Both Venus and Mercury revolve about the sun in orbits that lie inside the orbit of the Earth about the sun. Accordingly, when the planes of the planetary orbits coincide with the plane of the ecliptic, once during the synodic period of each planet, the object will pass between the Earth and the sun. Because of the small angular diameter of the planets relative to

that of the sun, at the time they pass between the Earth and the sun, they appear as small black spots moving across the brilliant disk of the sun. Such a phenomenon is known as a transit of Venus or a transit of Mercury. The first recorded observation of a transit of Venus was made by Horrocks in England in 1639. See also **Transit (Astronomy)**.

An early view of Venus from an earth-launched spacecraft is shown in Fig. 1. A chronology of missions to Venus, as of mid-1993, is given toward the end of this article and includes American and Russian ventures to the planet.

Fig. 1. Venus as viewed from a distance of 720,000 km (450,000 mi) when *Pioneer Venus* was approaching the planet in 1978. A whirlpool-like vortex in the polar clouds that provides a downward motion of the atmosphere was noted. The Venus spacecraft, scheduled to operate for 243 Earth-days (the time required by Venus to turn on its axis) performed so well that the life of the mission was extended. (*NASA Ames Research Center, Moffett Field, California*.)

Venus Unlike Earth

For many decades, scientists, including the very early astronomers, regarded Venus as a sister planet of Earth. There were many reasons for this comparison. Left unscrutinized, both planets appeared to have heavy vaporous atmospheres; the two planets have comparable masses and diameters, especially considering the large differences that exist between any two other planets in the solar system; and, in fact, its comparative nearness to Earth was a qualitative factor among some early scientists. By way of earthbound observatories, including spectroscopic observations, these similarities faded in recent years, but only since the late 1970s have they been discounted.

Prior to obtaining excellent images of Venus, there was an opinion among some experts that, although the two planets are quite different today, perhaps they did evolve via similar mechanisms. *Magellan* and *Galileo* findings refute this possibility. The active geologic period that Venus currently is experiencing has no parallel in the evolution of Earth.

This departure of prior entrenched opinions is giving Venusian exploration renewed vigor as the experts now attempt to explain why Earth and Venus did not develop as "twin" planets.

One supposition emanating out of the data thus far embraces the concept that a tremendous impact on Earth created the moon and removed much of its atmosphere, whereas Venus did not experience such an event, and thus the atmospheres of the two planets as we witness them today evolved differently. Another concept involves the lack of a hydrosphere (oceans) on Venus that prevents volatiles from recycling, inhibiting subduction and thus creating a more voluminous and thicker and heavier crust on Venus than on Earth. Observations suggest that the Venusian crust differs from Earth's because of the absence of volatiles and a significant energy source within the interior of the planet. This also matches magnetic measurements made thus far.

It has been proposed that the Venusian atmosphere, unlike Earth's, increases the planet's surface temperature (up to 730 K). Thus, Venus contrasts with Earth's oceans and its disequilibrium atmosphere.

These and other concepts are being reviewed, based upon the analysis of data from *Magellan* and *Galileo*. At a minimum, most researchers believe that it will require 5 additional years to develop cause-and-effect scenarios to match the data and to be acceptable to a majority of researchers who are pursuing the numerous aspects of Venusian evolution.

Surface Features of Venus. Sufficient information has not been analyzed thus far to explain the details of the various surface features, as shown in Figs. 2–10. One of the most publicized photos of Venus is shown in Fig. 11. This is a false-color perspective of the volcano *Sif Mons*. A radar altimetry map of a portion of the Venusian surface is shown in Fig. 12. Based upon data received from **Magellan**, scores of maps like this are in preparation.

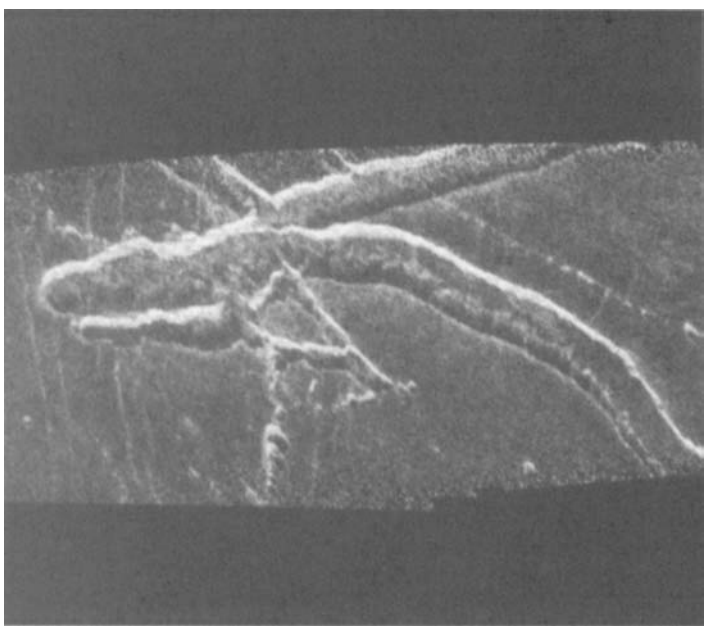

Fig. 2. Trough features on Venus, 28 km (17 mi) wide. Location: 60 S; 347 E. (*Jet Propulsion Laboratory*.)

Early Surface Theories. Because Venus is shrouded in clouds, observations of the planet's surface had to await the perfection of Earth-based radar techniques and, later, the probes which landed on the surface and orbiters equipped with radar and other instrumentation that would provide leads pertaining to the surface. The thick atmosphere also prevented traditional telescopes from determining the rate at which Venus rotates. Among the first radar observations of Venus were those made by the Lincoln Laboratory (Massachusetts Institute of Technology) in 1961. At that time, W.D. Smith and others sought evidence of frequency broadening in the returned radar echoes, assuming that if the planet were rotating, a differential Doppler shift would be noted in the signals reflected from different areas of the surface. Signals striking an approaching surface feature would be increased in frequency, whereas those signals striking a receding surface would be decreased in frequency. The net result is that the frequency spectrum of the echoes would be broadened. While information from the early experiments were fairly limited, Smith et al. did suggest (and was later proved to be correct) that Venus' orbital motion may be relatively slow and retrograde. These findings were soon confirmed by researchers

at the Jet Propulsion Laboratory (Pasadena, California) in 1962, at which time a period of rotation (retrograde) of 240 earth days was established for Venus.

In the middle and later 1960s, additional radar astronomy facilities studied Venus. These included the Arecibo installation in Puerto Rico, the deep-space tracking antenna at Goldstone, California, and the Haystack radar system in Massachusetts. With improvements in instrumental techniques, the accuracy of radar ranging was better than 1 kilometer (0.62 mile). As pointed out by Pettingill, Campbell, and Masursky (1980), it was eventually possible to observe variations in the radius of Venus as the reflecting region migrated around the equator of the planet. A correct value for radius is important in assessing other properties of the planet. For example, using measurement of refraction of the *Mariner 5* spacecraft's radio signal by the Venusian atmosphere, scientists calculated atmospheric pressure and temperature at the surface as a function of distance from the planet's center of mass.

Radar findings of the Venusian surface obtained by *Pioneer* Venus indicate that the planet is largely a lowland plain, which extends uninterrupted for thousands of kilometers, covering 95% of the surface mapped to date. Venus may be the flattest body in the inner solar system. The crusts of all other inner planets, including the earth's moon, exhibit considerable relief and owe this principally to the presence of two very different kinds of rock. The relatively dense basalt (see also **Basalt**) forms vast, low

plains, as found in the oceanic basins of the earth and the maria of the moon; and the less dense granite and anorthosite (see also **Anorthosite**; and **Granite**) form elevated continental regions. Scientists have found that less than 5% of the surface of Venus is elevated to the extent that it might be considered continental, whereas on earth over 30% of the surface is composed of continents (including the continental shelves). There are two small regions (about the size of Ohio) on Venus that are depressed over 1.5 kilometers (1 mile) below the mean radius altitude. It cannot readily be assumed that the vast lowlands of Venus are basalt, another surprise to researchers, because the Soviet *Venera 8* lander showed that radioactivity in the lowlands compared well with that of terrestrial granite. Another puzzling find is that the lowlands appear to contain craters — not the highlands. The craters appear to be shallow and thus would indicate a strong planetary crust. One hypothesis is that the very high temperatures at the planet's surface have weakened and possibly melted the crustal rock, a process that would decrease relief.

As reported by the *Pioneer* Venus orbiter mission team in 1979, the topographic results obtained by the orbiter radar operating in the altimetry mode indicated that the radar bright feature called Maxwell is a broad plateau with a rough surface 1000 kilometers (621 miles) by 700 kilometers (435 miles) in extent and rising some 6 kilometers (3.7 miles) above the surrounding plain. A ridge some 6 kilometers (3.7 miles) higher runs parallel to the northwest-southeast plateau margins. Actually, a series of ridges in this direction gives the feature a grainy pattern. A dark, circular spot has been observed and may be a crater partly filled with lava. The mountain ridges have proved thus far to be the highest features observed on the planet. See Fig. 12.

A smooth pear-shaped region west of Maxwell is a plateau 1000 kilometers (621 miles) across and elevated to 5 kilometers (3.1 miles) above the plains to its south and west. This feature appeared to be tectonic, whereas Maxwell may be either tectonic or of complex volcanic origin.

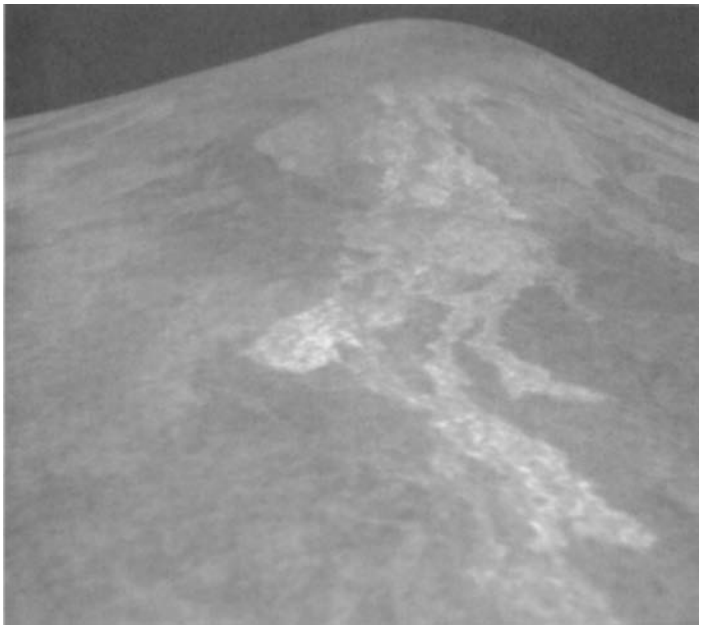

Fig. 11. False-color perspective of the volcano of *Sif Mons* on Venus. (*Jet Propulsion Laboratory*.)

The radar bright features known as Gauss and Hertz may be volcanic. The first data, obtained in the imaging mode at a longitude of about 340° in the Northern hemisphere, appeared to show impact craters about 250 kilometers (155 miles) in diameter with only about 600 meters (1969 feet). Scientists are somewhat puzzled by the ring-shaped features observed thus far on Venus. At this time, caution is followed in positively identifying some of these features as true impact craters. Some of the rims are not quite circular and the radial extent of small-scale roughness near them is greater than that of impact craters observed on other planetary bodies. Surface resolution is only about 10 kilometers (6.2 miles), so that detailed structure cannot be ascertained, and this, of course, is critical to the interpretation of the nature of a feature and an understanding of its origin and evolution.

Altimeter data gained thus far have revealed a significant difference between the topography of Venus and that of the Earth. Because Venus rotates so slowly, there is little if any bulge at the equator. Most radar mapping to date indicates that a high percentage of the surface of Venus lies within a range of one kilometer (3281 feet) of the mean surface altitude (equivalent to a radius of 6051.4 kilometers (3760.4 miles). Observers have indicated that Venus does have "continents" of a sort, that is, areas that rise over 2 kilometers (1.2 miles) above the mean surface altitude. At least two so-called continental areas have been found to date — the Lakshmi plateau to the west of aforementioned Maxwell and another (Aphrodite) just south of the equator between longitudes 70 and 140 degrees east.

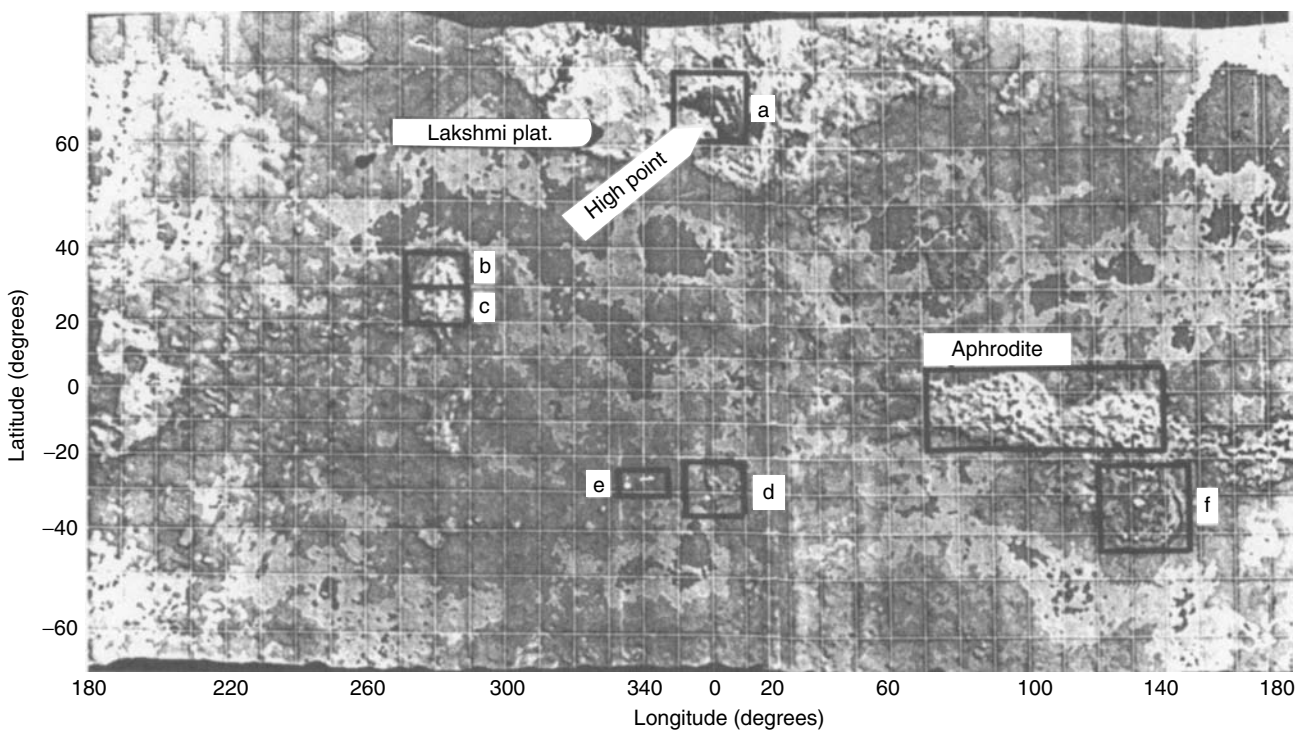

Fig. 12. Radar altimetry map of Venus from −65 °S to +70 °N latitude and covering 360 degrees of longitude. Purely black areas along upper and lower edges and the small black spot at about 60 °N and 260° are unmapped areas. Principal features of interest to scientists are (a) the Maxwell region (named after James Clerk Maxwell) and first noted by earth-based, low-resolution radar observations. This region contains the highest point on the Venusian surface (above surface calculated by using mean radius of planet). Arrow points to location of Montes Maxwell which rises some 10,670 meters (35,000 feet) above the lowland plain. Comparable in height to Mount Everest, the Venusian peak differs in that it appears to rise alone from the surrounding plains and plateaus. Large mountains on the earth usually are associated with somewhat greater gravitational pull than lowlands. Data taken thus far in this region indicate no such gravity anomaly for Montes Maxwell. (b) and (c) comprise the Beta region. Rhea Mons is located in area (b); Theia Mons in area (c). The Beta region (Regio Beta) is a highland with the two aforementioned shield volcanoes (so-named because they resemble low, expansive shields of rock). They rise along a fault zone from a plateau about 1600 kilometers (1000 miles) long. Extensive flat sheets typically formed by basalt flows (an example on earth is the Snake River Plateau in Idaho) surprisingly have not been detected in the Beta region. This has led to speculation that a water-poor Venusian flow may have been more viscous than other basalts and thus maintained their relief even at greater distances from the vent. (d) The Alpha region reveals a striking northeast-to-southwest grain similar to faulted basin ranges found in Nevada. Within this region, a feature called Eve has been observed. This bright central spot lies within a prominent ring-shaped feature that resembles many impact craters seen on the moon and Mercury. (e) Three craterlike features have been observed in the region to the left of (d). (f) In this region, a circular feature some 1800 kilometers (1116 miles) across has been observed and believed to be the remnant of a gigantic impact crater. The Lakshmi plateau (Planum Lakshmi) is a pear-shaped plateau that is larger and higher than any plateau on the earth. Some scientists suggest that it was uplifted with relatively little horizontal motion. A similar process was involved in the formation of the major plateaus of the earth. Some scientists suggest that it was uplifted with relatively little horizontal motion. A similar process was involved in the formation of the major plateaus of the earth. Another major feature and suggested "continental" area of Venus is known as Aphrodite. (*Based upon a computer colored map prepared by Eric Eliason, U.S. Geological Survey*.)

Burns (Arecibo Observatory) suggests that the surface of Venus exhibits close to the number of craters with a diameter larger than about 80 kilometers (496 miles) that cratering models predict should have been made within the past 600 million to one billion years. Because of the planet's dense atmosphere, the number of smaller craters (up to about 20 kilometers; 12.5 miles across) would be considerably less than in most other planetary bodies because such meteorites would have been consumed in the Venusian atmosphere. Unfortunately, limitations on radar techniques (either instrumental or distance from the planet) have made it impossible to confirm this prediction to date. As of the late 1980s, investigators are aggressively seeking answers to the question — What are the relative roles of three major processes that may have determined the Venusian land mass: meteorite impact, volcanism, and tectonism? Scientists are eagerly looking forward to the **Magellan** mission previously described.

Comments pertaining to past or active volcanism, the possible presence of lightning in the atmosphere, among other important and intriguing phenomena on Venus essentially remained ungelled at this juncture. Several of the references listed here, however, contain numerous hypotheses of interest.

Atmosphere of Venus — Early Theories

(1) *Missing Oxygen*. Some theorists have suggested that ancient Venus had an ocean, something like that of Earth. This has been part of the "sister" or "twin" planet concept which has persisted for decades. For this early chapter in a scenario, two fundamental questions require answers: (a) Where is the missing hydrogen? (b) Where is the missing oxygen from the H_2O that would have made up that ocean? The present water in the desiccated Venusian atmosphere has been detected to be only 0.0014% of a terrestrial ocean. Conditions at the Venusian surface appear to rule out any underground water. The mass spectrometer of Pioneer Venus detected in a cloud droplet of sulfuric acid a hydrogen sample whose isotopic ratio showed that at one time Venus had at least as much water as a few tenths of a percent of the Earth's present oceanic volume. Hydrogen from the missing water could easily have escaped to space. Thus, a disproportionate amount of deuterium would have remained. It has been suggested that perhaps the oxygen combined with dark, chemically reduced basalt on the surface, resulting in reddish, oxidized rock having the color of volcanic cinder cones found in Hawaiian volcanoes. Researchers at Brown University and the Russian Academy of Sciences made an intense study of color pictures of the Venus surface as returned by the *Venera 13* and *14* landers. The orange sunlight component had to be filtered out and corrections had to be made for discoloration of Veneras' camera coloration chips which had been seared by the 500 °C (932 °F) Venusian surface temperature. With all corrections made, the rocks were shown to be dark and nearly colorless. The researchers heated red, oxidized basalt to the same temperature and the sample appeared essentially the same as the reprocessed pictures from Venus. It was found, however, that oxidized basalt reflects more light than hot unoxidized basalt outside the visible range (wavelength of 1 micrometer). This led to the conclusion that the imaged Venusian rocks are indeed dark and *oxidized*. This yielded a clue to the effect that the missing oxygen is now part of the rock structure. Hunter of the University of Arizona estimated that the minimum amount of water required by the isotopic analysis could have formed an "ocean" 10 meters deep. Losing it would have required that oxygen combine with an amount of rock equivalent to a layer 40 meters thick that was then buried by volcanism. By comparison, a full terrestrial ocean would have required rock some 10 km thick in order to combine with the oxygen of a former ocean.

(2) *Missing Hydrogen*. McElroy, Prather, and Rodriguez (Harvard University) reported on the escape of hydrogen from Venus. The planet contains quantities of carbon and nitrogen similar to Earth, but hydrogen is deficient. The scenario: Recombination of O_2^+ represents a source of fast oxygen atoms in Venus' exosphere, and subsequent collisions of oxygen atoms with hydrogen atoms led to the escape of about 10^7 hydrogen atoms per square centimeter per second. The escape of deuterium atoms is considered negligible, with an expected increase of the ratio of deuterium to hydrogen over time. It is suggested that the mass-2 ion observed by *Pioneer Venus* is D^+, which implies a ratio of deuterium to hydrogen in the contemporary atmosphere of about 10^{-2}, an initial ratio of 5×10^{-5}, and an original H_2O abundance not less than 800 grams per square centimeter. The researchers derived a value for the primordial D/H ratio on Venus similar to ratios observed for Jupiter and Earth. The analysis implies an initial abundance for H_2O on Venus of 8×10^2 g cm^{-2}, or approximately 300 times less than the terrestrial value.

(3) *Atmospheric Composition*. Based upon data returned from *Venera 13* and *14*, it is estimated that carbon dioxide (CO_2) constitutes about 96% of the atmosphere and is 10 times more abundant than nitrogen (N_2) and about 10,000 times more abundant than sulfur dioxide (SO_2), which is present at a concentration of about 150 ppm. Venera data found higher levels of hydrogen sulfide (H_2S) and of carbonyl sulfide (OCS). The atmosphere also contains sulfuric acid cloud particles and traces of hydrochloric acid (10^{-1} ppm) and hydrofluoric acid (10^{-3} ppm). The presence of sulfur and acidic compounds poses the basic question — whence do they come?

(4) *Sulfur Compounds*. Prinn (Massachusetts Institute of Technology) reports (see 1985 reference) that sulfur is a minor atmospheric constituent on Venus. The gaseous progenitors of the clouds make up 0.02% and the cloud particles themselves constitute only 0.00002% of the atmosphere. Of importance, however, is that these sulfur-bearing clouds markedly affect the planet's climate. For example, they reflect nearly 80% of the total incident sunlight (notably at red and yellow wavelengths). Thus, even though Venus is closer to the sun than Earth, it receives much less solar energy. Two-thirds of that energy is retained in the Venusian clouds because the clouds are absorptive in the ultraviolet and near-infrared regions. Thus, about one-third of the incident solar energy reaches the Venusian surface. This is essentially opposite of the situation on Earth.

Prinn reports that the dominant constituent of the clouds is concentrated sulfuric acid, estimated at 75% by mass. The acid is in the form of liquid droplets. Polarization studies exclude other candidate substances and, in particular, they exclude water. Sulfur dioxide and water vapor present in the lower cloud region are believed to chemically react, forming sulfuric acid. The sulfuric acid component of Earth's atmosphere is easily explained, resulting from two main sources — fossil fuel burning and to a much lesser extent, volcanoes. The surface conditions of Venus (sometimes described as a sort of Hell) seem to favor volcanism as the source. There is, however, another view. Lewis (University of Arizona) has suggested that these gases are "cooked" out of surface rocks by intense heat. It is further suggested that the gases are added to the atmosphere at the same rate at which they are removed by reactions with the surface — thus no net flow of a compound into or out of the atmosphere. In essence, the sulfur gases, hydrogen chloride, and hydrogen fluoride in the atmosphere are in chemical equilibrium with minerals in the crust.

(5) *Outgassing Comparison — Venus and Earth*. Prinn observes that the Venusian atmosphere is 90 times as massive as that of Earth. The total amount of carbon dioxide and nitrogen on Venus is estimated to be about 30% less than that on Earth. The concentration of argon-40 is roughly one-third of the terrestrial value, while the abundance in the crust of the argon source (radioactive potassium 40) is about the same on both planets. This may indicate that comparable amounts of outgassing and thus comparable levels of volcanism may have occurred on the planets in the past. It should be emphasized, however, that the aforementioned gases are relatively stable and can survive in an atmosphere over geologic periods of time. Thus, they do not necessarily indicate outgassing on Venus in recent times. Evidence for recent volcanism on Venus lies in the clouds and in the sulfur gases that produce them.

Chronology of Missions to Venus

Interest in exploring Venus was manifested very early in the space programs of the United States, Russia, and other countries that have funded space ventures. Major missions to Venus have included:

Sputnik 7 (4, February 1961). This was the first Soviet attempt at a Venus probe. The probe was successfully launched into Earth orbit with a SL-6/A-2-e launcher. The launch payload consisted of an Earth orbiting launch platform (Tyazheliy Sputnik 4) and the Venera probe. The fourth stage (a Zond rocket) was supposed to launch the Venera probe towards a landing on Venus after one Earth orbit but ignition failed, probably due to a faulty timer, and the spacecraft remained in Earth orbit. Because of its large size 14,300 pounds (6,483 kilograms), the mission was originally thought by non-Soviet observers to be a failed manned mission, and later was described as a test of an Earth orbiting platform from which an interplanetary probe could be launched.

Venera 1 (12, February 1961). Venera 1 was the first spacecraft to fly by Venus. The probe consisted of a cylindrical body topped by a dome, totaling 2 meters in height. Two solar panels extended radially from the cylinder. A large (over 6.5 feet (2 meter diameter) high-gain net antenna was used to receive signals from the ground. This antenna was attached to the cylinder. A long antenna arm was used to transmit signals to Earth. The probe was equipped with scientific instruments including a magnetometer attached to the end of a 2 meter (6.5 feet) boom, ion traps, micrometeorite detectors, and cosmic radiation counters. The dome contained a pressurized sphere which carried a Soviet pennant and was designed to float on the putative Venus oceans after the intended Venus impact. Venera 1 had no on-board propulsion systems. Temperature control was achieved with thermal shutters.

Venera 1 was launched along with an Earth orbiting launch platform (Tyazheliy Sputnik 5 (61-003C)) with a SL-6/A-2-e launcher. From a 229×282 km orbit, the Venera 1 automatic interplanetary station was launched from the platform towards Venus with the fourth stage Zond rocket. On 19 February, 7 days after launch at a distance of about two million km from Earth, contact with the spacecraft was lost. On May 19 and 20, 1961, *Venera 1* passed within 100,000 km of Venus and entered a heliocentric orbit.

Mariner 1 (22, July 1962). This was to be the first Mariner mission. It was intended to perform a Venus flyby. The vehicle was destroyed by the Range Safety Officer 293 seconds after launch at 09:26:16 UT when it veered off course. The booster had performed satisfactorily until an unscheduled yaw-lift (northeast) maneuver was detected by the range safety officer. Faulty application of the guidance commands made steering impossible and were directing the spacecraft towards a crash, possibly in the North Atlantic shipping lanes or in an inhabited area. The destruct command was sent 6 seconds before separation, after which the launch vehicle could not have been destroyed. The radio transponder continued to transmit signals for 64 seconds after the destruct command had been sent.

Sputnik 19 (25, August 1962). Sputnik 19 was a Venera-type spacecraft intended to make a landing on Venus. The SL-6/A-2-e launcher put the spacecraft into Earth orbit, but the escape stage failed and the probe remained in geocentric orbit for three days until the orbit decayed on 28 August and it re-entered Earth's atmosphere.

This spacecraft was originally designated Sputnik 23 in the U.S. Naval Space Command Satellite Situation Summary.

Mariner 2. (27, August 1962). The Mariner 2 spacecraft was the second of a series of spacecraft used for planetary exploration in the flyby, or nonlanding, mode and the first spacecraft to successfully encounter another planet. *Mariner 2* was a backup for the Mariner 1 mission, which failed shortly after launch to Venus. The objective of the Mariner 2 mission was to fly by Venus and return data on the planet's atmosphere, magnetic field, charged particle environment, and mass. It also made measurements of the interplanetary medium during its cruise to Venus and after the flyby.

After launch and termination of the Agena first burn, the Agena-Mariner was in a 118 km altitude Earth parking orbit. The Agena second burn some 980 seconds later followed by Agena-Mariner separation injected the *Mariner 2* spacecraft into a geocentric escape hyperbola at 26 minutes 3 seconds after lift-off. Solar panel extension was completed about 44 minutes after launch. On 29 August 1962 cruise science experiments were turned on. The midcourse maneuver was initiated at 22:49:00 UT on 4 September and completed at 2:45:25 UT 5 September. On 8 September at 17:50 UT the spacecraft suddenly lost its attitude control, which was restored by the gyroscopes 3 minutes later. The cause was unknown but may have been a collision with a small object. On October 31 the output from one solar panel deteriorated abruptly, and the science cruise instruments were turned off. A week later the panel resumed normal function and instruments were turned back on. The panel permanently failed on 15 November, but *Mariner 2* was close enough to the Sun that one panel could supply adequate power. On December 14 the radiometers were turned on. *Mariner 2* approached Venus from 30 degrees above the dark side of the planet, and passed below the planet at its closest distance of 34,773 km at 19:59:28 UT 14 December 1962. After encounter, cruise mode resumed. Spacecraft perihelion occurred on 27 December at a distance of 105,464,560 km. The last transmission from *Mariner 2* was received on 3 January 1963 at 07:00 UT. Mariner 2 remains in heliocentric orbit.

Scientific discoveries made by *Mariner 2*; included a slow retrograde rotation rate for Venus; hot surface temperatures and high surface pressures; a predominantly carbon dioxide atmosphere; continuous cloud cover with a top altitude of about 60 km; and no detectable magnetic field. It was also shown that in interplanetary space the solar wind streams continuously and the cosmic dust density is much lower than the near-Earth region. Improved estimates of Venus' mass and the value of the astronomical unit were made.

Total research, development, launch, and support costs for the Mariner series of spacecraft (Mariners 1 through 10) was approximately $554 million.

Sputnik 20 (1, September 1962). Sputnik 20 (1962 Alpha Tau 1) was intended to be a Venus landing mission. The Venera-type spacecraft was successfully inserted into geocentric orbit by the SL-6/A-2-e launcher. The escape stage failed and the spacecraft was stranded in Earth orbit until it re-entered the Earth's atmosphere 5 days later.

This spacecraft was originally designated Sputnik 24 in the U.S. Naval SpaceCommand Satellite Situation Summary.

Sputnik 21 (12, September 1962). Sputnik 21 was an attempted Venus flyby mission. The SL-6/A-2-e launcher put the craft into Earth orbit, but the third stage exploded, destroying the spacecraft.

This spacecraft was originally designated Sputnik 25 in the U.S. Naval Space Command Satellite Situation Summary.

Cosmos 21 (11, November 1963). This mission has been tentatively identified as a technology test of the Venera series space probes. It may have been an attempted Venus flyby, presumably similar to the later Cosmos 27 mission, or it may have been intended from the beginning to remain in geocentric orbit. In any case, the spacecraft never left Earth orbit after insertion by the SL-6/A-2-e launcher. The orbit decayed on 14 November, three days after launch.

Beginning in 1963, the name Cosmos was given to Soviet spacecraft which remained in Earth orbit, regardless of whether that was their intended final destination. The designation of this mission as an intended planetary probe is based on evidence from Soviet and non-Soviet sources and historical documents. Typically Soviet planetary missions were initially put into an Earth parking orbit as a launch platform with a rocket engine and attached probe. The probes were then launched toward their targets with an engine burn with a duration of roughly 4 minutes. If the engine misfired or the burn was not completed, the probes would be left in Earth orbit and given a Cosmos designation.

Venera 1964A (19, February 1964). Attempted Venus Flyby (Launch Failure).

Venera 1964B (1, March 1964). Attempted Venus Flyby (Launch Failure).

Cosmos 27 (27, March 1964). This mission was intended as a Venus flyby. The SL-6/A-2-e launcher successfully achieved Earth orbit, but the spacecraft failed to escape orbit for its flight to Venus, and was designated Cosmos 27.

Zond 1 (2, April 1964). Zond 1 was launched from an earth orbiting platform Tyazheliy Sputnik (64-016A) towards Venus. It flew by Venus on July 14, 1964, at a distance of 100,000 km and entered a heliocentric orbit. The announced mission objectives were space research and testing of onboard systems and units. Communications from the spacecraft failed soon after May 14, 1964.

Venera 2 (12, November 1965). Venera 2 was launched from a Tyazheliy Sputnik (65-091B) towards the planet Venus and carried a TV system and scientific instruments. On February 27, 1966, the spacecraft passed Venus at a distance of 24,000 km and entered a heliocentric orbit. The spacecraft system had ceased to operate before the planet was reached and returned no data.

Venera 3 (16, November 1965). Venera 3 was launched from a Tyazheliy Sputnik (65-092B) towards the planet Venus. The mission of this spacecraft was to land on the Venusian surface. The entry body contained a radio communication system, scientific instruments, electrical power sources,

and medallions bearing the coat of arms of the U.S.S.R. The station impacted Venus on March 1, 1966. However, the communications systems had failed before planetary data could be returned.

Cosmos 96 (23, November 1965). This mission was intended as a Venus lander, presumably similar in design to the *Venera 3*, which had launched a week earlier. The spacecraft attained Earth orbit and the main rocket body (65-094B) separated from the orbiting launch platform. It is believed an explosion (perhaps during ignition for insertion of the spacecraft into a Venus transfer orbit) damaged the platform, resulting in at least six additional fragments (designated 65-094 C−H). The damaged spacecraft remained in orbit for 16 days and reentered the Earth's atmosphere on 9 December 1965.

Venera 1965A (23, November 1965). *Venera 1965A* was an attempted Venus flyby mission, possibly similar to the Venera 2 flyby mission launched two weeks earlier. It is believed the SL-6/A-2-e launcher failed.

Venera 4 (12, June 1967). *Venera 4* was launched from a Tyazheliy Sputnik (67-058B) towards the planet Venus with the announced mission of direct atmospheric studies. Part of a series of exploratory programs of Venus mounted by Russia, this spacecraft arrived at Venus within just a few hours of *Mariner 5's* rendezvous with the planet. *Venera 4* carried an instrument package designed to land on the planet's surface after a descent by parachute. Within about 75 minutes, after registering a temperature well above 260 °C (500 °F), data transmission ceased. Scientists later estimated that when transmission ceased the package was at an altitude some 30 km (20 mi) above the Venusian surface.

Mariner 5. On 14, June 1967 the Mariner 5 spacecraft was launched. *Mariner 5* was the fifth in a series of spacecraft used for planetary exploration in the flyby mode. Mariner 5 was a refurbished backup spacecraft for the Mariner 4 mission and was converted from a Mars mission to a Venus mission. The spacecraft was fully attitude stabilized, using the sun and Canopus as references. A central computer and sequencer subsystem supplied timing sequences and computing services for other spacecraft subsystems. The spacecraft passed 4,000 km from Venus on October 19, 1967. The spacecraft instruments measured both interplanetary and Venusian magnetic fields, charged particles, and plasmas, as well as the radio refractivity and UV emissions of the Venusian atmosphere.

Marner 5 traveled around the dark side of Venus at a distance of about 9655 km (6000 mi). Again, data confirmed that no significant magnetic field existed. Radio signals, passed through the Venusian atmosphere (once from the day side; once from the night side of the planet) evidenced a very heavy concentration of carbon dioxide (CO_2) in the atmosphere. The atmosphere was estimated to exert a pressure at the planet's surface of about 100 times the normal sea level pressure (1 atm) on Earth. The mission was termed a success.

Cosmos 167 (17, June 1967). This mission was intended to be a Venus lander, similar in design to the *Venera 4* spacecraft launched 5 days earlier on 12 June. The spacecraft became stranded in Earth orbit and was designated *Cosmos 167*. Its orbit decayed and it re-entered Earth's atmosphere 8 days after launch.

Venera 5 (5, January 1969). Venera 5 was launched from a Tyazheliy Sputnik (69-001C) towards Venus to obtain atmospheric data. The spacecraft was very similar to Venera 4 although it was of a stronger design. When the atmosphere of Venus was approached, a capsule weighing 405 kg and containing scientific instruments was jettisoned from the main spacecraft. During satellite descent towards the surface of Venus, a parachute opened to slow the rate of descent. For 53 min on May 16, 1969, while the capsule was suspended from the parachute, data from the Venusian atmosphere were returned. The spacecraft also carried a medallion bearing the coat of arms of the U.S.S.R. and a bas-relief of V.I. Lenin to the night side of Venus.

Venera 6 (10, January 1969). Venera 6 was launched from a Tyazheliy Sputnik (69-002C) towards Venus to obtain atmospheric data. The spacecraft was very similar to Venera 4 although it was of a stronger design. When the atmosphere of Venus was approached, a capsule weighing 405 kg was jettisoned from the main spacecraft. This capsule contained scientific instruments. During descent towards the surface of Venus, a parachute opened to slow the rate of descent. For 51 min on May 17, 1969, while the capsule was suspended from the parachute, data from the Venusian atmosphere were returned.

Venera 7 (17, August 1970). Venera 7 was launched from a Tyazheliy Sputnik in an earth parking orbit towards Venus to study the Venusian atmosphere and other phenomena of the planet. Venera 7 entered the atmosphere of Venus on December 15, 1970, and a landing capsule was jettisoned. After aerodynamic braking, a parachute system was deployed. The capsule antenna was extended, and signals were returned for 35 min. Another 23 min of very weak signals were received after the spacecraft landed on Venus. The capsule was the first man-made object to return data after landing on another planet.

Cosmos 359 (22, August 1970). This mission was an attempted Venus flight, perhaps a lander similar to the Venera 7 mission launched 5 days earlier on 17 August. The SL-6/A-2-e launcher successfully brought the spacecraft to Earth orbit and the spacecraft payload was separated from the Tyazheliy Sputnik, but the escape stage failed during firing, putting the payload into a slightly more elliptical geocentric orbit. The mission was designated Cosmos 359.

Venera 8 (27, March 1972). Venera 8 was a Venus atmospheric probe. Its instrumentation included temperature, pressure, and light sensors as well as radio transmitters. The spacecraft took 117 days to reach Venus, entering the atmosphere on 22 July 1972. Descent speed was reduced from 41,696 km/hr to about 900 km/hr by aerobraking. The 2.5 meter diameter parachute opened at an altitude of 60 km, and a refrigeration system was used to cool the interior components. Venera 8 transmitted data during the descent and continued to send back data for 50 minutes after landing. The probe confirmed the earlier data on the high Venus surface temperature and pressure returned by Venera 7, and also measured the light level as being suitable for surface photography, finding it to be similar to the amount of light on Earth on an overcast day.

Cosmos 482 (31, March 1972). This mission has been identified as an attempted Venus probe which failed to escape low Earth orbit. It was launched by an SL-6/A-2-e launcher 4 days after the *Venera 8* atmospheric probe and may have been similar in design and mission plan. After achieving an Earth parking orbit, the spacecraft made an apparent attempt to launch into a Venus transfer trajectory. It separated into four pieces, two of which remained in low Earth orbit and decayed within 48 hours, and two pieces (presumably the payload and detached engine unit) went into a higher 210 × 9800 km orbit. It is thought that a malfunction resulted in an engine burn which did not achieve sufficient velocity for the Venus transfer and left the payload in this elliptical Earth orbit.

Mariner 10 (4, November 1973). Mariner 10 was the seventh successful launch in the Mariner series and the first spacecraft to use the gravitational pull of one planet (Venus) to reach another (Mercury). The spacecraft flew by Mercury three times in a heliocentric orbit and returned images and data on the planet. Mariner 10 is the only spacecraft to have visited Mercury.

The spacecraft structure was an eight-sided framework with eight electronics compartments. It measured 1.39 m diagonally and 0.457 m in depth. Two solar panels, each 2.7 m long and 0.97 m wide, were attached at the top, supporting 5.1 sq m of solar cell area. The rocket engine was liquid-fueled, with two sets of reaction jets used to stabilize the spacecraft on three axes. It carried a low-gain omnidirectional antenna, composed of a honeycomb-disk parabolic reflector, 1.37 m in diameter, with focal length 55 cm. Feeds enabled the spacecraft to transmit at S-and X-band frequencies. The spacecraft carried a Canopus star tracker, located on the upper ring structure of the octagonal satellite, and acquisition sun sensors on the tips of the solar panels. The interior of the spacecraft was insulated with multilayer thermal blankets at top and bottom. A sunshade was deployed after launch to protect the spacecraft on the solar-oriented side.

Instruments on-board the spacecraft measured the atmospheric, surface, and physical characteristics of Mercury and Venus. Experiments included television photography, magnetic field, plasma, infrared radiometry, ultraviolet spectroscopy, and radio science detectors. An experimental X-band, high-frequency transmitter was flown for the first time on this spacecraft.

Mariner 10 was placed in a parking orbit after launch for approximately 25 minutes, then placed in orbit around the Sun en route to Venus. The orbit

direction was opposite to the motion of the Earth around the Sun. Midcourse corrections were made. The spacecraft passed Venus on February 5, 1974, at a distance of 4200 km. It crossed the orbit of Mercury on March 29, 1974, at 2046 UT, at a distance of about 704 km from the surface. The TV and UV experiments were turned on the comet Kohoutek while the spacecraft was on the way to Venus. A second encounter with Mercury, when more photographs were taken, occurred on September 21, 1974, at an altitude of about 47,000 km. A third and last Mercury encounter at an altitude of 327 km, with additional photography of about 300 photographs and magnetic field measurements occurred on March 16, 1975. Engineering tests were continued until March 24, 1975, when the supply of attitude-control gas was depleted and the mission was terminated.

Venera 9 (8, June 1975). On October 20, 1975, this spacecraft was separated from the Orbiter, and landing was made with the sun near zenith at 0513 UT on October 22. A system of circulating fluid was used to distribute the heat load. This system, plus precooling prior to entry, permitted operation of the spacecraft for 53 min after landing. During descent, heat dissipation and deceleration were accomplished sequentially by protective hemispheric shells, three parachutes, a disk-shaped drag brake, and a compressible, metal, doughnut-shaped, landing cushion. The landing was about 2,200 km from the *Venera 10* landing site. Preliminary results indicated: (A) clouds 30–40 km thick with bases at 30–35 km altitude, (B) atmospheric constituents including HCl, HF, Br, and I, (C) surface pressure about 90 (earth) atmospheres, (D) surface temperature 485 deg C, (E) light levels comparable to those at earth midlatitudes on a cloudy summer day, and (F) successful TV photography showing shadows, no apparent dust in the air, and a variety of 30–40 cm rocks which were not eroded.

Venera 10 (14 June 1975). On October 23, 1975, this spacecraft was separated from the Orbiter, and landing was made with the sun near zenith, at 0517 UT, on October 25. A system of circulating fluid was used to distribute the heat load. This system, plus precooling prior to entry, permitted operation of the spacecraft for 65 min after landing. During descent, heat dissipation and deceleration were accomplished sequentially by protective hemispheric shells, three parachutes, a disk-shaped drag brake, and a compressible, metal, doughnut-shaped, landing cushion. The landing was about 2,200 km distant from *Venera 9*. Preliminary results provided: (A) profile of altitude (km)/pressure (earth atmospheres)/temperature (deg C) of 42/3.3/158, 15/37/363, and 0/92/465, (B) successful TV photography showing large pancake rocks with lava or other weathered rocks in between, and (C) surface wind speed of 3.5 m/s.

Pioneer Venus. This was a major mission and arrived at Venus in December 1978. This was the first United States mission directed specifically at investigating the atmosphere of Venus on a planetary scale and radar mapping the planet's surface features. This was a two-spacecraft mission, consisting of an orbiter and a multiprobe spacecraft. The orbiter was launched (20, May 1978) and scheduled to arrive at Venus 5 days prior to the probe-carrying spacecraft. To effect this timing, the orbiter was launched on a trajectory that took it more than 180 degrees around the solar system in 8 months. The probes, launched at a later date (8, August 1978) and followed a direct-path trajectory from Earth to Venus, requiring just the right time span for the planned rendezvous. Data from *Pioneer Venus* was studied intensely and, in fact, continues today as a major part of the database used in studying, hypothecating, and building models of the physical and chemical features of the planet.

The probes confirmed the expected high surface temperature and the presence of high winds (320 km; 200 mph), these possibly accounting for the transfer of heat into the night side in spite of the planet's low rotational speed. Atmosphere and cloud chemistry were examined in detail. The probes detected four layers of clouds and more light on the surface than might be expected solely from sunlight. (This light enabled a later *Venera* mission to obtain images of rocks on the surface.) Investigators, using *Pioneer Venus* data, tentatively concluded that sulfur plays a major role and that sulfur could be responsible for the light glow at the surface. The *Pioneer* orbiter confirmed the Venusian cloud patterns and circulation previously noted by *Mariner 10*. A large variability in the ionosphere was noted.

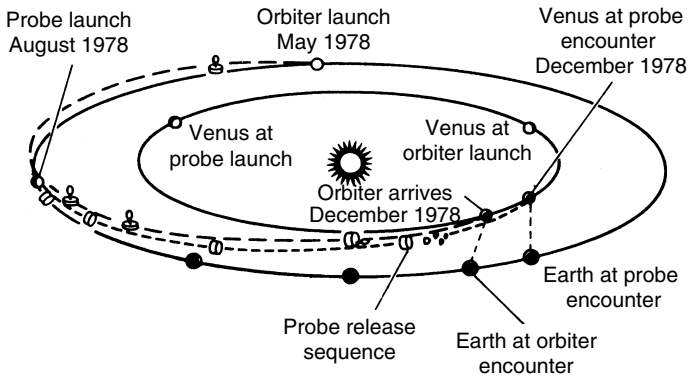

Fig. 13. Orbits of *Pioneer Venus* orbiter and probe bus. The program consisted of two scientifically related experiments and two spacecraft, an *orbiter* and a *multiprobe*. The orbiter was launched on May 20, 1978 and was inserted into a highly eccentric, near-polar orbit around Venus on December 4, 1978 after an interplanetary journey of 198 days. The multiprobe was launched on August 8, 1978 and reached Venus on December 9, 1978, just 5 days after orbital insertion. The orbiter trajectory and multiprobe impact locations matched nearly perfectly the conditions specified prior to launch. (*NASA Ames Research Center, Moffett Field, California*.)

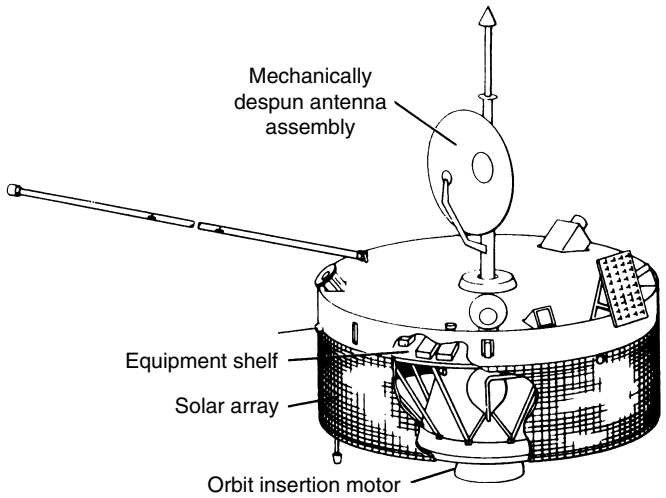

Fig. 14. *Pioneer Venus orbiter*. The orbiter was spin-stabilized in the range of 4.90 to 4.99 revolutions/minute in orbit, and the positive-spin-axis pointed in the direction of the planet's south ecliptic pole. Parameters of the orbiter included: Periapsis altitude, 150 to 260 km; apoapsis altitude, 66,900 km; eccentricity, 0.843; average period, 24.03 hours; inclination to equator, 105.6°; latitude of periapsis, 17°; longitude of periapsis, 170.2°; and original primary mission duration of 243 days. Despite its initial relatively short design life, as of 1987, the 8-year-old orbiter was still providing scientists with information about Venus and, in fact, in 1986, the orbiter was diverted from Venus to look at Halley's comet, the only United States spacecraft to observe the comet. (*NASA Ames Research Center, Moffett Field, California*.)

Details of the mechanics of the *Pioneer Venus* mission are given in Figs. 13, 14, 15, 16, and 17.

The *Pioneer Venus Orbiter* carried 17 experiments (with a total mass of 45 kg (99.2 pounds):

- A cloud photopolarimeter to measure the vertical distribution of the clouds.
- A surface radar mapper to determine topography and surface characteristics.
- An infrared radiometer to measure IR emissions from the Venus atmosphere.

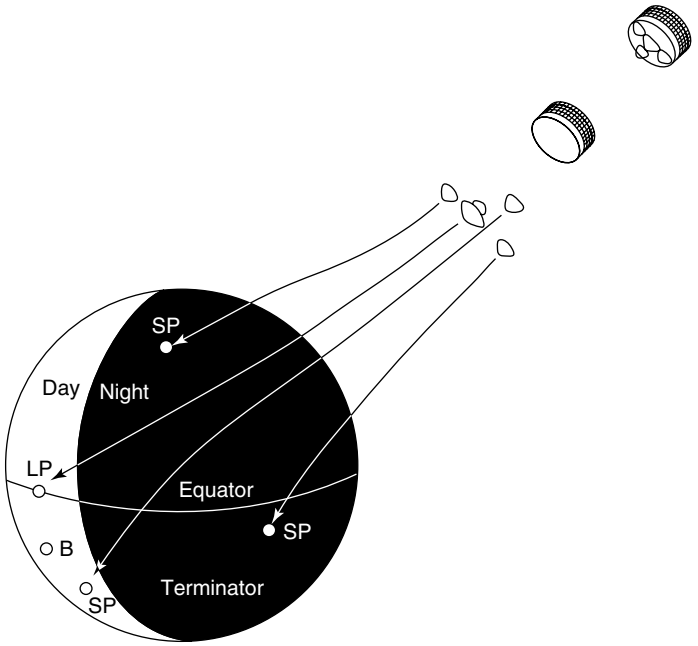

Fig. 15. Approximate entry points for *Pioneer Venus* atmosphere probes. The multiprobe during interplanetary cruise consisted of a bus transporting a large probe and three small probes, named north, day, and night. The spin-stabilized bus was oriented, and the large probe was released toward its planned Venus entry location on November 16, 1978. About 41/2 days later (November 20, 1978), the three small probes were released toward their planned entry locations. All probes were then silent before entry on December 9, when they were activated by pretimed internal sequencers. (*NASA Ames Research Center, Moffett Field, California*.)

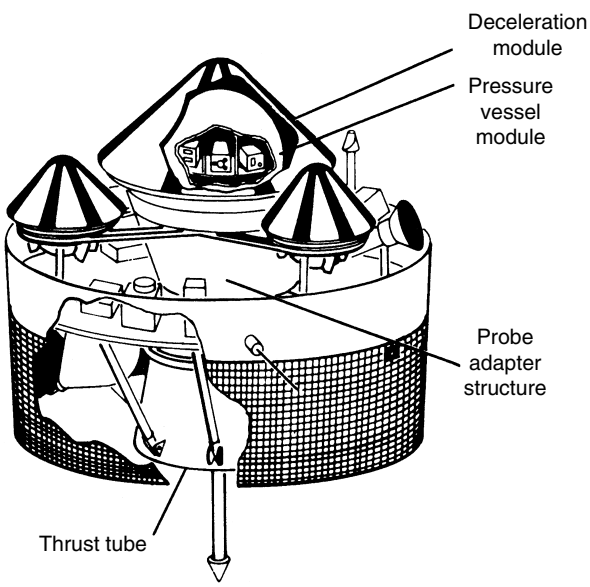

Fig. 16. *Pioneer Venus* multiprobe spacecraft. (*NASA Ames Research Center, Moffett Field, California*.)

- An airglow ultraviolet spectrometer to measure scattered and emitted UV light.
- A neutral mass spectrometer to determine the composition of the upper atmosphere.
- A solar wind plasma analyzer to measure properties of the solar wind.
- A magnetometer to characterize the magnetic field at Venus.
- An electric field detector to study the solar wind and its interactions.

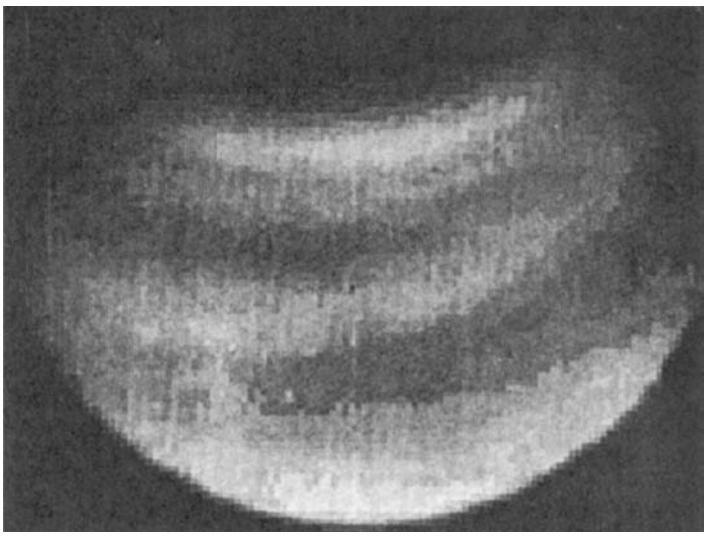

Fig. 17. Computer enhanced ultraviolet image of Venus made by *Pioneer Venus* orbiter on January 31, 1979. Probe instruments detected several hundred times more primordial argon and neon gases than on the Earth. The probes also detected an unexpected glow, perhaps caused by reactions of sulfur compounds in extreme heat near the surface. One of the mission probes survived for more than 67 minutes before succumbing to the searing environment. The Venusian atmosphere and surface databases were subsequently augmented and modified as the result of additional information obtained by the *Venera 13* and *14* missions. (*NASA Ames Research Center, Moffett Field, California*.)

- An electron temperature probe to study the thermal properties of the ionosphere.
- An ion mass spectrometer to characterize the ionospheric ion population.
- A charged particle retarding potential analyzer to study ionospheric particles.
- Two radio science experiments to determine the gravity field of Venus.
- A radio occultation experiment to characterize the atmosphere.
- An atmospheric drag experiment to study the upper atmosphere.
- A radio science atmospheric and solar wind turbulence experiment and
- A gamma ray burst detector to record gamma ray burst events.

The *Pioneer Venus Multiprobe* consisted of a bus which carried one large and three small atmospheric probes. The large probe was released on November 16, 1978 and the three small probes on November 20. All four probes entered the Venus atmosphere on December 9, followed by the bus.

The Pioneer Venus large probe was equipped with 7 science experiments, contained within a sealed spherical pressure vessel. This pressure vessel was encased in a nose cone and aft protective cover. After deceleration from initial atmospheric entry at about 11.5 km/s (37,700 feet/s) near the equator on the Venus night side, a parachute was deployed at 47 km (29.2 miles) altitude. The large probe was about 1.5 m (4.92 feet) in diameter and the pressure vessel itself was 73.2 cm (2.4 feet) in diameter. The science experiments were:

- A neutral mass spectrometer to measure the atmospheric composition.
- A gas chromatograph to measure the atmospheric composition.
- A solar flux radiometer to measure solar flux penetration in the atmosphere.
- An infrared radiometer to measure distribution of infrared radiation.
- A cloud particle size spectrometer to measure particle size and shape.
- A nephelometer to search for cloud particles.
- Temperature, pressure, and acceleration sensors.

The three small probes were identical to each other, 0.8 m (2.62 feet) in diameter. These probes also consisted of spherical pressure vessels surrounded by an aeroshell, but unlike the large probe, they had no

parachutes and the aeroshells did not separate from the probe. Each small probe carried a nephelometer and temperature, pressure, and acceleration sensors, as well as a net flux radiometer experiment to map the distribution of sources and sinks of radiative energy in the atmosphere. The radio signals from all four probes were also used to characterize the winds, turbulence, and propagation in the atmosphere. The small probes were each targeted at different parts of the planet and were named accordingly. The North probe entered the atmosphere at about 60 degrees north latitude on the day side. The night probe entered on the night side. The day probe entered well into the day side, and was the only one of the four probes which continued to send radio signals back after impact, for over an hour.

The *Pioneer Venus* bus also carried two experiments, a neutral mass spectrometer and an ion mass spectrometer to study the composition of the atmosphere. With no heat shield or parachute, the bus survived and made measurements only to about 110 km altitude before burning up. The bus was a 2.5 m (8.2 feet) diameter cylinder weighing 290 kg (639 pounds), and afforded us our only direct view of the upper Venus atmosphere, as the probes did not begin making direct measurements until they had decelerated lower in the atmosphere.

Venera 11 (9, September 1978). Venera 11 was part of a two-spacecraft mission to study Venus and the interplanetary medium. Each of the two spacecraft,

Venera 11 and *Venera 12*, consisted of a flight platform and a lander probe. Identical instruments were carried on both spacecraft. The flight platform had instruments to study solar-wind composition, gamma-ray bursts, ultraviolet radiation, and the electron density of the ionosphere of Venus. The lander probe carried instruments to study the characteristics and composition of the atmosphere of Venus.

The *Venera 11* descent craft carried instruments designed to study the detailed chemical composition of the atmosphere, the nature of the clouds, and the thermal balance of the atmosphere. Separating from its flight platform on December 23, 1978 it entered the Venus atmosphere two days later at 11.2 km/sec. During the descent, it employed aerodynamic braking followed by parachute braking and ending with atmospheric braking. It made a soft landing on the surface at 06:24 Moscow time on 25 December after a descent time of approximately 1 hour. The touchdown speed was 7–8 m/s. Information was transmitted to the flight platform for retransmittal to earth until it moved out of range 95 minutes after touchdown. It is unknown whether the Lander Probe carried an imaging system. No mention of it occurs in the Soviet literature examined by the author. Two other experiments on the Lander did fail, and their failure was acknowledged by the Soviets. Some U.S. literature on the subject notes that the imaging system "failed" but did return some data. Among the instruments on board was a gas chromatograph to measure the composition of the Venus atmosphere, instruments to study scattered solar radiation and soil composition, and a device named Groza which was designed to measure atmospheric electrical discharges. Results reported included evidence of lightning and thunder, a high Ar_{36}/Ar_{40} ratio, and the discovery of carbon monoxide at low altitudes.

Venera 12 (14, September 1978). The Venera 12 descent craft carried instruments designed to study the detailed chemical composition of the atmosphere, the nature of the clouds, and the thermal balance of the atmosphere. Separating from its flight platform on December 19, 1978, it entered the Venus atmosphere two days later at 11.2 km/sec. During the descent, it employed aerodynamic braking followed by parachute braking and ending with atmospheric braking. It made a soft landing on the surface at 06:30 Moscow time on 21 December after a descent time of approximately 1 hour. The touchdown speed was 7–8 m/s. Information was transmitted to the flight platform for retransmittal to earth, until it moved out of range 110 minutes after touchdown. It is unknown whether the Lander Probe carried an imaging system. No mention of it occurs in the Soviet literature examined by the author. Two other experiments on the Lander did fail, and their failure was acknowledged by the Soviets. Some U.S. literature on the subject notes that the imaging system "failed" but did return some data.

Venera 13 and 14. *Venera 13* was launched on 30, October 1981, and *Venera 14* was launched on 4, November, 1981. In March 1982, these Russian spacecraft explored the surface of Venus. The spacecraft landed on the surface, sampled the rock, and determined its chemical composition. Each spacecraft carried a miniature drilling rig for taking samples. These were conveyed through an air lock to a measuring cell. There each sample was bathed in radioactivity emitted by plutonium-238 and iron-55. The plutonium isotope elicited the emission of x-rays at characteristic frequencies from magnesium, aluminum, and silicon atoms; the iron isotope — for potassium, calcium, and titanium. The X-radiation was analyzed by on-board spectrometers, which were recalibrated when empty. Approximately 4 minutes after landing, the first soil sample was retrieved and analyzed.

Venera 13 landed on an upland rolling plain; *Venera 14* on a lowland. From prior radar mapping made by *Pioneer Venus*, it was estimated that the *Venera* samplings were representative of about 92% of the planet's surface. In total, *Venera 13* acquired 38 samples; *Venera* 14, 20 samples. See Table 1.

TABLE 1. SURFACE COMPOSITION OF VENUS AS DETERMINED BY *VENERA* SPACECRAFT

Element	*Venera 13*	*Venera 14*
Magnesium (MgO)	11.4 ± 6.2	8.1 ± 3.3
Aluminum (Al_2O_3)	15.8 ± 3.0	17.9 ± 2.6
Silicon (SiO_2)	45.1 ± 3.0	48.7 ± 3.6
Potassium (K_2O)	4.0 ± 0.6	0.2 ± 0.1
Calcium (CaO)	7.1 ± 1.0	10.3 ± 1.2
Titanium (TiO_2)	1.6 ± 0.5	1.3 ± 0.4
Manganese (MnO)	0.2 ± 0.1	0.2 ± 0.1
Iron (FeO)	0.3 ± 2.2	8.8 ± 1.8
Sulfur (SO_3)	1.6 ± 1.0	0.9 ± 0.8
Others	3.9	3.6

The Russian team reported that the *Venera* landers transmitted almost complete panoramic views of their landing sites, made possible by the aforementioned sulfur (?) light glow. Image analysis showed the presence of rock formations undergoing geomorphic degradation. The formations displayed ripple marks, thin layering, differential erosion, and curvilinear fracturings. Shortly after the mission, some researchers suggested that some of the rocky material observed could be interpreted as lithified elastic sediments. The lithification could have occurred at depth, or at the surface, resulting in a type of duricrust. The origin of the sediments remains unknown, but it could be aeolian, volcanic, or related to impacts, or possibly to turbidity currents. A number of hypotheses and scenarios have been developed, but none proved convincingly.

Venera 15 and 16. *Venera 15* was part of a two spacecraft mission (along with *Venera 16*) designed to use 8 cm band side-looking radar mappers to study the surface properties of Venus. *Venera 15* was launched on 2, June 1983 and *Venera 16* on 7, June 1983. The two spacecraft were inserted into Venus orbit a day apart with their orbital planes shifted by an angle of approximately 4 degrees relative to one another. This made it possible to reimage an area if necessary. Each spacecraft was in a nearly polar orbit with a periapsis at 62 N latitude. Together, the two spacecraft imaged the area from the north pole down to about 30 degrees N latitude over the 8 months of mapping operations.

The *Venera 15* and *16* spacecraft were identical and were based on modifications to the orbiter portions of the Venera 9 and 14 probes. Each spacecraft consisted of a 5 m long cylinder with a 6 m diameter, 1.4 m tall parabolic dish antenna for the synthetic aperture radar (SAR) at one end. A 1 meter diameter parabolic dish antenna for the radio altimeter was also located at this end. The electrical axis of the radio altimeter antenna was lined up with the axis of the cylinder. The electrical axis of the SAR deviated from the spacecraft axis by 10 degrees. During imaging, the radio altimeter would be lined up with the center of the planet (local vertical) and the SAR would be looking off to the side at 10 degrees. A bulge at the opposite end of the cylinder held fuel tanks and propulsion units. Two square solar arrays extended like wings from the sides of the cylinder. A 2.6 m radio dish antenna for communications was also attached to the side of the cylinder.

***VEGA 1* and *2* Venus Balloon Experiment.** In June 1985, this mission was undertaken jointly by France and Russian, with major cooperation by the United States. Several other countries participated in the establishment of a worldwide balloon-tracking network. A total of 20 tracking stations

participated, ranging from one in British Columbia, Canada, 5 in the United States, 6 in Russia, and one each in Puerto Rico, Brazil, Spain, England, Germany, Sweden, South Africa, and Australia. Very long baseline interferometry (VLBI) technology was used.

The experiment was first proposed in 1967 by Blamont (Centre National d'Etudes Spatiales (CNES)). The initial proposal was studied and refined by the Space Research Institute (IXI) of Russia, with cooperation of NASA (United States), particularly in organizing the international network of radio telescopes for tracking.

This spacecraft mission combined a Venus swingby and a Comet Halley flyby. Two identical spacecraft, Vega 1 and Vega 2, were launched December 15 and 21, 1984, respectively. After carrying Venus entry probes to the vicinity of Venus (arrival and deployment of probes were scheduled for June 11–15, 1985), the two spacecraft were retargetted using Venus gravity field assistance to intercept Comet Halley in March 1986. The first spacecraft encountered Comet Halley on March 6, 1986, and the second three days later. The flyby velocity was 77.7 km/s. Although the spacecraft could be targetted with a precision of 100 km, the position of the spacecraft relative to the comet nucleus was estimated to be known only to within a few thousand kilometers. This, together with the problem of dust protection, led to estimated flyby distances of 10,000 km for the first spacecraft and 3000 km for the second.

The spacecraft was three-axis stabilized. Its main features were large solar panels, a high-gain antenna dish, and an automatic pointing platform carrying those experiments that required pointing at the comet nucleus. The automatic platform could rotate through + or −110 deg and + or −40 deg in two perpendicular directions with a pointing accuracy of 5 arc-min and a stability of 1 arc-min/s. It carried the narrow- and the wide-angle camera, the three-channel spectrometer, and the infrared sounder. All other experiments were body-mounted, with the exception of two magnetometer sensors and various plasma probes and plasma wave analyzers which were mounted on a 5-m boom. The total scientific payload weighed 125 kg and had a data rate of 65 kbs in fast telemetry mode for encounter. There was also a slow telemetry mode for the cruise mode. The comet-encounter science data-take was from 2.5 h before until 0.5 h after the closest approach, with several periods of data-take before and after, each lasting about 2 h. Continuous coverage for plasma and dust instruments was provided by an onboard memory (5-megabit tape recorder). The spacecraft was shielded from hypervelocity dust impacts by a shield consisting of a 100-micrometer multilayer sheet 20 to 30 cm from the spacecraft, and a 1-mm Al sheet 5 to 10 cm from the spacecraft. Approximately half of the VEGA spacecraft was devoted to the Halley module, and half to the Venus lander package. The total scientific payload weight was 144.3 kg.

The Venus package consisted of a sphere 240 cm in diameter, which separated two days before arrival at Venus and entered the planet's atmosphere on an inclined path, without active maneuvers, as was done on previous Venera missions. The lander probe was identical to those of *Venera 9* through *14* and similarly had two objectives, the study of the atmosphere and the study of the superficial crust. In addition to temperature and pressure measuring instruments, the descent probe carried a UV spectrometer for measurement of minor atmospheric constituents, an instrument dedicated to measurement of the concentration of H_2O, and other instruments for determination of the chemical composition of the condensed phase: a gas-phase chromatograph; an X-ray spectrometer observing the fluorescence of grains or drops; and a mass spectrograph measuring the chemical composition of the grains or drops. The X-ray spectrometer separated the grains according to their sizes using a laser imaging device, while the mass spectrograph separated them according to their sizes using an aerodynamical inertial separator. After landing, a small surface sample near the probe was to be analyzed by gamma spectroscopy and X-ray fluorescence. The UV spectrometer, the mass spectrograph, and the pressure- and temperature-measuring instruments were developed in cooperation between French and Soviet investigators.

In addition to the lander probe, a constant-pressure instrumented balloon aerostat was deployed immediately after entry into the atmosphere at an altitude of 54 km (35 mi). The 3.4 meter diameter balloon supported a total mass of 25-kg. A 5-kg payload hung suspended 12 meters below the balloon. It floated at approximately 50 km altitude in the middle, most active layer of the Venus three-tiered cloud system. Data from the balloon instruments were transmitted directly to Earth for the 47-hr lifetime of the mission. (The batteries had a lifetime of 60 hrs.) Onboard instruments were to measure temperature, pressure, vertical wind velocity, and visibility (density of local aerosols). Very long baseline interferometry was used to track the motion of the balloon to provide the wind velocity in the clouds. The tracking was to be done by a 6-station network on Soviet territory and by a network of 12 stations distributed world-wide (organized by France and the NASA Deep Space Network). After two days and 9000 km, the balloon entered the dayside of Venus and expanded and burst due to solar heating.

Magellan Mission. The **Magellan** spacecraft was launched on May 4, 1989, from aboard the space shuttle *Atlantis* and went into orbit around Venus on August 10, 1990. The spacecraft was designed to complete one orbit around Venus every 3 hours and 15 minutes, passing as close to the planet as 294 km (183 miles) and as far away from Venus as 8472 km (5265 miles). The basic scientific instrument aboard the spacecraft is a synthetic aperture radar (SAR), which can look through the thick clouds that perpetually shield the surface of the planet. See Fig. 18. The radar provided images of 98 percent of the planet's surface with a resolution of 100 meters (330 feet).

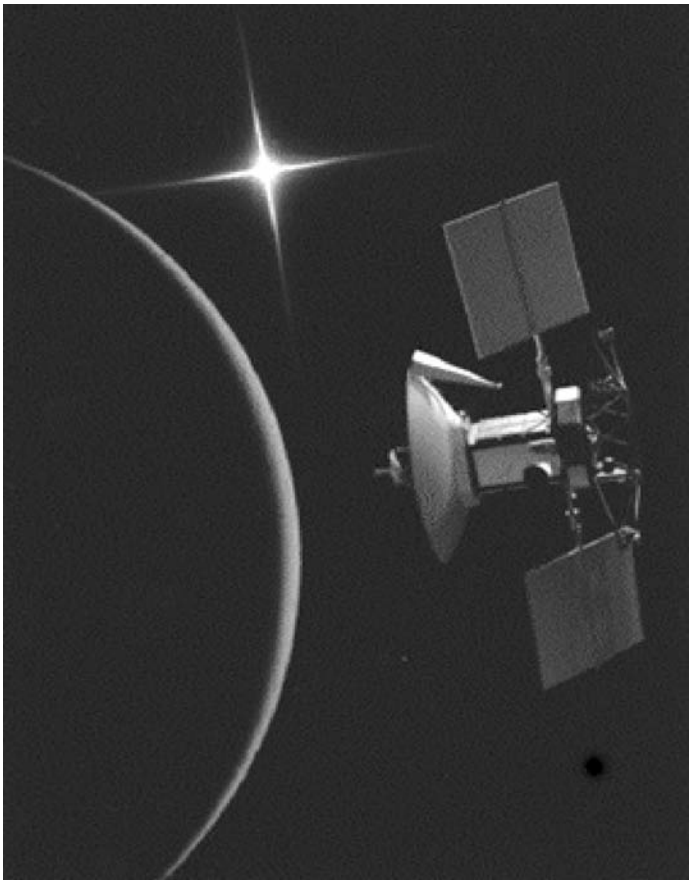

Fig. 18. During its primary mission at the planet of 243 days, approximately one Venusian year, the *Magellan* Spacecraft used synthetic aperture radar to penetrate Venus' thick cloud cover and return maps of about 98 percent of the planet's surface. Other experiments include measuring heights of surface features on Venus with a radar altimeter as well as studies of the planet's gravitational field. Designed as a low-cost scientific mission with a design life of four years, *Magellan* was manufactured by Martin Marietta Aerospace Company with spare parts from other JPL flight projects including Voyager and Galileo. (*Jet Propulsion Laboratory*.)

At the same excellent images of Venus were returned to Earth as the spacecraft continued on its approach in late August 1990, a series of electronic system disruptions occurred. On August 23, the spacecraft's signal faded for a period of 21 hours before engineers at the space center could reestablish it. Thereafter, *Magellan* operated in accordance with specifications and completed its initial mission.

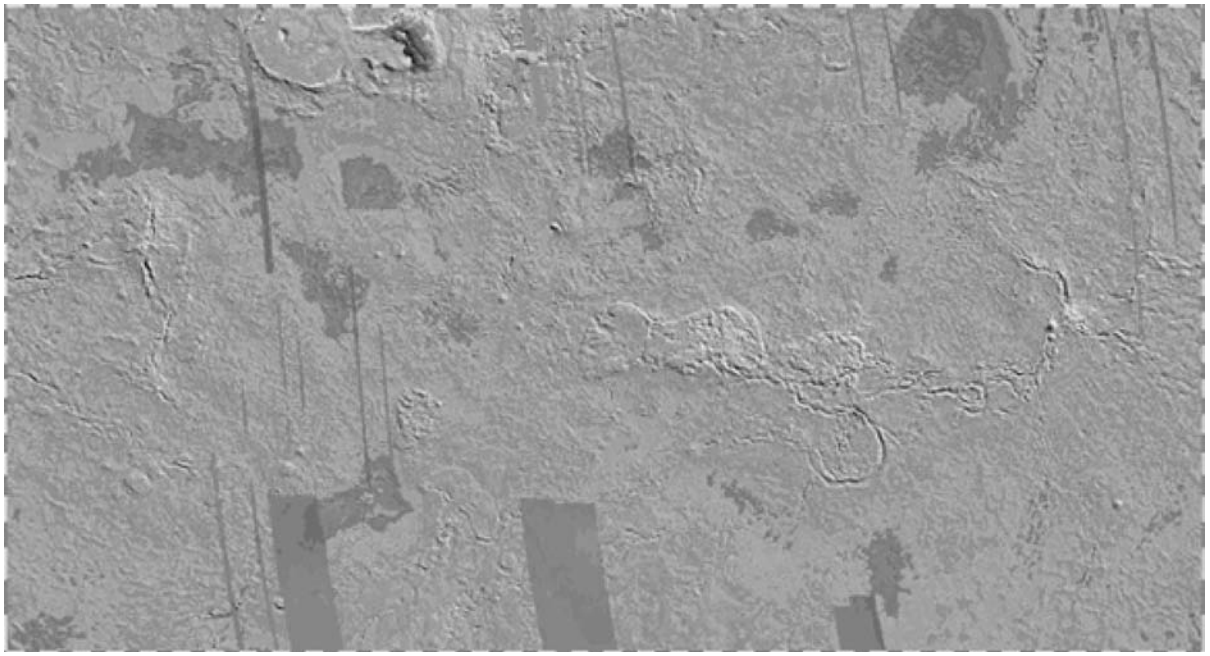

Fig. 19. This map of the topography of Venus was obtained by the *Magellan* radar altimeter during its 24 months of systematic mapping. Color is used to code elevation (see color bar), and simulated shading to emphasize relief. Red corresponds to the highest, blue to the lowest elevations. The upper image shows the portion of the planet between 69 degrees north and 69 degrees south latitude in Mercator projection; beneath it are the two polar regions, covering latitudes above 44 degree in stereographic projection. Height accuracy is better than 50 meters (165 feet); horizontal (footprint) resolution of the surface depends on spacecraft altitude, with a resolution of about 10 kilometers (6 miles) near the equator and as much as 25 kilometers (15.5 miles) at higher latitudes. The *Magellan* altimeter acquired topography data over 98 percent of the planet's surface. Gray areas show the coarser results from the *Pioneer Venus* (1978) and *Venera* 15/16 (1983) radar altimeters, and indicate where data was not obtained by *Magellan*. The elevated region in the north is Ishtar Terra, dominated by Maxwell Montes (the planet's highest mountains) which rise 11 kilometers (36,000 feet) above the planetary mean elevation. Southwest of Ishtar are the highlands of Beta Regio and Phoebe Regio, which are bisected by a major north-south trending rift zone. The scorpion-shaped feature extending along the equator between 70 and 210 degrees longitude is Aphrodite Terra, a continent-like highland that contains several spectacular volcanoes at its eastern limit: Maat, Ozza and Sapas Montes. The altimetric data shown here were compiled and analyzed at the Center for Space Research, Massachusetts Institute of Technology. (*Jet Propulsion Laboratory*.)

Venus completes one turn around its axis in 243 Earth days. That period of time (one Venus rotation) was specified as the time span for *Magellan's* primary mission. During that period, *Magellan* mapped approximately 80% of the surface of the planet. Thus, the primary mission of *Magellan* was completed by the spring of 1991. During the early days of *Magellan's* orbiting experience around the planet, sensational images of Venus were returned to Earth. Even though some criticism has been expressed over enhancement of some of the views, the images provided for the first time a comprehensive picture of the planet that exists under its cloud cover. The smallest visible objects in some views measure approximately 120 meters (400 feet).

The mission of the Magellan program was to develop an understanding and knowledge of the geological structure of Venus, including its density and distribution. During the four-year orbital tour of *Magellan* (1990–1994), detailed topographical images of the surface of Venus were obtained. In addition to the topographic maps, measurements of surface altitude were obtained using radar altimetry, and measurements of the planets gravitational field were obtained using precision radio tracking. See Figs. 19–24. At the end of its useful life, Magellan was directed into a gradual dive, which was designed to maximize information gathering on the atmospheric properties of Venus during the final days of the program. Magellan burned up in the Venusian atmosphere on October 12, 1994. See also **Magellan Mission to Venus**.

Galileo's Flyby of Venus. The primary mission of *Galileo*, launched on October 18, 1989, is that of exploring Jupiter, where it is scheduled to arrive on December 7, 1995. The spacecraft has encountered several difficulties, which are described in article on **Jupiter**. A part of *Galileo's* mission plan was that of flying by Venus in February 1990. This flyby was accomplished quite successfully. Important new information pertaining to Venus was returned, including the possible discovery of lightning in the atmosphere of Venus, magnetic field studies of the solar wind, plasma wave observations, determination of energetic particles, images of the Venusian cloud deck, middle infrared thermal maps of the planet, and ultraviolet spectrometric observations.

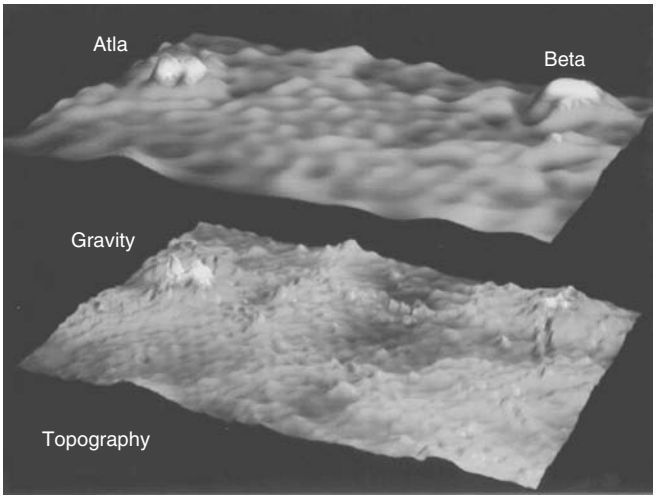

Fig. 20. The computer-generated perspective shown here compares gravity and topography over a region 12,700 kilometers by 8,450 kilometers (7,860 miles by 5,240 miles) and extends from longitudes 180 degrees east to 300 degrees east and latitudes 40 degrees north to 40 degrees south. The highlands of Beta Regio and Atla Regio, sites of rifting and large volcanoes, have corresponding high topography and high gravity. These areas are interpreted to be sites where hot mantle material is upwelling, forming "hot spots," similar to areas on Earth such as Hawaii. The two gravity highs at Atla correspond to the volcanoes Maat Mons, the higher of the two peaks, and Ozza Mons respectively. Gravity anomalies at Atla and Beta are the largest on Venus and these may be the sites of relatively young geologic features. In contrast to Earth, it is also seen that there is a near-perfect correlation between gravity and topography with anomalies, both positive (light blue) and negative (dark blue), being correlated with topographic highs and lows. This correspondence is interpreted to indicate that, relative to Earth, the formation of features on Venus is more strongly linked to fluid motions in the mantle. (*Jet Propulsion Laboratory*.)

Fig. 21. This global view of the surface of Venus is centered at 90 degrees east longitude. *Magellan* synthetic aperture radar mosaics from the three eight-month cycles of *Magellan* radar mapping are mapped onto a computer-simulated globe to create this image. *Magellan* obtained coverage of 98 percent of the surface of Venus. Remaining gaps are filled with data from previous Venus missions — the *Venera 15* and *16* radar and *Pioneer-Venus* Orbiter altimetry — and data from Earth-based radar observations from the Arecibo radio telescope. Simulated color is used to enhance small-scale structures. The simulated hues are based on color images obtained by the *Venera 13* and *14* landing craft. The bright feature near the center of the image is Ovda Regio, a mountainous region in the western portion of the great Aphrodite equatorial highland. The dark areas scattered across the Venusian plains consist of extremely smooth deposits associated with large meteorite impacts. The image was produced by the Solar System Visualization Project and the *Magellan* Science team at the Jet Propulsion Laboratory Multimission Image Processing Laboratory. (*Jet Propulsion Laboratory*.)

The *Galileo* spacecraft is described in more detail in article on **Jupiter**. See also **Galileo Mission to Jupiter**.

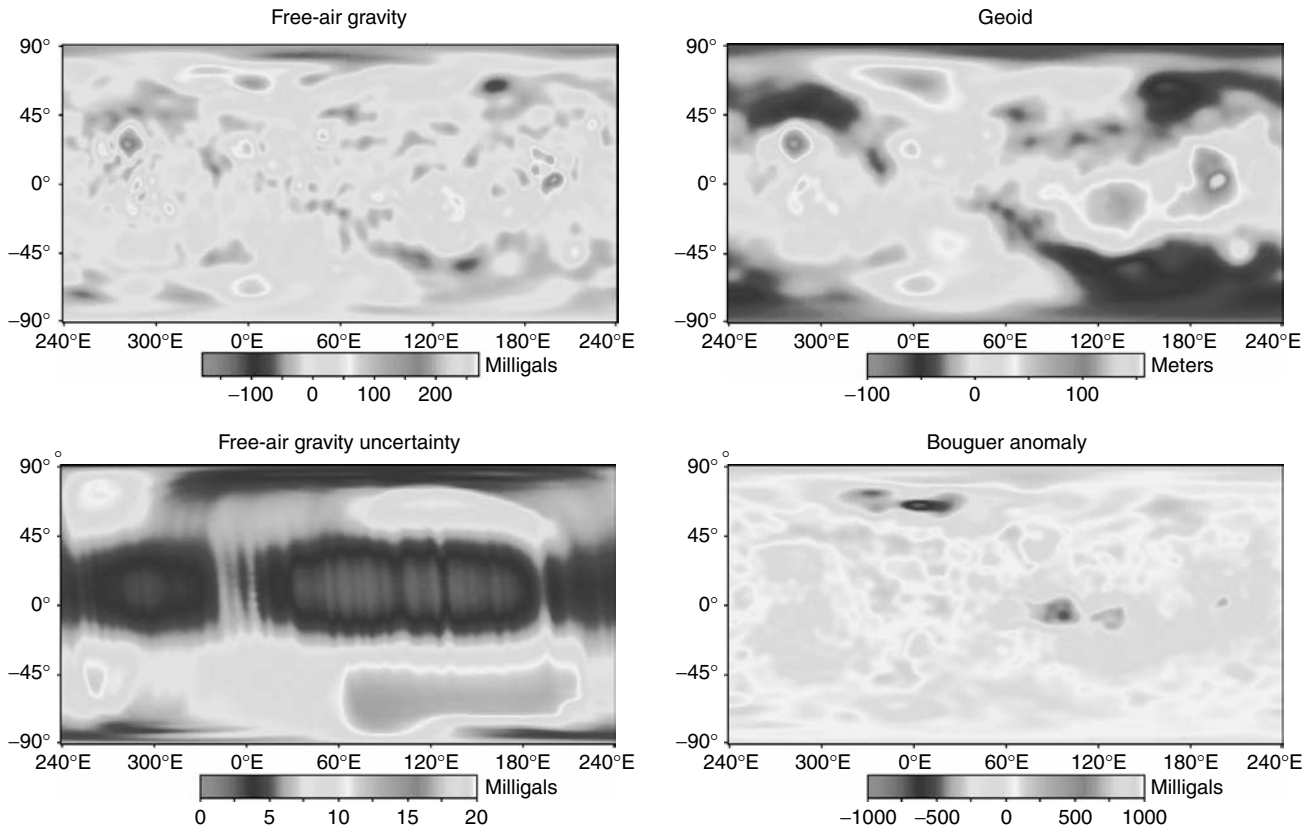

Fig. 22. These four images summarize the results of the *Magellan* gravity experiment on Venus.

FREE AIR GRAVITY MAP: "Free Air" means raw gravity measured in milligals (thousandths of a gal. One-gal = one centimeter per second squared). These variations are measured relative to the Venus average of 800 gals. The largest positive gravity effects are found at Beta Regio, latitude 25-north, longitude 281 east, and Atla Regio, 2 north, 199 east. The measurements were 200 milligals and 203 milligals, respectively. The largest negative effects are all in the low lands, ranging from 40 to 80 milligals. The differences are similar to those of the Earth, but unlike those of the moon and Mars, which are much larger. On Venus, however, there is almost perfect correlation of topography with gravity — highs with highs and lows with lows — which is not the case on Earth where some gravity highs occur in the oceans and some gravity lows occur over continents. Earth's major gravity features are produced by density variations deep in the mantle. That also is true for Venus, except on Venus the surface highs and lows are also tied to variations in the mantle.

FREE AIR GRAVITY UNCERTAINTY MAP: The smallest uncertainty in the gravity field solution is shown by the small values stretching across the equatorial zone. This is the result of excellent data from Magellan cycle 4 coverage from September 1992 to May 1993. Another block of excellent data was acquired during cycle 5 after a successful aerobraking, which placed the spacecraft in a near-circular orbit and provided data for the polar regions. The largest uncertainties between 90 east and 215 east are due to the fact that there was no coverage during cycle 5 in that area.

GEOID MAP: The surface geoid (theoretically, continuously level surface) shows height variations in a gravity surface that is equipotential, or has the same measured value. The peak measurements are again over Beta Regio (113.7 meters or 375.2 feet) and Atla Regio (141.4 meters or 466.6 feet).

BOUGUER ANOMALY MAP: (Named for 18th Century French scientist Pierre Bouguer) A Bouguer map is produced by subtracting from the observed free-air gravity a theoretical gravity based on the topography. If the observed gravity was produced from rigid surface topography only, the difference would be zero. There are very large differences, especially in the Aphrodite region, 70 east to 150 east, near the equator and the Ishtar Terra region, 65 north latitude. Those differences indicate that the interior of Venus contains variations in density, which may be related to large-scale motions or temperature differences in the planet's mantle. Bouguer anomalies are usually interpreted as variations in crustal thickness. Negative anomalies would indicate thickened crust and are seen in the Venus highlands. This also is the case for Earth where the most negative Bouguer anomalies occur in mountainous regions. (*Jet Propulsion Laboratory*.)

VENUS' GIRDLE *(Ctenophora, Cestida)*. A transparent marine animal of ribbon-like form. The longitudinal axis of the body lies across the width of the ribbon, hence the body is short and is greatly elongated on one transverse axis and very short on another.

VERMICULITE INSULATION. See **Insulation (Thermal)**.

VERNAL EQUINOX. 1. That point of intersection of the ecliptic and the celestial equator, occupied by the Sun as it changes from south to north declination, on or about March 21. Also called *March equinox, first point of Aries*.

2. That instant the Sun reaches the point of zero declination when crossing the celestial equator from south to north.

VERNALIZATION. Low-temperature treatment of seeds before sowing, which shortens the time to flowering of the plants which develop from them.

VERNIER. A scale or control used for fine adjustment to obtain a more precise reading of an instrument or closer adjustment of any equipment.

VERNIER ENGINE. A rocket engine of small thrust used primarily to obtain a fine adjustment in the velocity and trajectory of a rocket vehicle just after the thrust cutoff of the last sustainer engine, and used secondarily to add thrust to a booster or sustainer engine. Also called *vernier rocket*.

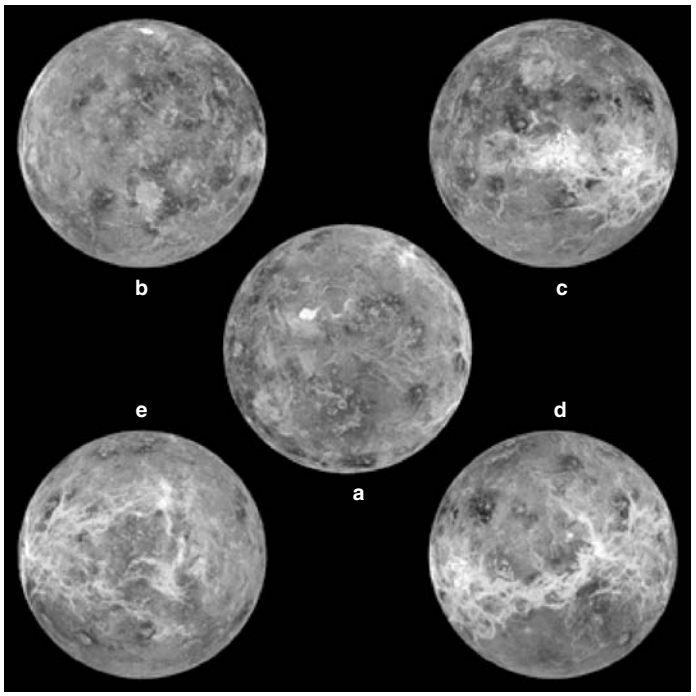

Fig. 23. These images are composites of the complete radar image collection obtained by the *Magellan* mission. The *Magellan* spacecraft was launched aboard space shuttle Atlantis in May 1989 and began mapping the surface of Venus in September 1990. The spacecraft continued to orbit Venus for four years, returning high-resolution images, altimetry, thermal emissions and gravity maps of 98 percent of the surface. *Magellan* spacecraft operations ended on October 12, 1994, when the radio contact was lost with the spacecraft during its controlled descent into the deeper portions of the Venusian atmosphere. The surface of Venus is displayed in these five global views. The center image (A) is centered at Venus's north pole. The other four images are centered around the equator of Venus at (B) 0 degrees longitude, (C) 90 degrees east longitude, (D) 180 degrees and (E) 270 degrees east longitude. *Magellan* synthetic aperture radar mosaics are mapped onto a rectangular latitude-longitude grid to create this image. Data gaps are filled with *Pioneer-Venus* Orbiter altimetric data, or a constant mid-range value. Simulated color is used to enhance small-scale structure. The simulated hues are based on color images recorded by the Soviet *Venera* 13 and 14 spacecraft. The bright region near the center in the polar view is Maxwell Montes, the highest mountain range on Venus. Ovda Regio is centered in the (C) 90 degrees east longitude view. Atla Regio is seen prominently in the (D) 180 east longitude view. The scattered dark patches in this image are halos surrounding some of the younger impact craters. This global data set reveals a number of craters consistent with an average Venus surface age of 300 million to 500 million years. The image was produced by the Solar System Visualization Project and the *Magellan* science team at the Jet Propulsion Laboratory's Multimission Image Processing Laboratory. (*Jet Propulsion Laboratory*.)

Fig. 24. This hemispheric view of Venus, as revealed by more than a decade of radar investigations culminating in the 1990–1994 *Magellan* mission, is centered at 0 degrees east longitude. The *Magellan* Spacecraft imaged more than 98 percent of Venus at a resolution of about 100 meters (330 feet); the effective resolution of this image is about 3 kilometers (1.8 miles). A mosaic of the Magellan images (most with illumination from the west) forms the image base. Gaps in the *Magellan* coverage were filled with images from the Earth-based Arecibo radar in a region centered roughly on 0 degrees latitude and longitude, and with a neutral tone elsewhere (primarily near the south pole). The composite image was processed to improve contrast and to emphasize small features, and was color-coded to represent elevation. Gaps in the elevation data from the *Magellan* radar altimeter were filled with altimetry from the Venera spacecraft and the U.S. *Pioneer Venus* missions. An Orthographic projection was used, simulating a distant view of one hemisphere of the planet. The *Magellan* mission was managed for NASA by the Jet Propulsion Laboratory (JPL), Pasadena, CA. Data processed by JPL, the Massachusetts Institute of Technology, Cambridge, MA, and the U.S. Geological Survey, Flagstaff, AZ. (*Jet Propulsion Laboratory*.)

VERSINE. See **Trigonometric Function**.

VERTEBRA. One of the 33 bones making up the spinal column. In humans, there are 7 cervical, 12 dorsal, 5 lumbar, 5 sacral, and 4 coccygeal vertebrae. See Fig. 1. See also **Skeletal System**.

Fig. 1. Vertebral column of human.

VERTEX. An endpoint of an edge. Point, O-cell, and node are other names used in the literature. As a rule, an isolated point is not considered a vertex. The term vertex also signifies the point common to the two straight lines forming an angle.

Vertices, adjacent. Two vertices of a graph G are adjacent if they are endpoints of an edge to G.

Vertex (cut). Let G be a connected separable graph. Then, by definition, there exists at least one subgraph G_s which has only one vertex β_c in common with its complement; β_c is a cut vertex. A necessary and sufficient condition for a graph G to be nonseparable is that it have no cut vertex.

Vertex degree. The number of edges incident at the vertex.

Vertex (final). The vertex of the last edge of an edge sequence not shared with the previous edge.

Vertex (initial). The vertex of the first edge of an edge sequence which is not common to the second edge.

Vertex (internal). A vertex of an edge sequence which is not terminal.

Vertex (terminal). The initial and final edges of an edge sequence.

VERTEX MATRIX. The vertex matrix $\mathbf{A}_a = (a_{ij})$ of a linear oriented graph G possessing v vertices β_i, $(i = 1, 2, \ldots, v)$ and e elements ε_j, $(j = 1, 2, \ldots, e)$, is a matrix with v rows and e columns such that

1. $a_{ij} = 1$ if element ε_j is incident at vertex β_i and oriented away from β_i;
2. $a_{ij} = -1$ if element ε_j is incident at β_i and oriented toward β_i,
3. $a_{ij} = 0$ if element ε_j is not incident at vertex β_i.

The vertex matrix has exactly two non-zero elements, one $+1$ and one -1 in each column and at least one non-zero element in each row. The rank of the vertex matrix of a connected graph is $v - 1$.

For a nonoriented graph the vertex matrix is defined similarly:

1. $a_{ij} = 1$ if element ε_j is incident at vertex β_i and
2. $a_{ij} = 0$ otherwise.

A graph is completely defined by its vertex matrix.

VERTICAL CIRCLE. Any great circle on the celestial sphere that passes through the zenith and nadir. Since the zenith and nadir are poles of the horizon, a vertical circle must be perpendicular to the horizon. The vertical circle that cuts the horizon at the north and south points is known as the local meridian, and the vertical circle that cuts the horizon at the east and west points is known as the prime vertical. See also **Celestial Sphere and Astronomical Triangle**.

VERTIGO. True vertigo arises as the result of a disturbance of the semicircular canals of the inner ear (auditory organ). *Objective vertigo* is the sensation that the external world is revolving about the patient; *subjective vertigo* is the sensation that the patient is himself moving in space. The disturbance may arise from a variety of causes: various diseases of the central nervous system; certain infectious diseases; the influence of certain toxic substances (such as alcohol, various sedatives, and some antibiotics); diseases of the visual system and of the blood; environmental factors (sunstroke, motion sickness); and, notably, Menière's disease. See also **Hearing and the Ear**.

VERTISOLS. See **Soil**.

VESICANT. A chemical substance that causes blisters to form on the skin. See also **Chlorinated Organics**.

VESICULAR (Petrology). Said of the texture of a rock, especially a lava, characterized by abundant vesicles (holes, pores, etc.) formed as a result of the spansion of gases during the fluid stage of the lava. A less-preferred synonym is *cellular*.

VESTIBULAR. Of or pertaining to the nature of a vestibule. In anatomy and zoology, a vestibule is a cavity or space that serves as an entrance to another cavity or space. The vestibule of the inner ear, for example, leads into the cochlea.

VESTIBULAR APPARATUS (Ear). See **Hearing and the Ear**.

VESTIGIAL STRUCTURES. Elements appearing in various life forms which, although often quite underdeveloped, are no longer needed or functional and represent a carry-over from more primitive forms. The human appendix is an example.

VESUVIANITE. The mineral vesuvianite is a very complex silicate of calcium and aluminum with fluorine which may also contain varying amounts of boron, iron, lithium, magnesium, manganese, potassium, sodium and titanium. A suggested formula is $Ca_{10}Mg_2Al_4(SiO_4)_5(Si_2O_7)_2(OH)_4$. Its tetragonal crystals are usually short, somewhat stoutish prisms, sometimes pyramids, but columnar to massive varieties are common. It is essentially without cleavage; fracture, uneven; brittle hardness, 6–7; specific gravity, 3.3–3.5; luster, vitreous to greasy resinous; color, commonly some shade of brown, green, or white, may be reddish, bluish or yellowish; may be transparent, but is usually translucent.

This mineral was formerly called idocrase, having been named Haüy from the Greek words meaning *form* and *mixture* because it resembled crystals of other species, scarcely a valid distinction. Werner gave it the name vesuvianite from Mt. Vesuvius where it was first found blocks of limestone appearing as inclusions in the lava. Vesuvianite not a constituent of the igneous rocks, but rather a contact metamorphic mineral resulting from the alteration of impure limestones and dolomites It is usually associated with diopside, wollastonite, epidote, grossularite and garnet. There are many localities worthy of mention among which are: The Urals, Central Europe, Rumania, Trentino and Monzoni in Italy, as well as at Mt. Vesuvius and Mt. Somma, Switzerland, Mexico and Japan. In the United States vesuvianite is found in Androscoggin and York Counties in Maine; Orange and Warren Counties, New York; Sussex County, New Jersey; Garland County, Arkansas; and Riverside and Tulare Counties in California.

VETCH. Of the family *Leguminoseae* (pea family), genus *Vicia*, vetch is the common designation for numerous herbs that are cultivated in several regions of the world, mainly for fodder, green manure, and as a cover, particularly for orchards. Vetch has the important advantage of all leguminous plants, namely, the ability to enrich poor soils with nitrogen, a factor that makes possible the planting of vetch in regions where other nutritious plants will not thrive.

VIBRATING SYSTEM (Oscillation). See **Oscillation**.

VIBRATION. Generally, any form of sustained motion, characteristic of a finite system, in which each particle or element of the system moves to-and-fro about an equilibrium position. In the simplest situation, such a motion possesses a unique "periodic time." The inverse of this quantity, the "frequency," is the number of complete to-and-fro excursions per unit time. A simple pendulum is an example of a form of vibration in which the motions are slow. See also **Pendulum**. Often one thinks of vibration in terms of much higher frequencies. Historically, pendulum motion was the first simple harmonic motion to be understood. Simple harmonic motion is referred to as "isochronous" because, in a given case, the periodic time is the same whatever the amplitude.

In vibratory motion, the restoring forces responsible for the individual motions of the constituent elements of a vibrating system may arise from *tensions* externally applied to the system — as with stretched strings and membranes; from *elastic stresses* developed internally as the system is deformed — as with rods vibrating longitudinally, transversely, or torsionally, or with air columns in organ pipes; or in *other ways*, such as *surface tension* forces — as involved in the pulsation vibrations of thin films of liquid.

The complete period for a small amplitude for a simple pendulum is

$$T = 2\pi\sqrt{\frac{l}{g}}; \quad g = 4\pi^2\frac{l}{T^2}$$

where l is length in centimeters; g is acceleration due to gravity in centimeters per $\sec_2$ and T is time in seconds.

If the period is P for an arc θ, the time of vibration in an indefinitely small arc is approximately

$$T = \frac{P}{1 + \frac{1}{4}\sin^2\frac{\theta}{4}}$$

For a compound pendulum, where the body of mass m is suspended from a point about which its moment of inertia is I, with its center of gravity a distance h below the point of suspension, the period is

$$T = 2\pi\sqrt{\frac{I}{mgh}}$$

The frequency of vibration of a closed pipe or air column, for the fundamental and first three overtones respectively, is

$$n_0 = \frac{V}{4l}, \quad n_1 = \frac{3V}{4l}, \quad n_2 = \frac{5V}{4l}, \quad n_3 = \frac{7V}{4l}$$

where l is the length of the column and V is the velocity of sound in air.

For an open pipe, the frequency of vibration is

$$n_0 = \frac{V}{2l}, \quad n_1 = \frac{2V}{2l}, \quad n_2 = \frac{3V}{2l}, \quad n_3 = \frac{4V}{2l}$$

The fundamental frequency of vibrating strings (stretched) is given by

$$n = \frac{1}{2l}\sqrt{\frac{T}{m}}$$

where l is the length; T is the tension; and m is the mass per unit length.

With essentially linear systems, such as strings and rods and organ pipes, when the conditions at the two ends of the system are the same as they are with a stretched string, and there is no internal constraint, the normal modes in general constitute a harmonic series. When the end conditions are different, as in a pipe which is closed at one end and open at the other, in general the even-numbered harmonics are not represented. In all cases, however, the theorem concerning the decomposition of the most complex sustained motion in terms of the normal modes applies.

As an example of elastic vibrations, consider the transverse vibrations of a thin, uniform rod, which is clamped at one end. For a displacement profile of arbitrary shape, the elastic forces are brought into play across any section of the rod at that section, and the unbalanced restoring force acting on a small finite element of the rod is similarly proportional to its displacement. But the proportionality constant relating restoring force per unit length to displacement will, in general, vary along the rod. Only for displacement profiles of certain shapes will this constant be the same overall. These are the shapes of displacement profile corresponding to the normal mode vibrations, and it is the object of theory to identify them and to deduce the corresponding frequencies. Even an approximate theory is complex. All that can be done in the interest of simplicity is to quote the ratios of the frequencies of the first three normal mode vibrations, i.e., 1:6.27:17.55. Very clearly, the normal modes in this case do not constitute a harmonic series; in musical parlance, the first overtone is some 2.5 octaves higher than the fundamental.

Vibration testing is important to many technologies, as for example, testing building structures, aircraft, missiles, and vehicles of all kinds. Testing techniques have become increasingly precise and are extended to deal with problems in such fields as the design of machines, construction of bridges, the development of new materials, and the study of earthquakes. Vibration can be measured in several ways. The linear piezoelectric accelerometer is widely used for measuring vibration. The piezoelectric element, which is acted on by the inertial force of the mass, may be made of polycrystalline ceramics, such as barium titanate or lead zirconate. See Fig. 1. The resonance is sharply underdamped. Over the useful frequency range, the equivalent circuit of the accelerometer is shown in Fig. 2. The frequency response of the accelerometer is shown in Fig. 3. Because of its high impedance, the accelerometer must be isolated from the data-conditioning equipment, and the signal must be amplified.

The manner in which an accelerometer is used to closely control sine-wave vibration testing is shown in Fig. 4. An electrodynamic vibration exciter is used. An oscillator puts out a sinusoidal signal which is fed via a variable gain (*AGC*) to a power amplifier (*PA*). The latter, in turn, drives the vibration exciter (*EX*). The accelerometer *A* has its output amplified by the signal-conditioning circuit *H*. The signal then is detected by *D*, and a dc voltage proportional to signal level is used to control the gain of the

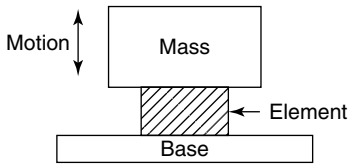

Fig. 1. Simplified representation of accelerometer.

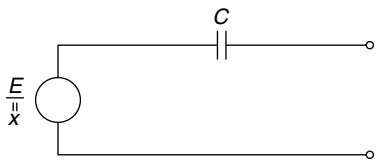

Fig. 2. Equivalent circuit of accelerometer over useful frequency range.

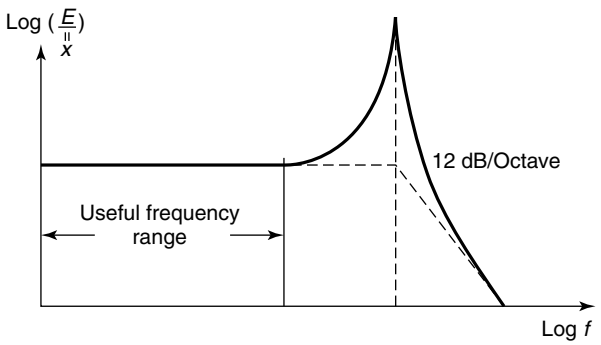

Fig. 3. Frequency response of an accelerometer.

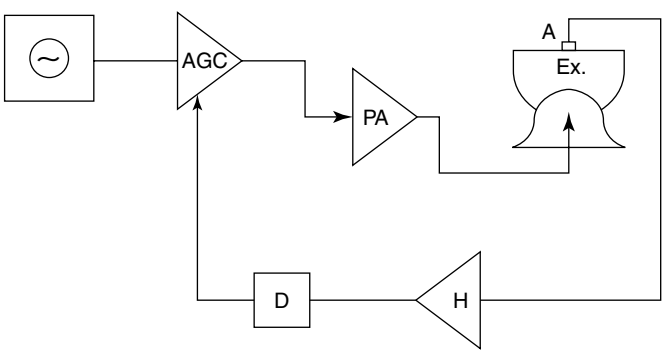

Fig. 4. Application of an accelerometer to closely controlled sine-wave vibration.

AGC stage. Thus, independent of the usual resonant effects at the exciter or specimen, the vibration level at *A* can be carefully controlled.

Use of an accelerometer to control a random vibration is shown in Fig. 5. An automatic random equalizer is used. A random-noise generator supplies the input to a set of contiguous bandpass filters. In some apparatus, these filters are crystal in nature. Each filter output is controlled by an *AGC* stage so as to maintain its spectral power at a desired level. The reference voltage at each servoloop summing point is used to determine the vibration level of the corresponding filter channel. A large loop gain makes it possible to calibrate the potentiometer supplying the reference voltage so as to follow any desired spectral-density plot. There is one such control for each filter channel.

Vibration testing using an accelerometer can be extended to force impedance testing or mechanical-impedance testing, using an impedance head. The latter consists of an accelerometer plus a force gage, measuring at the same point in the same direction. The force gage consists of a piezoelectric element between two plates and provides an output proportional to the pressure between the plates. The stiffness of the impedance head should be kept large, and the mass of the impedance head should be kept small.

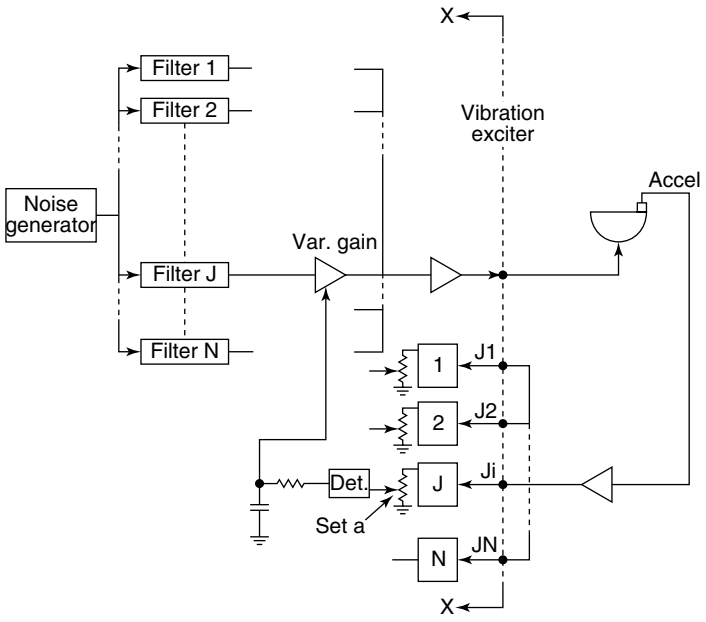

Fig. 5. Use of an accelerometer to control a random vibration.

Commercial accelerometers usually are small and cylindrical in form, weighing between 0.001 and 0.2 pound (0.5 and 91 grams). Accelerometer sensitivity generally increases with size. The resonant frequency commonly is from 25,000 to 100,000 Hz, a point two to three times the maximum operating frequency. See also **Accelerometer**.

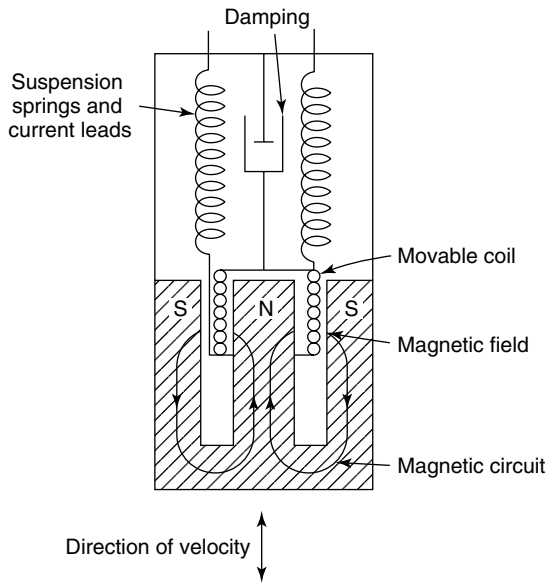

Fig. 6. Schematic representation of a velocity vibration pickup.

A velocity vibration pickup is a self-generating transducer having an output voltage proportional to velocity. The device senses the relative velocity between a coil and the magnetic field imposed on the coil by a self-contained magnetic source. In some types, a seismically suspended coil moves relative to a uniform magnetic field. A variation of this is a seismic magnet that moves relative to an anchored coil. Other types function by means of a coil that senses variations in the magnetic field. A typical pickup is shown in Fig. 6. The output signal of a velocity pickup normally is large enough so as not to require amplification. The velocity signal can be integrated and differentiated to obtain displacement and acceleration, respectively. The natural frequency of the suspended moving element usually is low, ranging from 2.5 to 10 Hz in various models. This natural frequency establishes the lower operating-frequency limit. Low velocities associated with high-frequency vibration and pickup structural resonances limit the upper frequency to approximately 2,000 Hz. The velocity pickup is useful over a range of amplitudes determined by the sensitivity and friction at low displacements and by space limitation on moving parts at high displacements.

VIBRATION ANALYSIS. See **Spectrum Analysis**.

VIBRATION EXCITER. A transducer used in simulation of predetermined mechanical vibration environments. A mounting or table surface is usually provided for threaded attachment of the item to be vibrated for testing. Vibration exciters can be classified into four main groups: (1) mechanical, (2) electromechanical, (3) electrohydraulic, and (4) pneumatic, depending upon the source of vibration-producing energy.

The least sophisticated types are pneumatic and electromagnetic. These types are limited in their capability to reproduce vibration over a wide and controllable range. Piezoelectric exciters generally are useful at high frequencies only. Hence, these devices are limited in application to calibration of instruments and ultrasonic apparatus. Mechanical exciters are driven by electric motors which generate vibration by use of cranks or cams (direct drive), or by use of eccentric weights (reaction).

These exciters are useful over a relatively narrow range of controllable frequencies and amplitudes. They are relatively low cost and hence are widely used wherever they can be applied.

Electrodynamic exciter construction is allied to that of a loudspeaker. Through the use of electronic amplifiers and accessories, a wide range of input signals can be converted to mechanical vibration output with excellent fidelity. The input signals commonly used are sinusoidal, complex, random, and tape recording, all with a high degree of controllability within the exciter system specifications.

VIDICON. A television pickup tube utilizing a photoconductor as the sensing element. In conjunction with a telescope this is known as a *vidicon telescope*.

VIGNETTING EFFECT. The falling-off in brightness toward the margin of an illuminated field, due to the mutilation of the more oblique bundles of light by the combined effects of diaphragm and lens aperture. This is a source of trouble in photographic objectives when they are used at large apertures, or close to the limit of their fully illuminated fields.

VIKING MISSION TO MARS. NASA's *Viking* Project was the culmination of a series of missions to explore Mars that had begun in 1964 with *Mariner 4*, and continued with the *Mariner 6* and *7* flybys in 1969, and the *Mariner 9* orbital mission in 1971 and 1972.

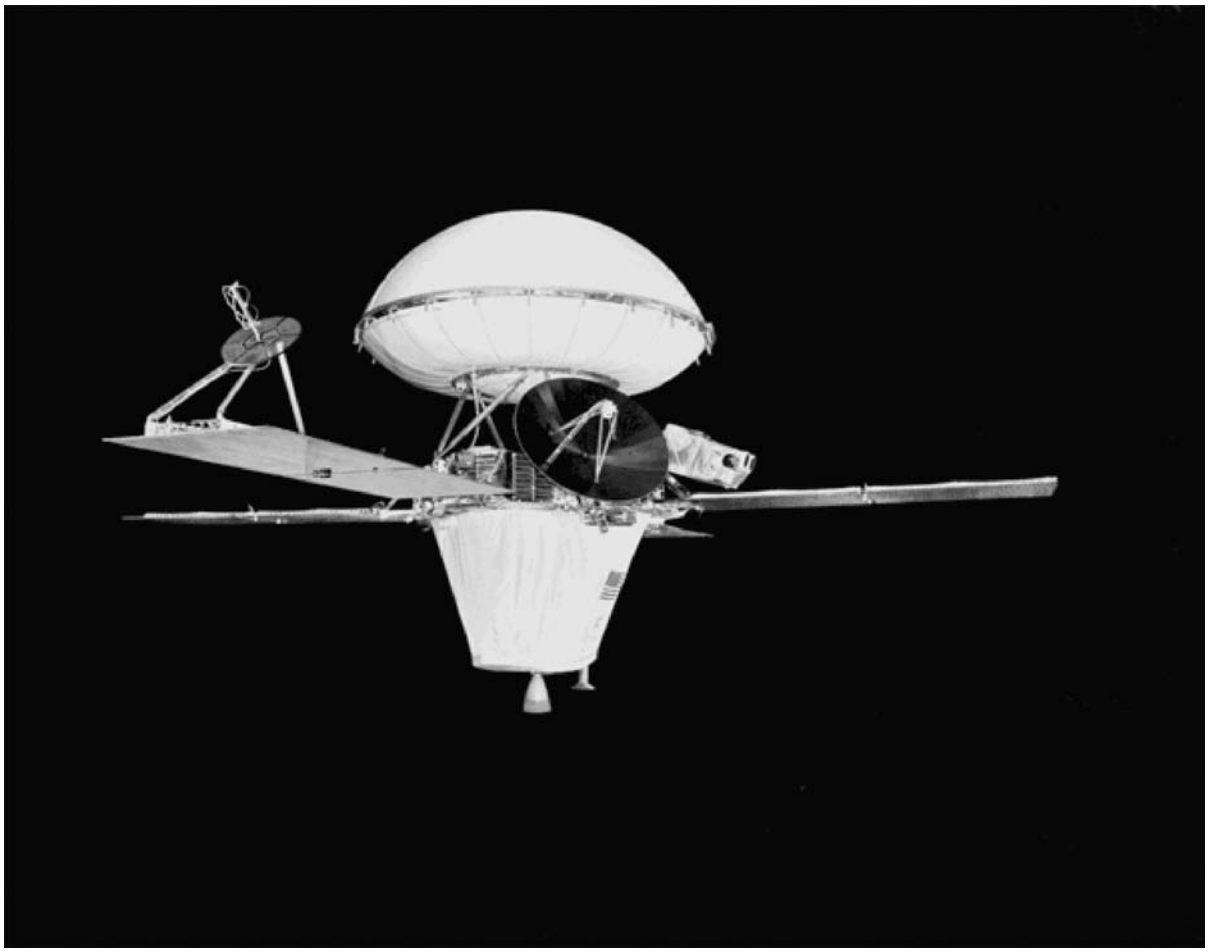

Fig. 1. *Viking* Orbiter.

Viking found a place in history when it became the first mission to land a spacecraft successfully on the surface of another planet. Two identical spacecraft, each consisting of a lander and an orbiter, were built. Each orbiter-lander pair flew together and entered Mars orbit; the landers then separated and descended to the planet's surface.

Mission Design

Both spacecraft were launched from Cape Canaveral, Florida — *Viking 1* on August 20, 1975, and *Viking 2* on September 9, 1975. The landers were sterilized before launch to prevent contamination of Mars with organisms from Earth. The spacecraft spent nearly a year cruising to Mars. *Viking 1* reached Mars orbit June 19, 1976; *Viking 2* began orbiting Mars August 7, 1976. See Fig. 1.

After studying orbiter photos, the Viking site certification team considered the original landing site proposed for *Viking 1* unsafe. The team examined nearby sites, and *Viking 1* landed on Mars July 20, 1976, on the western slope of Chryse Planitia (the Plains of Gold) at 22.3 degrees north latitude, 48.0 degrees longitude.

The site certification team also decided the planned landing site for *Viking 2* was unsafe after it examined high-resolution photos. Certification of a new landing site took place in time for a Mars landing September 3, 1976, at Utopia Planitia, at 47.7 degrees north latitude and 48.0 degrees longitude.

The *Viking* mission was planned to continue for 90 days after landing. Each orbiter and lander operated far beyond its design lifetime. *Viking Orbiter 1* exceeded four years of active flight operations in Mars orbit.

The *Viking* project's primary mission ended November 15, 1976, 11 days before Mars' superior conjunction (its passage behind the Sun). After conjunction, in mid-December 1976, controllers reestablished telemetry and command operations, and began extended mission operations.

The first spacecraft to cease functioning was *Viking Orbiter 2*, on July 25, 1978; the spacecraft had used all the gas in its attitude-control system, which kept the craft's solar panels pointed at the Sun to power the orbiter. When the spacecraft drifted off the Sun line, the controllers at Jet Prapulane Laboratory (JPL) sent commands to shut off power to *Viking Orbiter 2's* transmitter.

Viking Orbiter 1 began to run short of attitude-control gas in 1978, but through careful planning to conserve the remaining supply, engineers found it possible to continue acquiring science data at a reduced level for another two years. The gas supply was finally exhausted and *Viking Orbiter 1's* electrical power was commanded off on August 7, 1980, after 1,489 orbits of Mars.

The last data from *Viking Lander 2* arrived at Earth on April 11, 1980. *Viking Lander 1* made its final transmission to Earth Nov. 11, 1982. Controllers at JPL tried unsuccessfully for another six and one-half months to regain contact with *Viking Lander 1*. The overall mission came to an end May 21, 1983.

Viking Orbiters

The *Viking* spacecraft consisted of two large orbiters, each weighing 2,325 kilograms (5,125 pounds) with fuel. Each orbiter carried a lander, weighing 576 kilograms (1,270 pounds), and their design was greatly influenced by the size of these landers.

The orbiters were a follow-on design to the *Mariner* class of planetary spacecraft with specific design changes for the 1976 surface mission. Operational lifetime requirements for the orbiters were 120 days in orbit and 90 days after landing.

The combined weight of the orbiter and lander was one factor that contributed to an 11-month transit time to Mars, instead of the five months for *Mariner* missions. The longer flight time then dictated an increased design life for the spacecraft, larger solar panels to allow for longer degradation from solar radiation and additional attitude control gas.

The basic structure of the orbiter was an octagon approximately 2.4 meters (8 feet) across. The eight sides of the ring-like structure were

45.7 centimeters (18 inches) high and were alternately 1.4 by 0.6 meters (55 by 22 inches).

Electronic bays were mounted to the faces of the structure, and the propulsion module was attached at four points. There were 16 bays, or compartments, three on each of the long sides and one on each short side.

The orbiter was 3.3 meters (10.8 feet) high and 9.7 meters (32 feet) across the extended solar panels. With fuel, the orbiters weighed in excess of 2,300 kilograms (5,000 pounds).

Combined area of the four panels was 15 square meters (161 square feet), and they provided both regulated and unregulated direct current power; unregulated power was provided to the radio transmitter and the lander.

Two 30-amp-hour, nickel–cadmium, rechargeable batteries provided power when the spacecraft was not facing the Sun during launch, correction maneuvers, and Mars occultation.

The orbiter was stabilized in flight by locking onto the Sun for pitch and yaw references and onto the star Canopus for roll reference. The attitude control subsystem kept this attitude with nitrogen gas jets located at the solar panel tips. The jets would fire to correct any drift. A cruise Sun sensor and the Canopus sensor provided error signals. Before Sun acquisition four acquisition Sun sensors were used and then turned off.

The attitude control subsystem also operated in an all-inertial mode or in roll-inertial with pitch and yaw control, still using the Sun sensors. During correction maneuvers, the attitude control subsystem aligned the vehicle to a specified attitude in response to commands from the on-board computer. Attitude control during engine burns was provided in roll by the attitude control subsystem and in pitch and yaw by an autopilot that commanded engine gimballing.

If Sun lock was lost, the attitude control subsystem automatically realigned the spacecraft. In loss of Canopus lock, the subsystem switched to roll-inertial and waited for commands from the spacecraft computer. The nitrogen gas supply for the subsystem could be augmented by diverting excess helium gas from the propulsion module, if necessary.

Two on-board general purpose computers in the computer command subsystem decoded commands and either ordered the desired function at once or stored the commands in a 4,096-word plated-wire memory. All orbiter events were controlled by the computer command subsystem, including correction maneuvers, engine burns, science sequences and high-gain antenna pointing.

The main orbiter communications system was a two-way, S-band, high-rate radio link providing Earth command, radio tracking and science and engineering data return. This link used either a steerable 1.5 meters (59 inches) dish high-gain antenna or an omni-directional low-gain antenna, both of them on the orbiter. The low-gain antenna was used to send and receive near Earth, and the high-gain antenna was used as the orbiter journeyed farther from Earth.

S-band transmission rates varied from 8.3 or 33.3 bits per second for engineering data to 2,000 to 16,000 bits per second for lander and orbiter science data.

Relay from the lander was achieved through an antenna mounted on the outer edge of a solar panel. It was activated before separation and received from the lander through separation, entry, landing and surface operations. The bit rate during entry and landing was 4,000 bits per second; landed rate was 16,000 bits per second.

Data were stored aboard the orbiter on two eight-track digital tape recorders. Seven tracks were used for picture data and the eighth track for infrared data or relayed lander data. Each recorder could store 640 million bits.

Data collected by the orbiter, including lander data, were converted into digital form by the flight data subsystem and routed to the communications subsystem for transmission or to the tape recorders for storage. This subsystem also provided timing signals for the three orbiter science experiments.

Viking Lander

The lander spacecraft was composed of five basic systems: the lander body, the bioshield cap and base, the aeroshell, the base cover and parachute system and lander subsystems. See Figs. 2 and 3.

The completely outfitted lander measured approximately 3 meters (10 feet) across and was about 2 meters (7 feet) tall. It weighed about 576 kilograms (1,270 pounds) without fuel.

The lander and all exterior assemblies were painted light gray to reflect solar heat and to protect equipment from abrasion. The paint was made of rubber-based silicone.

The body was a basic platform for science instruments and operational subsystems. It was a hexagon-shaped box with three 109 centimeters (43 inches) side-beams and three 56-centimeter (22-inch) short sides. It looks like a triangle with blunted corners.

The box was built of aluminum and titanium alloys, and was insulated with spun fiberglass and dacron cloth to protect equipment and to lessen heat loss. The hollow container was 1.5 meters (59 inches) wide and 46 centimeters (18 inches) deep, with cover plates on the top and bottom.

The lander body was supported by three landing legs, 1.3 meters (51 inches) long, attached to the short-side bottom corners of the body. The legs gave the lander a ground clearance of 22 centimeters (8.7 inches).

Each leg had a main strut assembly and an A-frame assembly, to which was attached a circular footpad 30.5 centimeters (12 inches) in diameter. The main struts contained bonded, crushed aluminum honeycomb to reduce the shock of landing.

The two-piece bioshield was a pressurized cocoon that completely sealed the lander from any possibility of biological contamination until *Viking* left Earth's atmosphere.

The two bioshield halves generally resembled an egg, and the shield's white thermal paint heightened the resemblance. It measured 3.7 meters (12 feet) in diameter and was 1.9 meters (6.4 feet) deep. It was made of coated, woven fiberglass, 0.13 millimeters (0.005 inches) thin, bonded to an aluminum support structure.

The bioshield was vented to prevent over-pressurization and possible rupture of its sterile seal. The aeroshell was an aerodynamic heat shield made of aluminum alloy in a 140-degree, flat cone shape and stiffened with concentric rings. It fit between the lander and the bioshield base. It was 3.5 meters (11.5 feet) in diameter and its aluminum skin was 0.86 millimeters (0.034 inches) thin.

Bonded to its exterior was a lightweight, cork-like ablative material that burned away to protect the lander from aerodynamic heating at entry temperatures which may have reached 1,500 °C (2,730 °F).

The interior of the aeroshell contained twelve small reaction control engines, in four clusters of three around the aeroshell's edge, and two spherical titanium tanks that contained 85 kilograms (188 pounds) of hydrazine mono-propellant.

The engines controlled the pitch and yaw to align the lander for entry, help slow the craft during early entry, and maintain roll control.

During the long cruise phase, an umbilical connection through the aeroshell provided power from the orbiter to the lander; housekeeping data also flowed through this connection.

The aeroshell also contained two science instruments — the upper atmosphere mass spectrometer and the retarding potential analyzer — plus pressure and temperature sensors.

The base cover fit between the bioshield cap and the lander. It was made of aluminum and fiberglass; the fiberglass allowed transmission of telemetry data to the orbiter during entry. It covered the parachute and its ejection mortar, and protected the lander's top during part of the entry phase.

The parachute was made of lightweight dacron polyester 16 meters (53 feet) in diameter. It weighed 50 kilograms (110 pounds).

The parachute was packed inside a mortar 38 centimeters (15 inches) in diameter and mounted into the base cover. The mortar was fired to eject the parachute at about 139 kilometers per hour (75 miles per hour). The chute had an extra-long suspension line that trailed the capsule by about 30 meters (100 feet).

The lander subsystems were divided into six major categories: descent engines, communications equipment, power sources, landing radars, data storage, and guidance and control.

Three terminal descent engines provided attitude control and reduced the lander's velocity after parachute separation. The 2,600-newton (600-pound) throttleable engines were located 120 degrees apart on the lander's sidebeams. They burned hydrazine monopropellant.

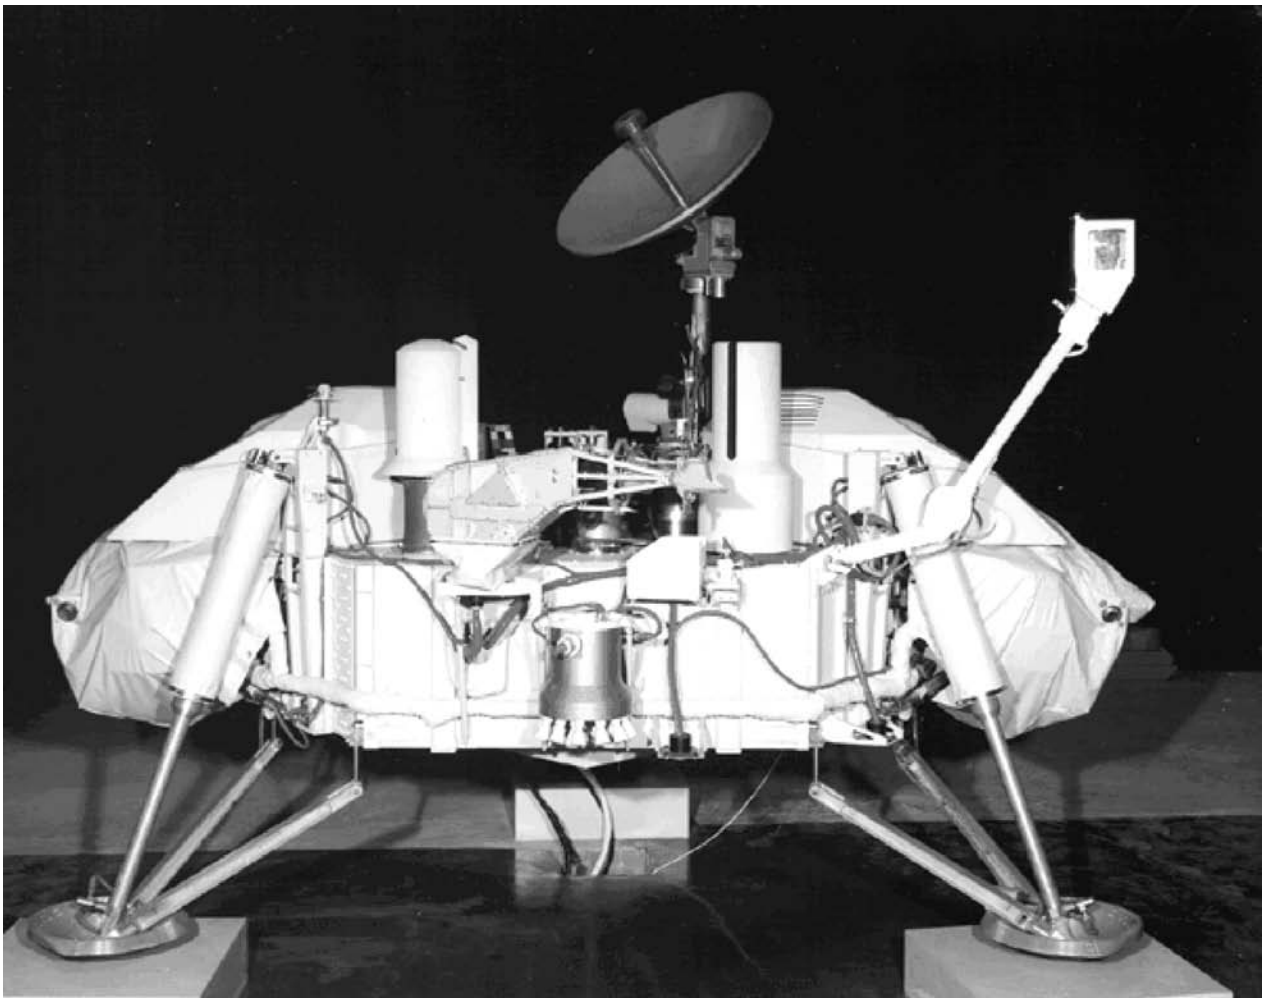

Fig. 2. *Viking* Lander 1.

The engines used an advanced exhaust design that wouldn't alter the landing site environment. An unusual grouping of 18 small nozzles on each engine would spread engine exhaust over a wide angle that wouldn't alter the surface or unduly disturb the chemical and biological experiments.

Two spherical titanium tanks, attached to opposite sides of the lander body beneath the RTG wind covers, fed the descent engines from an 85 kilograms (188 pounds) hydrazine propellant supply.

Four small reaction control engines used hydrazine mono-propellant thrusters to control lander roll attitude during terminal descent. The engines were mounted in pairs on the terminal descent engines' propellant tanks and were identical to those used on the aeroshell.

The lander was equipped to transmit information directly to Earth with an S-band communications system, or through the orbiter with an ultra-high frequency (UHF) relay system. The lander also received Earth commands through the S-band system.

Two S-band receivers provided total redundancy in both command receiving and data transmission. One receiver used the high-gain antenna, a 76 centimeters (30-inches) diameter parabolic reflector dish that could be pointed to Earth by computer control. The second receiver used a fixed low-gain antenna to receive Earth commands.

The UHF relay system transmitted data to the orbiter with a radio transmitter that used a fixed antenna. The UHF system operated during entry and during the first three days of landed operations. After that, it was operated only during specific periods.

The radar altimeter measured the lander's altitude during the early entry phase, alerting the lander computer to execute the proper entry commands. The radar was a solid-state pulse radar with two specially designed antennas: one was mounted beneath the lander and one was mounted through the aeroshell.

Altitude data were received from 1,370 kilometers down to 30.5 meters (740 miles to 100 feet).

The aeroshell antenna provided high-altitude data for entry science, vehicle control and parachute deployment. The lander antenna was switched into operation at aeroshell separation and provided altitude data for guidance and control, and for terminal descent engine ignition.

The terminal descent landing radar measured the horizontal velocity of the lander during the final landing phase. It was located directly beneath the lander and was turned on at about 12 kilometers (4,000 feet) above the surface. It consisted of four continuous-wave Doppler radar beams that could measure velocity to an accuracy of plus or minus one meter per second.

Both radars were essential for mission success, so the terminal descent landing radar could work with any three of its four beams, and identical sets of radar altimeter electronics could be switched to either of the radar antennas.

The "brain" of the lander was its guidance control and sequencing computer. That computer commanded everything the lander did through software (computer programs) stored in advance or relayed by Earth controllers.

The computer was one of the greatest technical challenges of *Viking*. It consisted of two general-purpose computer channels with plated-wire memories, each with an 18,000-word storage capacity. One channel would be operational while the other was in reserve.

Among other programs, the computer had instructions stored in its memory that could control the lander's first 22 days on Mars without any contact from Earth. These instructions would be updated and modified by Earth commands once communications had been established.

Basic power for the lander was provided by two SNAP 19-style, 35-watt radioisotope thermoelectric generators (RTGs) developed by the then U.S.

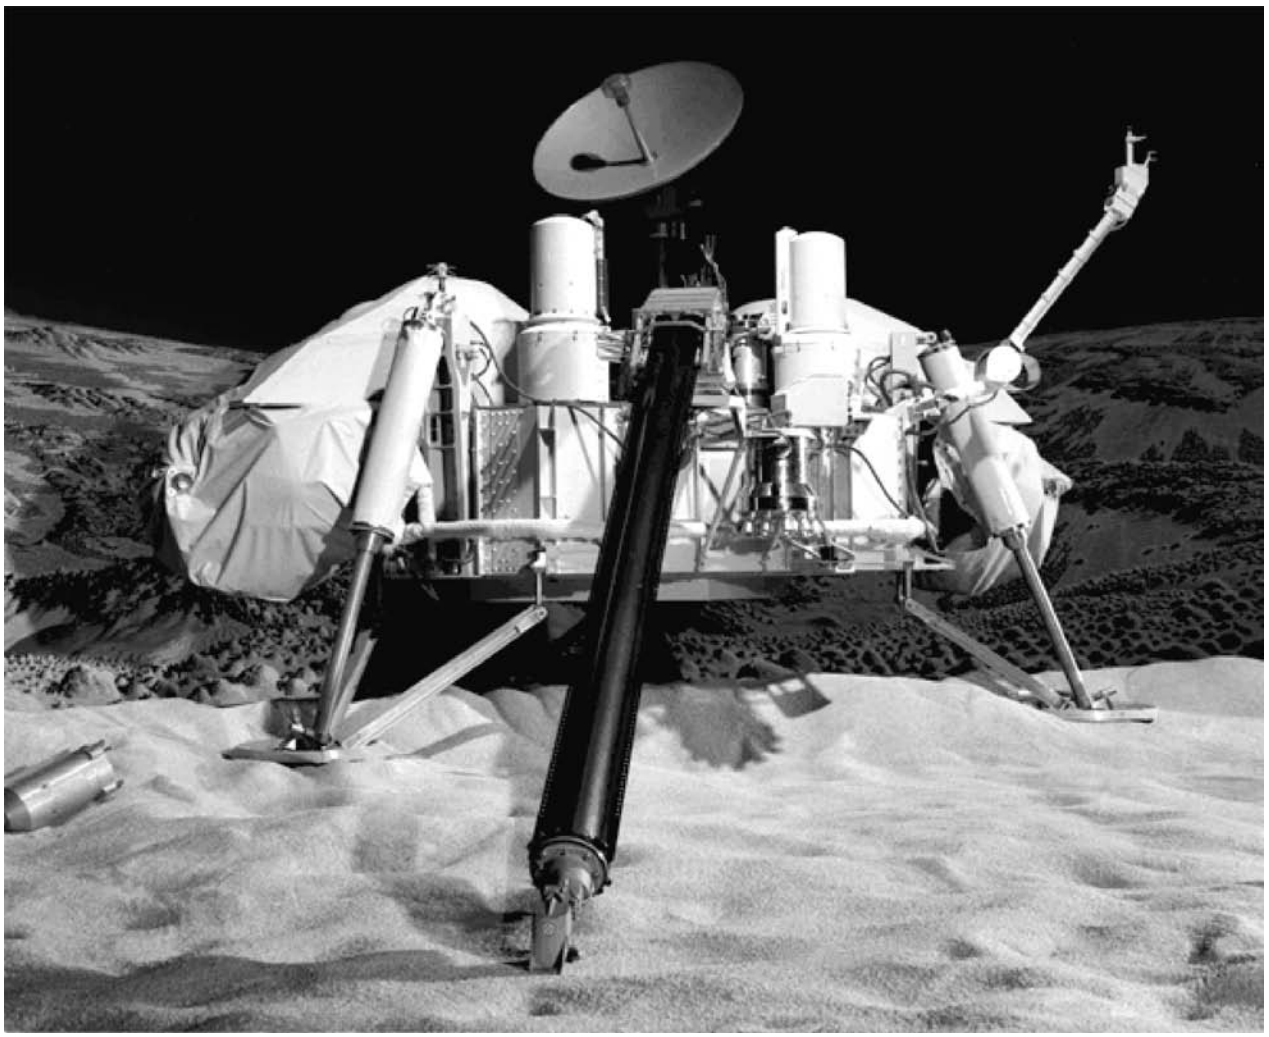

Fig. 3. *Viking* Lander 2.

Energy Research and Development Administration. They were located atop the lander and were connected in series to double their voltage and reduce power loss.

The SNAP 19 *Viking generator* was 147 centimeters (23 inches) across the housing fin tips, 96 centimeters (15 inches) in length and weighed 15.3 kilograms (34 pounds).

The first isotopic space generator was put into service in June 1961, on a Navy navigational satellite. Advances in SNAP systems were made with the development and flight of SNAP 19 aboard Nimbus III, launched in April 1969. This use of SNAP 19 represented a major milestone in the development of long-lived, highly reliable isotope power systems for space use by NASA. The SNAP 27 generator was developed to power five science stations left on the Moon by the *Apollo 12, 14, 15, 16* and *17* astronauts. The continuing operation of these generators provided new dimensions of data about the Moon and the universe. Four SNAP 19 nuclear generators later provided the electrical power for each of two NASA pioneering Jupiter flyby spacecraft known as *Pioneers 10* and *11*.

The generators provided a long-lived source of electricity and heat on Mars, where sunlight is half as strong as on Earth, and is non-existent during the Martian night, when temperatures can drop as low as $-120\,^{\circ}$C ($-184\,^{\circ}$F).

The generators used thermoelectric elements to convert heat from decaying plutonium-236 into 70 watts of electrical power.

Waste heat or unconverted heat was conveyed by thermal switches to the lander's interior instrument compartment, when required. Covers over the RTGs pre-vented excess heat dissipation into the environment.

Four nickel-cadmium, rechargeable batteries helped supply lander power requirements in peak activity periods. The batteries, mounted in pairs inside the lander, were charged by the RTGs with power available when other lander power requirements were less than RTG output.

This equipment collected and controlled the flow of lander scientific and engineering data. It consisted of a data acquisition and processing unit, a data storage memory and a tape recorder.

The data acquisition and processing unit collected the science and engineering information and routed it to one of three places: to Earth through the S-band high-gain antenna, to the data storage memory or to the tape recorder.

Information was stored in the data storage memory for short periods. Several times a day the memory would transfer data to the tape recorder or back to the data acquisition and processing unit for further transmission. The memory had a storage capacity of 8,200 words.

Data were stored on the tape recorder for long periods. The recorder could transmit at high speed back through the data acquisition and processing unit, and the UHF link to an orbiter passing overhead. The recorder could store as many as 40 million bits of information and it could record at two speeds and play back at five.

Science Experiments

With a single exception, the seismic instruments, the science instruments acquired more data than expected. The seismometer on *Viking Lander 1* would not work after landing, and the seismometer on *Viking Lander 2* detected only one event that may have been seismic. Nevertheless, it provided data on wind velocity at the landing site to supplement information from the meteorology experiment, and showed that Mars has very low seismic background.

The three biology experiments discovered unexpected and enigmatic chemical activity in the Martian soil, but provided no clear evidence for the

presence of living microorganisms in soil near the landing sites. According to mission biologists, Mars is self-sterilizing. They believe the combination of solar ultraviolet radiation that saturates the surface, the extreme dryness of the soil and the oxidizing nature of the soil chemistry prevent the formation of living organisms in the Martian soil. The question of life on Mars at some time in the distant past remains open.

The landers' gas chromatograph/mass spectrometer instruments found no sign of organic chemistry at either landing site, but they did provide a precise and definitive analysis of the composition of the Martian atmosphere and found previously undetected trace elements. The X-ray fluorescence spectrometers measured elemental composition of the Martian soil.

Viking measured physical and magnetic properties of the soil. As the landers descended toward the surface they also measured composition and physical properties of the Martian upper atmosphere.

The two landers continuously monitored weather at the landing sites. Weather in the Martian midsummer was repetitious, but in other seasons it became variable and more interesting. Cyclic variations appeared in weather patterns (probably the passage of alternating cyclones and anticyclones). Atmospheric temperatures at the southern landing site (*Viking Lander 1*) were as high as $-14\,^{\circ}C$ ($7\,^{\circ}F$) at midday, and the predawn summer temperature was $-77\,^{\circ}C$ ($-107\,^{\circ}F$). In contrast, the diurnal temperatures at the northern landing site (*Viking Lander 2*) during midwinter dust storms varied as little as $4\,^{\circ}C$ ($7\,^{\circ}F$) on some days. The lowest predawn temperature was $-120\,^{\circ}C$ ($-184\,^{\circ}F$), about the frost point of carbon dioxide. A thin layer of water frost covered the ground around *Viking Lander 2* each winter.

Barometric pressure varies at each landing site on a semiannual basis, because carbon dioxide, the major constituent of the atmosphere, freezes out to form an immense polar cap, alternately at each pole. The carbon dioxide forms a great cover of snow and then evaporates again with the coming of spring in each hemisphere. When the southern cap was largest, the mean daily pressure observed by *Viking Lander 1* was as low as 6.8 millibars; at other times of the year it was as high as 9.0 millibars. The pressures at the *Viking Lander 2* site were 7.3 and 10.8 millibars. (For comparison, the surface pressure on Earth at sea level is about 1,000 millibars.)

Martian winds generally blow more slowly than expected. Scientists had expected them to reach speeds of several hundred miles an hour from observing global dust storms, but neither lander recorded gusts over 120 kilometers (74 miles) an hour, and average velocities were considerably lower. Nevertheless, the orbiters observed more than a dozen small dust storms. During the first southern summer, two global dust storms occurred, about four Earth months apart. Both storms obscured the Sun at the landing sites for a time and hid most of the planet's surface from the orbiters' cameras. The strong winds that caused the storms blew in the southern hemisphere.

Photographs from the landers and orbiters surpassed expectations in quality and quantity. The total exceeded 4,500 from the landers and 52,000 from the orbiters. The landers provided the first close-up look at the surface, monitored variations in atmospheric opacity over several Martian years, and determined the mean size of the atmospheric aerosols. The orbiter cameras observed new and often puzzling terrain and provided clearer detail on known features, including some color and stereo observations. *Viking's orbiters* mapped 97 percent of the Martian surface.

The infrared thermal mappers and the atmospheric water detectors on the orbiters acquired data almost daily, observing the planet at low and high resolution. The massive quantity of data from the two instruments will require considerable time for analysis. Understanding of the global meteorology of Mars *Viking* also definitively determined that the residual north polar ice cap (that survives the northern summer) is water ice, rather than frozen carbon dioxide (dry ice) as once believed.

Analysis of radio signals from the landers and the orbiters — including Doppler, ranging and occultation data, and the signal strength of the lander-to-orbiter relay link — provided much valuable information. See also **Mars**.

Other Significant Discoveries

Other significant discoveries of the *Viking* mission included:

- The Martian surface is a type of iron-rich clay that contains a highly oxidizing substance that releases oxygen when it is wetted.
- The surface contains no organic molecules that were detectable at the parts per billion level, less in fact, than soil samples returned from the Moon by Apollo astronauts.
- Nitrogen, never before detected, is a significant component of the Martian atmosphere, and enrichment of the heavier isotopes of nitrogen and argon relative to the lighter isotopes implies that atmospheric density was much greater than in the distant past.
- Changes in the Martian surface occur extremely slowly, at least at the Viking landing sites. Only a few small changes took place during the mission life-time.
- The greatest concentration of water vapor in the atmosphere is near the edge of the north polar cap in midsummer. From summer to fall, peak concentration moves toward the equator, with a 30% decrease in peak abundance. In southern summer, the planet is dry, probably also an effect of the dust storms.
- The density of both of Mars' satellites is low, about two grams per cubic centimeter, implying that they originated as asteroids captured by Mars' gravity. The surface of Phobos is marked with two families of parallel striations, probably fractures caused by a large impact that may nearly have broken Phobos apart.
- Measurements of the round-trip time for radio signals between Earth and the *Viking* spacecraft, made while Mars was beyond the Sun (near the solar conjunctions), have determined delay of the signals caused by the Sun's gravitational field. The result confirms Albert Einstein's prediction to an estimated accuracy of 0.1%. This is 20 times greater than any other test.
- Atmospheric pressure varies by 30% during the Martian year because carbon dioxide condenses and sublimes at the polar caps.
- The permanent north cap is water ice; the southern cap probably retains some carbon dioxide ice through the summer.
- Water vapor is relatively abundant only in the far north during the summer, but subsurface water (permafrost) covers much if not all of the planet.
- Northern and Southern Hemispheres are drastically different climatically, because of the global dust storms that originate in the south in summer.

VILLEMIN, JEAN-ANTOINE (1827–1912). Villemin was a French physician who in animal experiments demonstrated the transmissibility of tuberculosis against prevailing beliefs in heredity as the only determining factor.

Born in a small village in the Vosges, south of Strasbourg, Villemin was orphaned at an early age. He was fortunate to be helped by an uncle through an education which culminated in medical studies at the military teaching hospital at Strasbourg, where he went on the advice of the colonel of the regiment in which he had served by conscription during the historically eventful year of 1848. He qualified there in 1863, and then spent another year at the Imperial School at Val-de-Grâce, before serving for four years as an army doctor in a mounted regiment. It was said that it was here that he first formed his hypothesis after seeing three of Napoleon III's sturdy *cent-gardes*, accommodated in the same barrack-room, presenting successively with tuberculosis. This may or may not be anecdotal; but the structure of anatomical lesions in tuberculous patients struck him as remarkably similar to changes produced in glanders and syphilis, which had already proved to be 'specific and virulent diseases *par excellence*'. They had by then been shown by others to be *inoculable*; now Villemin set out to demonstrate a similar mode of transmission in tuberculosis in animal experiments, an essential part of the experimental comparative medicine and pathology founded in France by Claude Bernard (1813–1878) and François Magendie. See also **Bacteriology (The History)**; **Magendie, François (1783-1855)**; and **Tuberculosis**.

On 6 March 1865, he began his experiments with two healthy rabbits from the same litter. One was inoculated behind each ear with two small fragments and a quantity of liquid from the lungs of a patient recently deceased. Three months and two more inoculations later, the young animal still appeared healthy, having grown normally; but at postmortem both its intestines and lungs were found to contain numerous tubercles. The control animal kept throughout with its brother and sharing the hutch, showed no sign of tubercles. Many careful inoculation experiments followed: from cattle to rabbit, from rabbit to rabbit, from human to guinea-pig; and finally by injection of saliva and blood, respectively, from patients into rabbits.

With positive results from all experiments Villemin was satisfied he had proved his point; but his critics were still not convinced. He tirelessly continued to defend his doctrine of the spread of tuberculosis by contagion; but final vindication came only in 1882, when Robert Koch isolated the tubercle bacillus. CHRISTOPH GRADMANN, University of Heidelberg,
Heidelberg, Germany

VINEGAR. Vinegar is the liquid condiment or food flavoring used to give a sharp or sour taste to foods. It is also used as a preservative in pickling and as the sour component in many different sauces, dressings, and gravies.

Vinegar results from the action of the enzymes of bacteria of the genus *Acetobacter* and some others on dilute solutions of ethyl alcohol such as cider, wine, beer, or diluted distilled alcohol. See also **Ethyl Alcohol**. Most vinegars for table use, e.g., in the dressing of salads, derive from the acetic acid–bacterial fermentation of wine or cider. See also **Acetic Acid**. These latter, in turn, are produced by alcoholic fermentation of dilute sugar solutions such as grape juice, apple juice, or malt. See also **Fermentation**. *Saccharomyces cerevisiae* is the yeast involved most frequently in alcoholic fermentation, i.e., in the enzymatic conversion of fermentable sugars to dilute alcoholic solutions. See also **Yeasts and Molds**. Although fruits and honey are used most frequently as sources of fermentable sugar for vinegar production, barley malt and, in the Orient, rice, after hydrolysis of starch, serve as primary sources. See also **Food Processing**.

A number of factors govern the composition of vinegar: the nature of the raw material, the substances added to promote alcoholic fermentation and the growth and activity of *Acetobacter*, the procedure used for the acetification, and finally the aging, stabilization, and bottling operations. Vinegars are made from natural solutions containing fermentable sugars, such as fruit juices and honey; solutions in which the sugars are produced by hydrolysis of starch, such as beers and sake; and solutions of distilled ethyl alcohol. Distilled alcohol, in turn, can be derived from the sugars of fruits or that from hydrolysis of starch, or from synthetic processes such as the hydration of ethylene from petroleum. Most countries distinguish between fermentation vinegars and synthetic vinegars. Mediterranean countries usually permit only fermentation vinegars (some only wine vinegar) as foods, whereas in some northern European countries even dilute solutions of synthetic acetic acid are acceptable. Grape and apple juices usually contain all of the trace nutrients required by *Saccharomyces* for fermentation of sugars to alcohol. Other fruit and diluted honey, as well as barley malt and rice extract, frequently need additions of nitrogen, phosphorus, and potassium compounds, together with some autolyzed yeast to facilitate the yeast growth necessary for fermentation.

Manufacture

Primitive people very likely encountered vinegar-like liquids in hollows in rocks or downed timber into which berries or fruit had fallen. Wild yeasts and bacteria would convert the natural sugars to alcohol and acetic acid. Later, when early peoples had learned to make wines and beers, they certainly would have found that these liquids, unprotected from air, would turn to vinegar. One can postulate that such early vinegars were frequently sweet, because the fruit sugars would have been acted on simultaneously by both bacteria and yeast. Only since the mid-1800s has it been known that yeast and bacteria are the cause of fermentation and vinegar formation.

Starch Hydrolysis and Alcoholic Fermentation. In general, because yeasts cannot utilize starch directly as a carbon source, the starch must first be hydrolyzed to sugar. Malt vinegars are made from malted barley or a mixture of malted barley with other starchy grains. Malt enzymes convert starch to sugars readily fermentable by *Saccharomyces* yeasts. In Japan, where vinegars are made from rice, a mixture of hydrolyzing enzymes produced by the fungus *Aspergillus oryzae* converts rice starches to sugars. Alcoholic fermentation is frequently conducted in two phases, although in a modern vinegar plant it can be conducted in one. The first phase is a vigorous fermentation during which the rapid evolution of carbon dioxide protects the alcoholic solution from air. The second or slower phase is fermentation of the residual sugar at a lower rate, during which, again, protection from air is required. In the first phase, 50–100 mg SO_2/L of sugarcontaining mash is added, followed after approximately 1 h by 1–3% of an actively fermenting, pure-culture starter of *Saccharomyces cerevisiae*. The fermentation process is monitored for disappearance of sugar and increase in temperature. Rates of alcoholic fermentation are highest at ca 25–30 °C; higher temperatures tend to damage enzyme systems.

Both the fermentation of hexose sugars to ethanol and carbon dioxide and the oxidation of ethanol to acetic acid are exothermic (heat yielding) processes. See also **Sugar**. Depending on the size of the fermenter and the rates of fermentation and aeration, loss of waste heat is apportioned among radiation, conduction, and vaporization of water and ethanol plus carbon dioxide. Although small fermenters may require no cooling, large ones require more cooling than occurs through natural radiation and conductance.

Acetic Acid. Ethyl alcohol is converted to acetic acid by air oxidation catalyzed by the enzymes within bacteria of the genus *Acetobacter*:

$$46\text{g}C_2H_5OH + 32\text{g}O_2 \longrightarrow \text{g}CH_3COOH + 18\text{g}H_2O + 487.2\text{kJ}(116.4)\text{kcal}$$

One gram of ethanol should yield 1.304 g acetic acid. Practical yields are 77–85%. In contrast with the well-known Embden-Meyerhof-Parnass glycolysis pathway for the conversion of hexose sugars to alcohol, the steps in conversion of ethanol to acetic acid remain in some doubt.

Orleans Process. In the Orleans process, wine oxidizes slowly in a barrel where it is covered with a film of *Acetobacter*. Holes that are covered with screens to exclude insects are bored in each barrel head to permit access to air. Wine is added through the bung hole with a long-stemmed funnel below the surface of the bacterial film and without disturbing the film. Wines with 10–12% ethanol give vinegars of 8–10% acetic acid concentration. Orleans vinegars are characterized by a relatively high concentration of ethyl acetate, detected by its pleasantly strong fruity odor.

Modena-Style or Balsamic Vinegar Process. Balsamic vinegars are made in and around the city of Modena in central Italy and consist of two general types. The traditional product is made from juice of the Trebbiano grape concentrated to about 40% sugar by direct flame heating of the container. *Zygosaccharomyces, Saccharomyces cerevisiae*, and *Gluconobacter* in barrels convert the sugars to ethyl alcohol and gluconic acid as principal products. The ethyl alcohol is converted to acetic acid by the *Acetobacter* and *Gluconobacter*. Subsequent reactions form many taste and odor substances, among which the ester ethyl acetate is of key importance. Years of age in barrels result in a condiment having a harmonious balance of sweetness and tartness. Aceto Balsamico di Modena differs from the Tradizionale in that it is a blend of ordinary wine vinegar with concentrate. Lacking the complex character of Tradizionale and being younger, it is much less expensive.

Generator Process. Generators are packed with shavings of beech wood, which tend to curl and thus provide packing that does not consolidate but allows open spaces for the free flow of liquid and air. Beech wood does not contribute undesirable flavors or impurities to the vinegar. In the modern generator, a recirculating pump transfers the partially acetified alcoholic mixture from the bottom section of the generator to a distributing system at the top of the packed section. Cooling coils may be located in the packed section, but more frequently are placed at the bottom of the receiver section or are incorporated in the line for recirculating the liquid.

Various species and many strains of *Acetobacter* are used in vinegar production. Aeration rates, optimum temperatures and nutrient requirements vary with individual strains. In general, fermentation alcohol substrates require minimal nutrient supplementation while their addition is necessary for distilled alcohol substrates.

Adaptation of the surface-film growth procedure for producing antibiotics to an aerated submerged-culture process has been successful in making vinegar.

The most widely used submerged-culture oxidizer is the Frings acetator. It uses a bottom-driven hollow rotor turning in a field of stationary vanes arranged in such a way that the air which is drawn in is intimately mixed with the liquid throughout the whole bottom area of the tank.

Submerged-culture oxidizers are usually operated on a semicontinuous basis. In most cases, ca half the liquid in the tank is removed every 1–2 d, when the alcohol concentration has dropped to 0.1–0.2 vol %. The removed vinegar is replaced with wine or mash of richer ethanol and

lower acetic acid concentration, giving a mixture in the tank of 5–6 vol % ethanol and 6–8 vol % of acetic acid. These are the optimum conditions for *Acetobacter* growth.

Foam production is most troublesome under conditions adverse to bacterial growth and thus can be minimized by keeping nutrient, ethanol, and acetic acid concentrations in the optimum ranges. See also **Defoaming Agents**. Temperature and aeration rate are also critical.

Submerged culture oxidizers can also be operated on a continuous basis. Optimum production, however, is achieved by semicontinuous operation because the composition of vinegar desired in the withdrawal stream is so low in ethanol that vigorous bacterial growth is impeded. Bacterial concentrations up to 100×10^6cells/cm^3 have been reported in generators making about 20% vinegars.

Fluidized-Bed Vinegar Reactors. Intimate contact of air with *Acetobacter* cells is achieved in fluidized-bed or tower-type systems. Air introduced through perforations in the bottom of each unit suspends the mixture of liquid and microorganisms within the unit. Air bubbles penetrating the bottom plate keep *Acetobacter* in suspension and active for the ethanol oxidation in the liquid phase.

Vinegars with High Concentrations of Acetic Acid. The U.S. regulations require at least 4 g acetic acid/100 cm^3 vinegar. Commercial vinegar and many quality table vinegars are significantly more concentrated. Submerged-culture oxidizers easily give acetic acid concentrations of 10–13 g/cm^3. Submerged-culture oxidizer techniques that produce vinegars with acetic acid concentrations ranging from 15–20% are now in commercial use. Continuous aeration, careful stepwise addition of ethanol as it is oxidized and careful control of temperature seem to be the keys to successful operation.

Vinegar Eels and Mother of Vinegar. Although esthetically undesirable, nematodes, known as vinegar eels, may actually be of some assistance in consuming dead bacteria from the surface of the packing material in the vinegar tank, and thus may aid in prolonging the operation of the system. Vinegar eels are removed from the raw vinegar by filtration and pasteurization before the vinegar is sold or used further in pickling or other processes.

Processing

Raw vinegars vary widely in stability and may contain materials that form cloudiness or deposits. Vinegars that carry a high and cloud suspension of bacterial cells are clarified and stabilized with bentonite and similar agents or activated carbon. Membrane filtration can be combined with aseptic bottling to provide a product free of all microorganisms. Wine, cider, and malt vinegars benefit from aging, which improves the character of the product. Vinegars bottled for table use and pickling usually are pasteurized at 77–78 °C.

VINEGAR EEL *(Nematoda)*. A minute roundworm, *Anguillula (Turbatrix) aceti*, found in the "mother" of vinegar. It reaches a length of 2 millimeters. The worms have been found in other situations, including the human bladder.

VINYL CHLORIDE. [CAS: 75-01-4] Vinyl chloride, $CH_2{=}CHCl$, by virtue of the wide range of application for its polymers in both flexible and rigid forms, is a major commodity chemical in the U.S. and an important item of international commerce. Growth in vinyl chloride production is directly related to demand for its polymers and, on an energy-equivalent basis, rigid poly(vinyl chloride) (PVC) [CAS: 9002-86-2] is one of the most energy-efficient construction materials available.

Vinyl chloride (also known as chloroethylene or chloroethene) is a colorless gas at normal temperature and pressure, but is typically handled as the liquid (bp −13.4 °C (7.9 °F). However, no human contact with the liquid is permissible. Vinyl chloride is an OSHA-regulated material.

The early history of vinyl chloride has been documented Justus von Liebig at the University of Giessen, Germany, won the distinction of being the first person to synthesize vinyl chloride when, in the 1830s, he reacted the so-called oil of the Dutch chemists, dichloroethane [CAS: 1300-21-6], with alcoholic potash to make vinyl chloride. Liebig's student, Victor Regnault, confirmed his discovery and was allowed to publish it as sole author in 1835. In 1872, E. Baumann observed that white flakes precipitated from vinyl chloride upon prolonged exposure to sunlight in a sealed tube. This material was further investigated in the early 1900s by Ivan Ostromislensky, who named it *Kauprenchlorid* (cauprene chloride), and gave it the empirical formula $(C_2H_3Cl)_{16}$. However, vinyl chloride was of little commercial interest until Waldo Semon's work with plasticized PVC for the B.F. Goodrich Company beginning in 1926. Some years earlier, Fritz Klatte had developed the first practical route to vinyl chloride while looking to find uses for acetylene [CAS: 74-86-2] for Chemische Fabrik Griesheim-Elektron. This process, in which hydrogen chloride [CAS: 7647-01-0], HCl, is added to acetylene over a mercuric chloride [CAS: 7487-94-7] catalyst, was patented in 1912. By 1926, Griesheim-Elektron had concluded that the patent held no commercial value and allowed it to lapse. Klatte's process eventually formed the basis of the vinyl chloride industry for many years from its beginnings in the 1930s, but it was ultimately supplanted by a balanced process from ethylene [CAS: 74-85-1] and chlorine [CAS: 7782-50-5] in which vinyl chloride is made by pyrolysis of 1,2-dichloroethane [CAS: 107-06-2] (ethylene dichloride (EDC)).

Properties. Vinyl chloride and water [CAS: 7732-18-5] are nearly immiscible. Vinyl chloride is soluble in hydrocarbons, oil, alcohol, chlorinated solvents, and most common organic liquids.

Reactions

Polymerization. The most important reaction of vinyl chloride is its polymerization and copolymerization in the presence of a radical-generating initiator.

Vinyl chloride is generally considered inert to nucleophilic replacement compared to other alkyl halides. However, the chlorine atom can be exchanged under nucleophilic conditions in the presence of palladium [CAS: 7440-05-3], Pd, and certain other metal chlorides and salts. Vinyl alcoholates, esters, and ethers can be readily produced from these reactions.

Use of alcohol as a solvent for carbonylation with reduced Pd catalysts gives vinyl esters. A variety of acrylamides can be made through oxidative addition of carbon monoxide [CAS: 630-08-0], CO, and various amines to vinyl chloride in the presence of phosphine complexes of Pd or other precious metals as catalyst

Vinylmagnesium chloride [CAS: 3536-96-7] (Grignard reagent) can be prepared from vinyl chloride and then used to make a variety of useful end products or intermediates by adding a vinyl anion to organic functional groups. For instance, the vinylmagnesium compounds can be coupled with cuprous chloride [CAS: 7758-89-6], CuCl, at −60 °C (−76 °F) to give 1,3-butadiene [CAS: 106-99-0], while vinyl ketones and alcohols can be prepared by the addition of vinylmagnesium chloride to organic acids.

Vinyl chloride similarly undergoes Grignard reactions with other organomagnesium halide compounds. For example, cross-coupling with 1- or 2-phenylethylmagnesium bromide [CAS: 41745-02-2 or CAS: 3277-89-2] yields 4- or 3-phenyl-1-butene [CAS: 768-56-9 or CAS: 934-10-1], respectively, whereas 4-(3-methyl-2-butenyl)styrene [CAS: 85964-33-6] (*p*-prenylstyrene) is obtained by coupling 4-(3-methyl-2-butenyl)phenylmagnesium chloride [CAS: 106364-41-4] with vinyl chloride.

Vinyllithium [CAS: 917-57-7] another reactive intermediate, can be formed directly from vinyl chloride by means of a lithium [CAS: 7439-93-2] dispersion containing 2 wt % sodium [CAS: 7440-23-5] at 0–10 °C (32–50 °F). This compound is a reactive intermediate for the formation

of vinyl alcohols from aldehydes, vinyl ketones from organic acids, vinyl sulfides from disulfides, and monosubstituted alkenes from organic halides.

Vinyl chloride reacts with sulfides, thiols, alcohols, and oximes in basic media. Reaction with hydrated sodium sulfide [CAS: 1313-82-2] in a mixture of dimethyl sulfoxide [CAS: 67-68-5] (DMSO) and potassium hydroxide [CAS: 1310-58-3], KOH, yields divinyl sulfide [CAS: 627-51-0] and sulfur-containing heterocycles.

Finally, the reaction of vinyl chloride with hydrogen fluoride [CAS: 7664-39-3], HF, over a chromia [CAS: 1308-38-9], Cr_2O_3, on alumina [CAS: 1344-28-1], Al_2O_3, catalyst at 380 °C (716 °F) yields vinyl fluoride.

Oxidation. The chlorine atom [CAS: 22537-15-1]-initiated, gas phase oxidation of vinyl chloride yields 74% formyl chloride [CAS: 2565-30-2] and 25% CO at high oxygen [CAS: 7782-44-7], O_2, to Cl_2 ratios. It is unique among chloro olefin oxidations because CO is a major initial product and because the reaction proceeds by a nonchain path.

The oxidation of vinyl chloride with oxygen in the gas phase proceeds by a nonradical path which, again, is unique among the chloro olefins. No C_2 carbonyl compounds are made; the major products are formyl chloride, CO, HCl, and formic acid [CAS: 64-18-6]. Complete oxidation of vinyl chloride with oxygen in the gas phase can be achieved using a cobalt chromite [CAS: 12016-69-2] catalyst. At −15 to −20 °C, vinyl chloride reacts with oxygen, with ultraviolet (uv) light initiation, to give a peroxide, reported as $[OCH_2CHClO]_2$. On heating to 35 °C (95 °F), this peroxide decomposes to formaldehyde [CAS: 50-00-0], CO, and HCl.

Oxidation of vinyl chloride with ozone [CAS: 10028-15-6] in either the liquid or the gas phase gives formic acid and formyl chloride. The ozone reaction with vinyl chloride can be used to remove it from gas streams in vinyl chloride production plants.

Vinyl chloride can be completely oxidized to CO_2 and HCl using potassium permanganate [CAS: 7722-64-7] in an aqueous solution at pH 10. The combustion of vinyl chloride in air produces mainly CO_2 and HCl, along with CO and a trace of phosgene.

Vinyl chloride undergoes a wide variety of addition reactions. Chlorine adds to vinyl chloride to form 1,1,2-trichloroethane [CAS: 79-00-5] by either an ionic or a radical path. Hydrogen halides add to vinyl chloride, usually to yield the 1,1-adduct. Many other vinyl chloride adducts can be formed under acid-catalyzed Friedel-Crafts conditions. Vinyl chloride can be hydrogenated to ethyl chloride and ethane over a platinum on alumina catalyst.

Vinyl chloride is subject to photodissociation. Photoexcitation at 193 nm results in the elimination of HCl fragments and Cl atoms in an approximately 1.1:1 ratio. Both vinylidene ($^3B_2$) [CAS: 2143-69-3] and acetylene have been observed as photolysis products, as have H_2 molecules and H atoms [CAS: 12385-13-6].

Vinyl chloride is more stable than saturated chloroalkanes to thermal pyrolysis. That is why nearly all vinyl chloride made commercially comes from thermal dehydrochlorination of ethylene dichloride (EDC). When vinyl chloride is heated to 450 °C (842 °F), only small amounts of acetylene form. Decomposition of vinyl chloride via a free-radical chain process begins at approximately 550 °C (1,022 °F), and increases with increasing temperature. Acetylene, HCl, chloroprene, and vinylacetylene [CAS: 689-97-4] are formed in about 35% total yield at 680 °C (1,256 °F). At higher temperatures, tar and soot formation becomes increasingly important. When dry and in contact with metals, vinyl chloride does not decompose below 450 °C (842 °F). However, if water is present, vinyl chloride can corrode iron, steel, and aluminum because of the presence of trace amounts of HCl. This HCl may result from the hydrolysis of the peroxide formed between oxygen and vinyl chloride.

Manufacture. Vinyl chloride monomer was first produced commercially in the 1930s from the reaction of HCl with acetylene derived from calcium carbide [CAS: 75-20-7]. After ethylene became plentiful in the early 1950s, commercial processes were developed to produce vinyl chloride from ethylene and chlorine. These processes included direct chlorination of ethylene to form EDC, followed by pyrolysis of EDC to make vinyl chloride. However, because the EDC cracking process also produced HCl as a coproduct, the industry did not expand immediately, except in conjunction with acetylene-based technology. The development of ethylene oxychlorination technology in the late 1950s encouraged new growth in the vinyl chloride industry. In this process, ethylene reacts with HCl and oxygen to form EDC. Combining the component processes of direct chlorination, EDC pyrolysis, and oxychlorination provided the so-called balanced process for production of vinyl chloride from ethylene and chlorine with no net consumption or production of HCl.

Although a small fraction of the world's vinyl chloride capacity is still based on acetylene or mixed acetylene–ethylene feedstocks, nearly all production is conducted by the balanced process based on ethylene and chlorine.

Direct chlorination of ethylene is usually conducted in liquid EDC in a bubble column reactor. Under typical process conditions, the reaction rate is controlled by mass transfer, with absorption of ethylene as the limiting factor. Ferric chloride is a highly selective and efficient catalyst for this reaction, and is widely used commercially. The direct chlorination process may be run with a slight excess of either ethylene or chlorine, depending on how effluent gases from the reactor are subsequently processed. Conversion of the limiting component is essentially 100%, and selectivity to EDC is greater than 99%. The direct chlorination reaction is exothermic ($\Delta H = -180$ kJ/mol for eq. 1) and requires heat removal for temperature control. One widely used method involves operating the reactor at the boiling point of EDC, allowing the pure product to vaporize, and then either recovering heat from the condensing vapor or replacing one or more EDC fractionation column reboilers with the reactor itself.

In oxychlorination, ethylene reacts with dry HCl and either air or pure oxygen to produce EDC and water. While commercial oxychlorination processes may differ from one another to some extent because they were developed independently by many different vinyl chloride producers, in each case the reaction is carried out in the vapor phase in either a fixed- or fluidized-bed reactor containing a modified Deacon catalyst. Cupric chloride is usually the primary active ingredient of the catalyst, supported on a porous substrate such as alumina, silica–alumina, or diatomaceous earth. The oxychlorination reaction is highly exothermic ($\Delta H = -239$ kJ/mol for eq. 3) and requires heat removal for temperature control.

Fluidized bed reactors typically are vertical cylindrical vessels equipped with a support grid and feed sparger system for adequate fluidization and feed distribution, internal cooling coils for heat removal, and either external or internal cyclones to minimize catalyst carryover. Fluidization of the catalyst assures intimate contact between feed and product vapors, catalyst, and heat-transfer surfaces, and results in a uniform temperature within the reactor. Reaction heat can be removed by generating steam within the cooling coils or by some other heat-transfer medium.

Fixed-bed reactors resemble multitube heat exchangers, with the catalyst packed in vertical tubes held in a tubesheet at top and bottom. Reaction heat can be removed by generating steam on the shell side of the reactor or by some other heat-transfer fluid. However, temperature control is more difficult in a fixed-bed than in a fluidized-bed reactor because localized hot spots tend to develop in the tubes.

In the air-based oxychlorination process with either reactor type, ethylene and air are fed in slight excess of stoichiometric requirements to ensure high conversion of HCl and to minimize losses of excess ethylene that remains in the vent gas after product condensation. Under these conditions, typical feedstock conversions are 94–99% for ethylene and 98–99.5% for HCl with EDC selectivities of 94–97%. The use of oxygen instead of air in the oxychlorination process with either reactor type allows operation with excess ethylene and at lower temperatures. This enables recycling of unconverted ethylene, resulting in improved operating efficiency and product yield. An important advantage of oxygen-based oxychlorination technology over air-based operation is the drastic reduction in volume of the vent gas discharged. Since nitrogen is no longer present in the reactor feed streams, only a small amount of purge gas (about 2–5% of the vent gas volume for air-based operation) is vented.

Direct chlorination usually produces EDC with a purity greater than 99.5 wt %, so that, except for removal of the $FeCl_3$, little further purification is needed before it can be cracked. EDC from the oxychlorination process, however, is less pure and requires purification by distillation.

Thermal pyrolysis or cracking of EDC to vinyl chloride and HCl occurs as a vapor-phase, homogeneous, first-order, free-radical chain reaction. The endothermic cracking of EDC ($\Delta H = 71$ kJ/mol EDC reacted for eq. 2) is relatively clean at atmospheric pressure and at temperatures of 425–550 °C (797–1,022 °F). Commercial pyrolysis units, however,

generally operate at gauge pressures of 1.4–3.0 MPa (200–435 psig) and at temperatures of 475–525 °C (887–977 °F) to provide for better heat transfer and reduced equipment size, and to allow separation of HCl from vinyl chloride by fractional distillation at noncryogenic temperatures. EDC conversion per pass through the pyrolysis reactor is normally maintained at 53–63%. Cracking reaction selectivity to vinyl chloride of > 99% can be achieved at these conditions. Increasing cracking severity beyond this level gives progressively smaller increases in EDC conversion, with progressively lower selectivity to vinyl chloride. Higher conversion also increases pyrolysis tube coking rates and causes problems with downstream product purification. To minimize coke formation, it is necessary to quench or cool the pyrolysis reactor effluent quickly. Therefore, the hot effluent gases are normally quenched and partially condensed by direct contact with cold EDC in a quench tower. Alternatively, the pyrolysis effluent gases can first be cooled by heat exchange with cold liquid EDC furnace feed in a transfer line exchanger (TLE) prior to quenching in the quench tower.

Quenched pyrolysis product is typically distilled to remove first HCl and then vinyl chloride. The vinyl chloride is usually further treated to produce specification product, recovered HCl is sent to the oxychlorination process, and unconverted EDC is purified for removal of by-products before it is recycled to the cracking furnace.

By-product disposal from vinyl chloride manufacturing plants is complicated by the need to process a variety of gaseous, organic liquid, aqueous, and solid streams, while ensuring that no chlorinated organic compounds are inadvertently released. Each class of by-product streams requires its own treatment and disposal system.

Vent streams from the different unit operations may contain traces (or more) of HCl, CO, methane, ethylene, chlorine, and vinyl chloride. The common treatment method is either incineration or catalytic combustion, followed by removal of HCl from the effluent gas. Organic liquid streams contain a variety of chlorinated compounds. When there is economic justification, these streams can be fractionated to recover specific, useful components, and the remainder subsequently incinerated and scrubbed to remove HCI. Alternative methods include catalytic oxidation or combustion, and may involve recycle of HCI to oxychlorination and recovery of the heat of combustion to make high pressure steam. Process water streams from vinyl chloride manufacture are typically steam-stripped to remove volatile organics, neutralized, and then treated in a conventional wastewater treatment process. Solid by-products include sludge from wastewater treatment, spent catalyst, and coke from the EDC pyrolysis process. These need to be disposed of in an environmentally sound manner, e.g., by sludge digestion, incineration, landfill, etc.

Environmental Considerations. Since the early 1980s, there has been much debate among environmental activist organizations, industry, and government about the impact of chlorine chemistry on the environment. One aspect of this debate involves the incidental manufacture and release of trace amounts of hazardous compounds such as polychlorinated dibenzodioxins, dibenzofurans, and biphenyls (PCDDs, PCDFs, and PCBs, respectively, but often referred to collectively as dioxins) during the production of chlorinated compounds like vinyl chloride. In 1994, the EPA released a review draft of its reassessment of the impact of dioxins in the environment on human health, which prompted speculation as to the amount of dioxins that might be attributed to chlorine-based industrial processes. The U.S. vinyl industry responded by committing to a voluntary characterization of dioxin levels in its products and in emissions from its facilities to the environment. The results of this study to date support the vinyl industry's position that it is a minor source of dioxins in the environment. In addition, a global benchmark study released recently by the American Society of Mechanical Engineers found no relationship between the chlorine content of waste and dioxin emissions from combustion processes.

Because of the toxicity of vinyl chloride, the EPA in 1975 proposed emission standards for vinyl chloride manufacture. This proposal was subsequently enacted as EPA Regulation 40 CFR 61, Subpart F. Compliance testing began in 1978. Environmental concerns and government regulations have prompted a major increase in the amount of add-on technology used in U.S. vinyl chloride production plants.

Health and Safety Factors

Vinyl chloride is an OSHA-regulated substance. Current OSHA regulations impose a permissible exposure limit (PEL) to vinyl chloride vapors of no more than 1.0 ppm averaged over any 8-h period. Short-term exposure is limited to 5.0 ppm averaged over any 15-min period. Wherever exposure is above the OSHA limit, respirators are required. Contact with liquid vinyl chloride is prohibited.

Chronic exposure to vinyl chloride at concentrations of 100 ppm or more is reported to have produced Raynaud's syndrome, lysis of the distal bones of the fingers, and a fibrosing dermatitis. However, these effects are probably related to continuous intimate contact with the skin. Chronic exposure to large amounts of vinyl chloride gas over a period of many years is also reported to have produced a rare cancer of the liver (angiosarcoma) in a small number of workers.

Vinyl chloride also poses a significant fire and explosion hazard. It has a wide flammability range, from 3.6% to 33.0% by volume in air. Large fires of the compound are very difficult to extinguish, while vapors represent a severe explosion hazard.

Vinyl chloride is generally transported via pipeline, and in railroad tank cars and tanker ships. Because hazardous peroxides can form on standing in air, especially in the presence of iron impurities, vinyl chloride should always be handled and transported under an inert atmosphere.

Uses

Vinyl chloride has gained worldwide importance because of its industrial use as the precursor to PVC. It is also used in a wide variety of copolymers. The inherent flame-retardant properties, wide range of plasticized compounds, and low cost of polymers from vinyl chloride have made it a significant industrial chemical. About 95% of current vinyl chloride production worldwide ends up in polymer or copolymer applications. Vinyl chloride also serves as a starting material for the synthesis of a variety of industrial compounds. The primary nonpolymeric uses of vinyl chloride are in the manufacture of vinylidene chloride and tri- and tetrachloroethylene [CAS: 127-18-4].

VINYL ESTER RESINS. The vinyl ester resins are a relatively recent addition[1] to thermosetting-polymer-chemistry. Superficially, they are similar to unsaturated polyester resins insofar as they contain ethylmic unsaturation and are cured through a free-radical mechanism, usually in the presence of a vinyl monomer, such as styrene. However, close examination

[1] The first literature reference was a patent issued in 1962 for a tooth-filling compound. Commercialization did not start until the late 1960s.

of the chemistry and structure of the vinyl ester resins demonstrates several basic differences which lead to their unique characteristics.

Vinyl ester resins are manufactured through an addition reaction of an epoxy resin with an acrylic monomer, such as acrylic acid, methacrylic acid, or the half-ester product of an hydroxyalkyl acrylate and anhydride. In contrast, the polyester resins are condensation products of dibasic acids and polyhydric alcohols. The relatively low-molecular-weight precise polymer structure of the vinyl ester resins is in contrast to the high-molecular-weight random structure of the polyesters.

Of particular importance in describing the difference between these two families of resins are the locations of the reactive unsaturation. In the polyester resin, these groups are located along the backbone of the polymer with terminal hydroxyl or carboxylic acid groups. In contrast, the vinyl ester resins contain no significant acidity but terminate in reactive vinyl ester groups. Because of the location of these reactive sites, the vinyl ester resins will homopolymerize as well as coreact with various vinyl monomers.

Resin Properties. Vinyl esters, because of their relatively low molecular weight and precise structure, can be characterized as low-viscosity, fast-wetting, consistent-reactivity products. Typical property profiles for some uncured vinyl ester resins are given in Table 1. Properties of some cured resins are given in Table 2. Typically, 6-month stability can be expected at 25 °C (77 °F) with decreased storage life under elevated temperatures. In general, anyone familiar with the proper storage and handling of unsaturated polyester resins and styrene monomer experiences no difficulty with these materials.

TABLE 1. PROPERTIES OF TYPICAL UNCURED VINYL ESTER RESINS

Property	Standard Resin	Low Viscosity Resin
Monomer type	styrene	styrene
Level, %	45	45
Viscosity at 77 °F (25 °C), centipoises	550	200
Acid number	5	5
Specific gravity	1.04	1.04
SPI gel time (1% benzoyl peroxide), minutes		
at 82 °C (180 °F)	10	12
at 121 °C (250 °F)	1.4	1.5
Flash point (Tag open cup)		
°C	34	34
°F	93	93

Cure Mechanism. The free-radical cure mechanism of the vinyl ester resins is well understood. In most respects, it is similar to that of the unsaturated polyester resins. To initiate the curing process, it is necessary to generate free radicals within the resin mass. Organic peroxides are the most common source of free radicals. These peroxides will decompose under the influence of elevated temperatures or chemical promoters, e.g., organometallics or tertiary amines, to form free radicals. Generation of free radicals also can be effected by ultraviolet or high-energy radiation applied directly to the resin system. The free radicals thus formed react to open the double bond of the vinyl group. Once opened, the resin vinyl group is highly reactive and rapidly combines with several more vinyl groups available from both the unreacted resin and the monomer. This exothermic reaction is rapidly carried to completion, forming a 3-dimensional thermosetting network.

Applications. As might be expected from the wide variation in resin properties that can be built into the molecule, the vinyl ester resins find many applications. Chief among these are fiberglass-reinforced plastics, where the inherent characteristics of the vinyl ester resin provide a cost and performance advantage over other materials. The largest application is in the manufacture of corrosion-resistant reinforced plastic structures. Because of the reduced number of ester groups within the resin structure, the corrosion-resistant vinyl ester resins are less prone to attack by hydrolysis than the bisphenol A-fumaric acid polyesters. In addition, the resilience of the vinyl ester resins (4–6% ultimate tensile elongation) results in a fabricated part which is less prone to damage during shipping, field erection, and service.

All fabrication methods commonly used in the manufacture of reinforced plastics can be used with the vinyl ester resins. In those applications, such as filament winding and bag molding, where fast wetting is important, significant increases in output can be realized. One technique to which vinyl ester resins are particularly suited is the use of sheet molding compound (SMC). Here, the resin system (usually with a high filler loading) is combined in sheet form with the glass reinforcement and chemically thickened through the use of metal oxides, such as MgO. The SMC then is molded, usually in a matched-die molding operation, to give the desired final product, e.g., automotive parts, appliance housings, electrical structures, and panel configurations. Vinyl ester resins diluted with vinyl toluene monomer are used in the production of high-temperature electrical laminating systems. See Structures 1 and 2.

VIPER FISHES *(Osteichthyes).* Of the order *Isospondyli*, family *Chauliodontidae*, viper fishes have an unattractive, snake-like appearance, which is dramatized by their large fanglike teeth. The three species all inhabit deep ocean waters, ranging from very cold to tropical. The longest of these species attains a length of about 10 inches (25 centimeters). In catching its prey, the fish swims with its mouth wide open and upper fangs extended so as to spear the victim. Studies have shown that these fishes engage in vertical migrations, moving upward some 1500 feet (450 meters) at night, but not known to surface.

VIPERINE SNAKES. See **Snakes**.

VIRAL HEMORRHAGIC FEVERS. The term viral hemorrhagic fever (VHF) refers to a group of illnesses that are caused by several distinct families of viruses. While some types of hemorrhagic fever viruses can cause relatively mild illnesses, many of these viruses cause severe, life-threatening disease.

The Special Pathogens Branch (SPB) primarily works with hemorrhagic fever viruses that are classified as biosafety level four (BSL-4) pathogens. A listing of these viruses appears in Table 1. The Division of Vector-Borne Infectious Diseases, also in the National Center for Infectious Diseases, works with the non-BSL-4 viruses that cause two other hemorrhagic fevers, dengue hemorrhagic fever and yellow fever.

VHFs are caused by viruses of four distinct families: arenaviruses, filoviruses, bunyaviruses, and flaviviruses. Each of these families share a number of features:

- They are all RNA viruses, and all are covered, or enveloped, in a fatty (lipid) coating.
- Their survival is dependent on an animal or insect host, called the natural reservoir.
- The viruses are geographically restricted to the areas where their host species live.
- Humans are not the natural reservoir for any of these viruses. Humans are infected when they come into contact with infected hosts. However, with some viruses, after the accidental transmission from the host, humans can transmit the virus to one another.
- Human cases or outbreaks of hemorrhagic fevers caused by these viruses occur sporadically and irregularly. The occurrence of outbreaks cannot be easily predicted.
- With a few noteworthy exceptions, there is no cure or established drug treatment for VHFs.

In rare cases, other viral and bacterial infections can cause a hemorrhagic fever; scrub typhus is a good example.

Viruses associated with a majority of the VHFs are zoonotic. This means that these viruses naturally reside in an animal reservoir host or arthropod vector. They are totally dependent on their hosts for replication and overall survival. For the most part, rodents and arthropods are the main reservoirs for viruses causing VHFs. The multimammate rat, cotton rat, deer mouse, house mouse, and other field rodents are examples of reservoir hosts. Arthropod ticks and mosquitoes serve as vectors for some of the illnesses. However, the hosts of some viruses remain unknown, Ebola and Marbur viruses are well-known examples.

The viruses that cause VHFs are distributed over much of the globe. However, because each virus is associated with one or more particular host species, the virus and the disease it causes are usually seen only where the host species live(s). Some hosts, such as the rodent species carrying several of the New World arenaviruses, live in geographically restricted areas. Therefore, the risk of getting VHFs caused by these viruses is restricted to those areas. Other hosts range over continents, such as the rodents that carry viruses which cause various forms of Hantavirus pulmonary syndrome (HPS) in North and South America, or the different set of rodents that carry viruses which cause hemorrhagic fever with renal syndrome (HFRS) in Europe and Asia. A few hosts are distributed nearly worldwide, such as the common rat. It can carry Seoul virus, a cause of HFRS; therefore, humans can get HFRS anywhere where the common rat is found.

Although people usually become infected only in areas where the host lives, occasionally people become infected by a host that has been exported from its native habitat. For example, the first outbreaks of Marburci hemorrhagic fever, in Marburg and Frankfurt, Germany, and in Yugoslavia, occurred when laboratory workers handled imported monkeys infected with Marburg virus. Occasionally, a person becomes infected in an area where the virus occurs naturally and then travels elsewhere. If the virus is a type that can be transmitted further by person-to-person contact, the traveler could infect other people. For instance, in 1996, a medical professional treating patients with Ebola hemorrhagic fever (Ebola HF) in Gabon unknowingly became infected. When he later traveled to South Africa and was treated for Ebola HF in a hospital, the virus was transmitted to a nurse. She became ill and died. Because more and more people travel each year, outbreaks of these diseases are becoming an increasing threat in places where they rarely, if ever, have been seen before.

Viruses causing hemorrhagic fever are initially transmitted to humans when the activities of infected reservoir hosts or vectors and humans overlap. The viruses carried in rodent reservoirs are transmitted when humans have contact with urine, fecal matter, saliva, or other body

TABLE 1. HEMORRHAGIC FEVER VIRUSES

Arenaviruses	Bunyaviruses	Filoviruses	Flaviviruses
Argentine Hemorrhagic fever	Crimean-Congo hemorrhagic fever (CCHF)	Ebola hemorrhagic fever	Tick-borne Encephalitis
Bolivian Hemorrhagic fever	Rift Valley fever	Marburg hemorrhagic fever	Kyasanur Forest disease
Sabia-associated Hemorrhagic fever	Hantavirus Pulmonary syndrome (HPS)		Omsk hemorrhagic fever
Lassa fever	Hemorrhagic fever with renal syndrome (HFRS)		
Lymphocytic Choriomeningitis (LCM)			
Venezuelan hemorrhagic fever			

excretions from infected rodents. The viruses associated with arthropod vectors are spread most often when the vector mosquito or tick bites a human, or when a human crushes a tick. However, some of these vectors may spread virus to animals, livestock, for example. Humans then become infected when they care for or slaughter the animals.

Some viruses that cause hemorrhagic fever can spread from one person to another, once an initial person has become infected. Ebola, Marburg, Lassa, and Crimean-Congo hemorrhagic fever viruses are examples. This type of secondary transmission of the virus can occur directly, through close contact with infected people or their body fluids. It can also occur indirectly, through contact with objects contaminated with infected body fluids. For example, contaminated syringes and needles have played an important role in spreading infection in outbreaks of Ebola hemorrhagic fever and Lassa fever.

Specific signs and symptoms vary by the type of VHF, but initial signs and symptoms often include marked fever, fatigue, dizziness, muscle aches, loss of strength, and exhaustion. Patients with severe cases of VHF often show signs of bleeding under the skin, in internal organs, or from body orifices like the mouth, eyes, or ears. However, although they may bleed from many sites around the body, patients rarely die because of blood loss. Severely ill patients cases may also show shock, nervous system malfunction, coma, delirium, and seizures. Some types of VHF are associated with renal (kidney) failure.

Treatment

Patients receive supportive therapy, but generally speaking, there is no other treatment or established cure for VHFS. Ribavirin, an antiviral drug, has been effective in treating some individuals with Lassa fever or HFRS. Treatment with convalescent-phase plasma has been used with success in some patients with Argentine hemorrhagic fever.

With the exception of yellow fever and Argentine hemorrhagic fever, for which vaccines have been developed, no vaccines exist that can protect against these diseases. Therefore, prevention efforts must concentrate on avoiding contact with host species. If prevention methods fail and a case of VHF does occur, efforts should focus on preventing further transmission from person to person, if the virus can be transmitted in this way.

Because many of the hosts that carry hemorrhagic fever viruses are rodents, disease prevention efforts include: controlling rodent populations; discouraging rodents from entering or living in homes or workplaces; and encouraging safe cleanup of rodent nests and droppings.

For hemorrhagic fever viruses spread by arthropod vectors, prevention efforts often focus on community-wide insect and arthropod control. In addition, people are encouraged to use insect repellant, proper clothing, bednets, window screens, and other insect barriers to avoid being bitten.

For those hemorrhagic fever viruses that can be transmitted from one person to another, avoiding close physical contact with infected people and their body fluids is the most important way of controlling the spread of disease. Barrier nursing or infection control techniques include isolating infected individuals and wearing protective clothing. Other infection control recommendations include proper use, disinfection, and disposal of instruments and equipment used in treating or caring for patients with VHF, such as needles and thermometers.

In conjunction with the World Health Organization, the CDC has developed practical, hospital-based guidelines, titled *Infection Control for Viral Haemorrhagic Fevers In the African Health Care Setting*. The manual can help health-care facilities recognize cases and prevent further hospital-based disease transmission using locally available materials and few financial resources.

Scientists and researchers are challenged with developing containment, treatment, and vaccine strategies for these diseases. Another goal is to develop immunologic and molecular tools for more rapid disease diagnosis, and to study how the viruses are transmitted and exactly how the disease affects the body (pathogenesis). A third goal is to understand the ecology of these viruses and their hosts in order to offer preventive public health advice for avoiding infection. See also **Arenaviruses**; **Dengue Fever and Dengue Hemorrhagic Fever**; **Ebola Hemorrhagic Fever**; **Filoviruses**; **Lassa Fever (African Hemorrhagic Fever)**; **Lymphocytic Choriomeningitis (LCM)**; **Marburg Hemorrhagic Fever**; **Rift Valley Fever**; and **Virus**.

An alphabetical listing of common terms that frequently occur in epidemiological and health prevention articles is listed below.

Aerosol: A fine mist or spray that contains minute particles.

Antibody: Proteins produced by an organism's immune system to recognize foreign substances.

Antigen: Any substance that stimulates an immune response by the body. The immune system recognizes such substances as being foreign, and produces cellular antibodies to fight them. Antigen/antibody response is an important part of a person's immunity to disease.

Assay: A quantitative or qualitative evaluation, or test, of a substance. Frequently used to describe tests of the presence or concentration of infectious agents, antibodies, etc.

Biosafety level: Specific combinations of work practices, safety equipment, and facilities, which are designed to minimize the exposure of workers and the environment to infectious agents. Biosafety level 1 applies to agents that do not ordinarily cause human disease. Biosafety level 2 is appropriate for agents that can cause human disease, but whose potential for transmission is limited. Biosafety level 3 applies to agents that may be transmitted by the respiratory route that can cause serious infection. Biosafety level 4 is used for the diagnosis of exotic agents that pose a high risk of life-threatening disease, which may be transmitted by the aerosol route and for which there is no vaccine or therapy.

Carrier: A person or animal that harbors a specific infectious agent without visible symptoms of the disease. A carrier acts as a potential source of infection.

Case-fatality proportion: The number of cases of a disease ending in death compared to the number of cases of the disease. Usually expressed as a percentage. Deaths from other diseases are often expressed as mortality rates; SPB normally uses case-fatality proportions. This is due to the fact that rates include a time determinant, for example, 100 deaths per 1000 cases per year. However, the diseases with which SPB works break out sporadically and occur as brief epidemics.

Case-to-infection ratio or proportion: The number of cases of a disease (in humans) compared to the number of infections with the agent that causes the disease (in humans).

Cotton rat *(Siqmodon hispidus):* Typically found in the southeastern United States and way down into Central and South America. The cotton rat has a bigger body than the deer mouse: head and body about 5–7 inches, and another 3–4 inches for the tail. The hair is longer and coarser, of a grayish brown color, even grayish black. The cotton rat prefers overgrown areas with shrubs and tall grasses.

Deer mouse *(Peromyscus maniculatus):* A deceptively cute animal, with big eyes and big ears. Its head and body are normally about 2–3 inches long, and the tail adds another 2–3 inches in length. A variety of colors, from gray to reddish brown, depending on its age may be seen. The underbelly is always white and the tail has sharply defined white sides. The deer mouse is found almost everywhere in North America. Usually, the deer mouse likes woodlands, but also turns up in desert areas.

Disease: Formally speaking, a disease is the condition in which the functioning of the body or a part of the body is interfered with or damaged. In a person with an infectious disease, the infectious agent that has entered the body causes it to function abnormally in some way or ways. The type of abnormal functioning that occurs is the disease. Usually the body will show some signs and symptoms of the problems it is having with functioning. Disease should not be confused with infection.

ELISA (enzyme-linked-immunosorbent serologic assay): A technique that relies on an enzymatic conversion reaction. It is used to detect the presence of specific substances, such as enzymes, viruses, antibodies or bacteria.

Endemic: Disease that is widespread in a given population.

Enzootic: A disease that is constantly present in the animal community, but only occurs in a small number of cases.

Epidemic: The occurrence of cases of an illness in a community or region which is in excess of the number of cases normally expected for that disease in that area at that time.

Epizootic: An outbreak or epidemic of disease in animal populations.

Host: An organism in which a parasite lives and by which it is nourished.

IgG: One of many antibodies present in blood serum that is usually indicative of a recent or remote infection. IgG is most prevalent about three weeks after an infection begins.

Igm: One of many antibodies present in blood serum that is usually indicative of an acute infection.

Immunohistochemistry: A type of assay in which specific antigens are made visible by the use of fluorescent dye or enzyme markers.

Infection: The entry and development of an infectious agent in the body of a person or animal. In an apparent "manifest" infection, the infected person outwardly appears to be sick. In an inapparent infection, there is no outward sign that an infectious agent has entered that person at all. For example, although humans have become infected with Ebola-Reston, a species of Ebola virus, they have not shown any sign of illness. By contrast, in recorded outbreaks of Ebola hemorrhagic fever caused by Ebola-Zaire, another species of Ebola virus, severe illness followed infection with the virus, and a great proportion of the case-patients died. Infection should not be confused with disease.

Multimammate rat *(M. elythroleucus or M. huberti):* Any of several species of the genus *Mastomys. Mastomys* rodents breed very frequently, producing large numbers of offspring. They are numerous in the savannas and forests of West, Central, and East Africa. Some species, like the *M. huberti* prefer to live in human homes.

Multimammate rats are known carriers of Lassa virus. See also **Lassa Fever (African Hemorrhagic Fever)**.

Nosocomial infection: An infection occurring in a patient which is acquired at a hospital or other healthcare facility. Commonly called a cross infection.

Report of a disease: An official report that notifies an appropriate health authority of the occurrence of a disease in a human or in an animal. Human diseases usually are reported first to the local health authority, such as a county health department.

Reservoir: Any person, animal, arthropod, plant, soil or substance in which an infective agent normally lives and multiplies. The infectious agent primarily depends on the reservoir for its survival.

Rice rat *(Orvzomys Palustris):* Slightly smaller than the cotton rat, having a head and body 5–6 inches long, plus a very long, 4- to 7-inch tail. The Rice rat has short soft grayish brown fur on top, and gray or tawny underbellies. Their feet are whitish. As you might expect from the name, this rat likes marshy areas and is semiaquatic. Typically the Rice rat can be found in the southeastern United States and in Central America.

Risk: (*1*) The chance of being exposed to an infectious agent by its specific transmission mechanism. (*2*) The chance of becoming infected if exposed to an infectious agent by its specific transmission mechanism.

RT-PCR (reverse transcriptase polymerase chain reaction): Powerful technique for producing millions of copies of specific parts of the genetic code of an organism so that it may be readily analyzed. More specifically, RT-PCR produces copies of a specific region of complementary DNA that has been converted from RNA. The technique is often used to help in the identification of an infectious agent.

Surveillance of disease: The ongoing systematic collection and analysis of data and the provision of information which leads to action being taken to prevent and control an infectious disease.

Transmission of infectious agents (such as a virus): Any mechanism through which an infectious agent, such as a virus, is spread from a reservoir (or source) to a human being. Usually, each type of infectious agent is spread by only one or a few of the different mechanisms.
There are several types of transmission mechanism:

Direct transmission: This type of transmission is, at base, immediate. The transfer of the infectious agent is, as the name implies, directly into the body. Different infectious agents may enter the body using different routes. Some routes by which infectious diseases are spread directly include personal contact, such as touching, biting, kissing, or sexual intercourse. In these cases the agent enters the body through the skin, mouth, an open cut or sore, or sexual organs. Infectious agents may spread by tiny droplets of spray directly into the conjunctiva (the mucus membranes of the eye), or the nose or mouth during sneezing, coughing, spitting, singing or talking (although usually this type of spread is limited to about within one meter's distance.) This is called droplet spread.

Indirect transmission: Indirect transmission may happen in any of several ways:

Vehicle-borne transmission: In this situation, a vehicle i.e., an inanimate object or material called in scientific terms a "fomite,"-becomes contaminated with the infectious agent. The agent, such as a virus, may or may not have multiplied or developed in or on the vehicle. The vehicle contacts the person's body. It may be ingested (eaten or drunk), touch the skin, or be introduced internally during surgery or medical treatment. Examples of vehicles that can transmit diseases include cooking or eating utensils, bedding or clothing, toys, surgical or medical instruments (like catheters) or dressings. Water, food, drinks (like milk) and biological products like blood, serum, plasma, tissues or organs can also be vehicles.

Vector-borne transmission: When researchers talk about vectors, often they are talking about insects, which as a group of invertebrate animals carry a host of different infectious agents. (However, a vector can be any living creature that transmits an infectious agent to humans.)

Vectors may mechanically spread the infectious agent, such as a virus or parasite. In this scenario the vector, for instance a mosquito, contaminates its feet or proboscis ("nose") with the infectious agent, or the agent passes through its gastrointestinal tract. The agent is transmitted from the vector when it bites or touches a person. In the case of an insect, the infectious agent may be injected with the insect's salivary fluid when it bites. Or the insect may regurgitate material or deposit feces on the skin, which then enter a person's body, typically through a bite wound or skin that has been broken by scratching or rubbing.

In the case of some infectious agents, vectors are only capable of transmitting the disease during a certain time period. In these situations, vectors play host to the agent. The agent needs the host to develop and mature or to reproduce (multiply) or both, (called cyclopropagative). Once the agent is within the vector animal, an incubation period follows during which the agent grows or reproduces, or both, depending on the type of agent. Only after this phase is over does the vector become infective. That is, only then can it transmit an agent that is capable of causing disease in the person.

Airborne transmission: In this type of transmission, infective agents are spread as aerosols, and usually enter a person through the respiratory tract. Aerosols are tiny particles, consisting in part or completely of the infectious agent itself, which become suspended in the air. These particles may remain suspended in the air for long periods of time, and some retain their ability to cause disease, while others degenerate due to the effects of sunlight, dryness or other conditions. When a person breathes in these particles, they become infected with the agent-especially in the alveoli of the lungs. How do infectious aerosols get into the air? Small particles of many different sizes contaminated with the infective agent may rise up from soil, clothes, bedding or floors when these are moved, cleaned, or blown by wind. These dust particles may be fungal spores (infective agents themselves) tiny bits of infected feces, or tiny particles of dirt or soil that have been contaminated with the agent.

Droplet nuclei can remain in the air for a long time. Droplet nuclei are usually the small residues that appear when fluid emitted from an infected host evaporates. In the case of the virus causing hantavirus pulmonary syndrome, the rodent carriers produce urine. The act of spraying the urine may create the aerosols directly, or the virus particles may rise into the air as the urine evaporates. In other situations, the droplets may occur as an unintended result of mechanical or work processes or atomization by heating, cooling, or venting systems in microbiology laboratories, autopsy rooms, slaughterhouses, or elsewhere.

Both kinds of particles are very tiny. Larger droplets or objects that may be sprayed or blown, but that immediately settle down on something rather than remaining suspended, are not considered to belong to the airborne transmission mechanism. Such sprays are considered direct transmission.

Vector: A carrier which transmits infective agent from one host to another.

Virus: A virus is an extremely tiny infectious agent that is only able to live inside a cell. Basically, viruses are composed of just two parts. The outer part is a protective shell made of protein. This shell is often surrounded by another protective layer or envelope, made of protein or lipids (fats). The inner part is made of genetic material, either RNA or DNA.

A virus does not have any other structures (called organelles) that living cells have, like a nucleus or mitochondria. These organelles are the tiny organs that maintain a cell's metabolism (life processes). A virus has no metabolism at all.

Because a virus lacks organelles, it cannot reproduce by itself. To reproduce, a virus invades a cell within the body of a human or other creature, called the host. Each type of virus has particular types of host creatures and host cells that it will invade successfully.

Once within the host cell, the virus uses the cell's own organelles to produce more viruses. In essence, the virus forces the cell to replicate the

virus' own genetic material and protective shell. Once replicated, the new viruses leave the host cell and are ready to invade others. See also **Cell (Biology)**; and **Virus**.

White-footed mouse *(Peromyscus leucopus):* This mouse is hard to distinguish from the deer mouse. The head and body together are about four inches long. The tail is normally shorter than its body (about 2–4 inches long). The fur White-footed mouse ranges from pale brown to reddish brown, while its underside and feet are white. The white-footed mouse is found through southern New England, the Mid-Atlantic and Southern states, the Midwestern and Western states, and Mexico. It prefers wooded and brushy areas, although sometimes it will live in more open ground.

Zoonotic disease or infection: An infection or infectious disease that may be transmitted from vertebrate animals (such as a rodent) to humans.

VIRAZON. See **Winds and Air Movement**.

VIRCHOW, RUDOLF CARL (1821–1902). Rudolf Virchow was a German pathologist, reformer and man of science who first systematically applied cell theory to the understanding of pathological processes.

Virchow dominated pathology internationally during the second half of the nineteenth century. Yet, although he became an important member of the Prussian scientific and political elite, he always retained the integrity, intellectual independence and liberal sentiments that featured so prominently during the revolutions of 1848.

He was born in Schivelbein, Pomerania (now Poland), the only son of a merchant. A gifted child with an early interest in science, he obtained a scholarship to study medicine in Berlin, where Johannes Müller and Johann Schönlein encouraged his research aspirations. After graduating in 1843, he worked at the major Berlin hospital, the Charité, where his interests in pathology were further kindled. Even at this period, he was an articulate spokesman for the importance of scientific rigor within medicine. He was also convinced that both health and the medical profession had fundamental roles to play in the creation of a democratic, liberal German state.

In 1848, revolutions occurred in many European countries, and Virchow was active in the one in Prussia, of which Berlin was the capital. He was sent by the Prussian government to investigate an outbreak of epidemic typhus in Silesia. The experience convinced him that epidemics were in some measure a result of social disequilibrium, and that the introduction of social equality, education and democracy was the best way to control disease in backward societies such as Silesia. As he once famously said, "Medicine is a social science, and politics nothing but medicine on a grand scale."

True to his beliefs, Virchow actively participated in the Revolution, both on the barricades and, more consistently, through his writings. With a colleague, he edited a journal called *Die medizinische Reform* (Medical Reform), in which many of his own essays appeared. He sought to make doctors more aware of their social responsibilities and to encourage the Prussian government to pay more attention to the social and economic conditions that generate disease and deprivation.

When the Revolution collapsed in 1849, Virchow was removed from Berlin, the centre of political life. He became Professor of Pathological Anatomy at the University of Würzburg, during which time he devoted himself primarily to medical and scientific work. He had already established a scientific journal, *Archiv für pathologische Anatomie und Physiologie*, which he edited from 1845 until his death. He also edited an annual yearbook of medicine and a six-volume handbook on pathology and therapeutics. In Würzburg he began a happy marriage which produced six children.

During the 1850s, Virchow became increasingly convinced that the cell is the centre of all biological phenomena, physiological as well as pathological. Building on the earlier work of microscopists such as Theodor Schwann and Jacob Henle, Virchow re-evaluated pathology in terms of cell theory. But whereas Schwann had likened cell formation to crystallization, Virchow recognized that all cells during processes such as inflammation and embryological development actually come from other cells: 'omnis cellula e cellula', as he summarized it. This important insight was the central feature of his most influential book, *Die Cellularpathologie* (1858), which went through three further editions during Virchow's lifetime. He always emphasized the dynamic elements of pathology, arguing that a new pathological physiology of cells should replace the older anatomical pathology of organs. Virchow never lost his concern with the clinical applications of pathological insights, both as aids in diagnosis and as guides for therapeutics. See also **Henle, Friedrich Gustav Jakob (1809–1885)**; and **Schwann, Theodor Ambrose Hubert (1810–1882)**.

Virchow himself contributed to the knowledge of a number of diseases. He did important work on phlebitis, pulmonary embolism, amyloidosis and cancer, the latter condition the subject of an enormous but unfinished work, *Die krankhaften Geschwülste* (Morbid Tumors), three volumes of which appeared between 1862 and 1867. Few diseases escaped his notice, although he remained cautious about bacteriology and evolutionary theory, remarking after Robert Koch's 1882 discovery of the tubercle bacillus, "Phthisis has remained what it was." His point was not that bacteria and other microorganisms were irrelevant in the causation of many diseases, but that there was much more to disease. He supported the antiseptic surgery of Joseph Lister. See also **Koch, Heinrich Hermann Robert (1843–1910)**; and **Lister, Joseph (1827–1912)**.

In 1856, Virchow returned to Berlin, as the director of a new Pathological Institute there. It became the training ground for a whole generation of pathologists from all over the world. Few major pathologists in the second half of the nineteenth century did not spend at least some time in Virchow's Institute. The move to Berlin also brought Virchow back into politics, both local and national. He played a major role in the introduction of modern sanitation to Berlin, helping to implement a new sewage system. He also advocated the building of more hospitals, the provision of clean water and the institution of a formal school medical service. For many years he was a member of the German Parliament, where he was one of Bismarck's chief opponents. Bismarck once challenged him to a duel, which honor Virchow wisely declined.

Virchow also contributed significantly to the development of anthropology in Germany. He undertook a survey of the physical features of German schoolchildren, incidentally showing that there was no such thing as a pure Germanic "race" of Aryans. He also spent much time in archaeological excavations, both in northern Europe and in the Middle East, where he worked with Heinrich Schliemann at Hissarlik, the Troy of Homer's great epic poems.

During the last third of his life, Virchow was recognized as one of the giants of medical science. He participated in many international gatherings and delivered many eponymous lectures. Although he became something of an authoritarian, he never lost his optimistic belief that scientific rationality could guide human progress. He retained his vigor until January 1902, when he fell, jumping off a Berlin streetcar, and broke his hip.

VIRGA. See **Precipitation and Hydrometeors**.

VIRGO. One of the earliest named constellations; the sixth sign of the zodiac. References to Virgo are found in every known literature and are

always connected in some manner with a maiden and the harvest. Among the Egyptians, Virgo was associated with Isis, who was said to have formed the Milky Way by dropping innumerable wheat heads in the sky.

Astronomically, the constellation is famous for the large cluster of galaxies found in it. Sir William Herschel found no less than 323 galaxies in this part of the sky, and more recent observations have raised the number to more than 500. It also contains a large number of variable stars and the well-known bright star, Spica. (See map accompanying entry on **Constellations**.) See also **Galaxy**.

VIROLOGY (The History). If the history of virology is circumscribed as a twentieth century sequence, comprising studies that make up the increasingly complex and sophisticated science of virology practiced today in specialist laboratories around the world, viruses and virus diseases have been with the human race, as perennial threats of plagues and pestilence, for millennia.

One virus disease, rabies, in humans and dogs, is easily recognized in classical texts, from the Greek of Aristotle (384–322 BC) to the Latin of Celsus (fl *c*. AD25), who even introduced the term virus, Latin for 'poison' or 'slimy liquid'. The terrifying manifestations and the inevitable fatality of the frank disease in humans has earned it much attention from writers and medical philosophers through the centuries; out of all proportion it may be said to its ravages in terms of human lives lost, which are slight when compared with the major scourges of humankind. At the other end of the scale, in terms of impact on medieval communities and history of the Western world in general, smallpox is equaled only by the bacterial disease bubonic plague; together they played a major role for popular acceptance of the principle of disease transmissibility from the sixteenth to the eighteenth centuries.

The first indications that there were infectious entities even smaller than and perhaps somehow different from the bacteria seen, described and defined by the schools of Robert Koch and Louis Pasteur in the second half of the nineteenth century, came to the fore in 1892, when the young Russian botanist D.I. Ivanovski (1864–1920) published a report on the tobacco mosaic disease decimating Russian crops during the 1880s and 1890s. He believed the disease to be of bacterial aetiology; but unable to isolate and cultivate a microbe, he suggested a bacterial toxin as the cause of the disease (the bacterial toxin of diphtheria had been discovered four years earlier at the Institut Pasteur in Paris). See also **Koch, Heinrich Hermann Robert (1843–1910)**; and **Pasteur, Louis (1822–1895)**.

In the late 1890s, and into the turn of the century, what came to be labeled 'filterable viruses' or 'invisible viruses' (throughout the nineteenth century 'virus', in France in particular, had been used as a blanket term for the 'new' infectious agents) were identified in increasing numbers. In 1897–1898 in Delft, W.M. Beijerinck (1851–1931), a former student of Adolf Mayer in Wageningen, where Mayer had also been interested in tobacco mosaic disease in the 1880s, elaborated experiments on the filterability of the agent, with more far-reaching results and a very different, more constructive, interpretation. In Berlin, also in 1897–1898, F. Loeffler and P. Frosch showed the agent of foot-and-mouth disease in cattle to be 'filterable'; but as faithful followers of Koch, they merely assumed it to be a very small bacterium. W. Reed and J. Carroll, having confirmed mosquito (*Aëdes aegypti*) transmission of yellow fever in Havana at the turn of the century, went on to show the agent's filterability. The filterability of rabies virus was finally proved by Paul Remlinger in 1903, of fowl plague virus by Eugenio Centanni in 1901, and of African horse sickness by John M'Fadyean in 1900. The virus of myxomatosis was described by Giuseppe Sanarelli as 'invisible' in 1898. See also **Foot-and-Mouth Disease**.

Among this growing list, Beijerinck's initial experiments, and his interpretation of the results, deserves most attention. For he was not content merely to label the agent 'filterable' and 'invisible'; he allowed himself further speculation on the nature of the 'non-particulate' infective 'organism' in a way which, although impossible to prove at the time, anticipated results concerning the nature of viruses half a century later. Beijerinck labeled the putative agent at the centre of his research a *Contagium vivum fluidum*. It was perhaps not a felicitous choice; his interpretation fed the disbelief and misunderstanding of his opponents, who included all but the most unorthodox of contemporary microbiologists. Based on early discussions in student days with his friend Jan van't Hoff, who was to make history in stereochemistry, he concluded that the agent must be a 'soluble' molecule rather than a 'particulate' substance suspended in surrounding fluids: in fact, a possibly water-soluble molecule, able to replicate, but only when 'incorporated into the living protoplasm of the cell, into whose reproduction it is, in a manner of speaking, passively drawn'. It was a conclusion far ahead of its time: not until the second half of the century would work on the same virus of tobacco mosaic, and on bacteriophages, by then supported by advances in methodology and technology, prove how right Beijerinck had been in his 'improbably wild' speculation. See also **Beijernick, Martinus Willem (1851–1931)**.

The early decades of the twentieth century saw few advances in research on 'filterable viruses', except for the steady addition to the numbers of known pathogens small enough to pass through bacterial filters without losing infectivity, and so to be classed as 'filterable', or indeed as 'invisible' in the microscopes of the time. The most advanced views of pathologists, in an age with scant knowledge of the nature and structure of protein molecules, described them as consisting of 'colloid globulin'. One development, however, took place during the years of World War I; its importance would only be realized to its full extent many years later. It was the discovery of bacteriophage, the bacterial viruses, by F.W. Twort at the Brown Institution in London in 1915 and, whether independently or not, by the Canadian born Félix d'Herelle of the Institut Pasteur in Paris in 1917. They both observed the lysis of intact bacterial cultures by 'invisible microbes', later referred to as the Twort–d'Herelle phenomenon, and named by d'Herelle in his classic work first published in 1921, *The Bacteriophage*. From the beginning both Twort and d'Herelle hoped for therapeutic use of specific bacteriophage in the battle against specific bacterial diseases. At the time, it appeared to be a vain hope, not justified in practice; but not before, as early as 1925, it found its way into the literature of the period when Sinclair Lewis's *Martin Arrowsmith* disastrously failed to control a plague epidemic by means of bacteriophage. In the last decade of the twentieth century there are some indications that phages in the end might be of use against 'superbugs', resistant to known antibiotics. See also **Bacteriophage**.

Within the scientific community, others were not slow to see the wider implications of the discovery of phage. The geneticist H.J. Muller was the first to observe the possibility of an analogy between bacteriophage and gene, and hence to anticipate the future importance of phage in the study of genetics. And Beijerinck, who had not added to his writings on tobacco mosaic virus since the turn of the century, wrote in 1922: 'The dialysis test shows in my opinion very clearly that *Bacteriophagus* is of the same order of magnitude as a molecule of protein, and that the term "*contagium vivum fluidum*" which I long ago used of the virus of tobacco mosaic disease, is a fitting one.'

With the discovery of bacteriophage there came a number of other developments in the 1920s, which were to be of particular importance for definitive studies of viruses, and later to be closely linked to parallel attempts to elucidate genetic determination and mechanisms, centered around the work of the physical chemist Max Delbrück and of the Italian-American medical biologist Salvador Luria (1912–1991). Together they founded the 'phage group' and laid the foundations for the American school of molecular genetics - and with it the whole enormously influential movement towards molecular biology as it evolved before, during and after World War II. Those developments, and virus research in general, depended on advances in methodology and technology: the ultracentrifuge introduced by T. Svedberg and R. FÅhraeus in 1926 became an immensely valuable tool in difficult filtration experiments; and the development of the electron microscope in the 1930s began to facilitate determination of size and structure of bacteriophages and other viruses. The brick-shaped pox viruses were established at the head of any table recording sizes of viruses, with diameters of 250–300 nm; the arbovirus of yellow fever, transmitted by mosquitoes, near the lower limit at 17–28 nm by filtration, 29–31 nm by centrifugation. See also **Delbruck, Max Ludwig Henning (1906–1981)**.

With regard to structure, the use of electron microscopes began to reveal just how great were the differences between individual viruses, and presented possibilities (other than clinical) of constructing a systematic classification, adding to the fundamental division into RNA and DNA viruses further basic criteria concerned with their cubical or helical symmetry in arrangement of protein subunits, and with presence or absence of an outer envelope around a more rigid inner structure. Structural studies

again began with tobacco mosaic virus, carried out by electron microscope pioneers H. Ruska, E. Pfankuch and G.A. Kausche in 1939–1940, before they turned to bacteriophage. At the same time, the phage group used a newly installed electron microscope at the Marine Biological Laboratory at Wood's Hole, Massachusetts, to explore questions concerning ways of entry of virus into the host cell prior to replication, and the overall nature of phage replication (Wood's Hole was affectionately known as 'the biologists' summer camp'; the main centre for the phage group was at Cold Spring Harbor on Long Island Sound). The work of Delbrück, Luria, and their colleagues in the phage group laid the foundations for a deeper understanding of (a) the pathogenesis of virus infections, and (b) the mechanisms of lysogeny, for so long the province of Eugene and Elizabeth Wollman (both died after deportation to a German concentration camp during World War II), and later of André Lwoff (1902–1994), all of the Institut Pasteur, Paris. In addition, studies by the phage group further developed the suggestions concerning analogies between viruses and genes first made by H.J. Muller in the 1920s, and to the whole emerging subject of molecular biology. See also **Electron Microscope**; **Lwoff, André Michel (1902–1994)**; and **Virus**.

Better understanding of pathogenicity and clinical features of the many important virus diseases of humans and domestic animals developed in parallel with advances in theoretical and experimental virology. The term 'virology' became established in its own right, no longer just a subdivision of bacteriology, gradually throughout the 1930s. After World War II, the first textbook, S.E. Luria's *General Virology*, was published in 1953, and the first issue of the journal *Virology* appeared in 1955.

Examples of Important Virus Diseases

Smallpox. Historically, smallpox and other 'eruptive fevers', not always easily distinguished in the past, have been at the center of many of the great epidemics influencing population statistics and demography for centuries past. From the time of Rhazes's *Treatise on the smallpox and measles* (tenth century) measles has been described as a separate entity, although sometimes regarded in early literature as a milder or occasionally more virulent form of smallpox, until the work of Enlightenment physicians in the eighteenth century. At that time severe smallpox epidemics in Britain and on the European continent were reflected copiously in the literature of the time, with much emphasis on results of inoculation practices first introduced in Britain by Emanuel Timone at the Royal Society in 1714, and more publicly by Lady Mary Wortley Montagu from 1721 onwards; in Venice a treatise by G. Pylarino appeared in 1715, and in all these cases the procedure was based on the Middle Eastern pattern of 'engrafting' as practiced in Constantinople. Catherine the Great took an interest in the practice of inoculation–the deliberate introduction of 'lymph' from mild cases of smallpox into healthy children and adults to prevent later severe cases. She herself was inoculated by Thomas Dimsdale in 1768. See also **Smallpox**.

In France, however, there was resistance to the practice, in spite of recommendation by Voltaire, who had himself suffered an attack of smallpox in 1723, until the death of Louis XV from the disease in 1774 caused the public and the authorities to view the procedure in a more favorable light. Two decades later Edward Jenner introduced cowpox vaccination against smallpox, and with it a new era which towards the end of the nineteenth century would see an accelerating development and use of vaccines against a number of diseases caused by bacteria and by 'filterable' viruses. Jenner's development of cowpox vaccination was a successful outcome of a purely empirical approach by an observant eighteenth-century doctor, with no taste for experimentation but favored by a good deal of luck and the possession of common sense. Although Thomas Jefferson's prophecy in 1806 that Jenner's vaccine would ensure that 'Future nations will know by history only that the loathsome smallpox has existed' was wildly premature, Jenner's system of vaccination — the variolae vaccinae — did in the end clear the world of smallpox, if not until 1979 when the World Health Organization (WHO), after a final campaign, could declare the disease eradicated — the first, and so far the only, example of a deliberate, and ultimately successful, attempt at global eradication of an infectious disease. See also **Jenner, Edward (1749–1823)**.

Measles. Measles, on the other hand, one of the most important and severe of childhood virus diseases, has been brought under control in the Western world, but remains a major threat in developing countries. A satisfactory vaccine was developed by J. F. Enders and his group at Harvard Medical School as an extension of his tissue culture techniques when applied to virology: he successfully adapted Alexis Carrell's much earlier method for growing cells in slowly rolling tubes. Enders' successful measles vaccine proved its worth in clinical trials and has been used in the USA and elsewhere in the West since 1961. Recent public doubts concerning the safety of the combined measles–mumps–rubella vaccine in Britain remain unproven, and it is to be hoped will not interfere with present policies of prevention. See also **Enders, John Franklin (1897–1985)**; and **Measles**.

Rabies. If Jenner's development of cowpox vaccine against smallpox was a wholly fortuitous first use of the principle of attenuation whose successful conclusion owed much, if not all, to luck, the use of attenuation as a tool in developing vaccines against known bacteria and viruses in the 1880s by Pasteur and his staff owed little to chance and much to experimentation, carefully thought out and planned. Admittedly, the first observation was fortuitous: a virulent strain of fowl cholera was left by chance longer than intended (as with Fleming's penicillin half a century later); when later re-examined it was found on inoculation to protect fowl against infection rather than produce the frank disease (1880). Pasteur, realizing the implications, went on to develop, with C. Chamberlain and E. Roux, a vaccine against anthrax (1881) in sheep and cattle, and finally tackled the age-old problem of rabies. Having confirmed the neurotropic character of the virus by its presence in brain and nervous tissues, but with no means of seeing, let alone using cultures of, the agent, Pasteur's only alternative was to use infected spinal cords of sacrificed rabbits, attenuated by drying in air-tight glass containers. Pasteur and his co-workers inoculated dogs with carefully graded material, beginning with samples totally inactivated after 14 days' drying, and working backwards through daily doses increasing in virulence until, on day 14, the inoculation contained fully virulent material from a freshly killed, rabid rabbit. By September 1884, they were able to render dogs wholly resistant to experimental rabies. From there to human prophylaxis, the next step was daunting. Pasteur hoped to make definite progress within two years. His 'trembling hand' was forced less than a year later. After a couple of false starts with tragic outcomes (the patients, including a 10-year girl, were seen too late), young Joseph Meister, 9 years old, savaged by a rabid dog on his way to school in a small town in Alsace, was brought to see him in July 1885. Pasteur, faced with the small boy in pain from multiple wounds which would almost certainly kill him if left untreated, overcame his scruples, encouraged by medical colleagues. The post-exposure prophylaxis worked, and Joseph survived; so did a shepherd boy from the Jura treated 3 months later. Rabies vaccination had been successfully launched. There were to be problems ahead, stretching well into the twentieth century. Work to perfect the vaccine continues; and there is still no effective therapy for those unfortunate patients bitten and not receiving prophylaxis in time. See also **Rabies**.

Yellow Fever. Yellow fever, endemic in West Africa, traveled to the Americas and elsewhere on board trading ships carrying cargoes of slaves from the sixteenth century onwards. During the nineteenth century there were occasional reverse, if short-lived, importations of the disease to European ports in Spain, France and the west of England. See also **Yellow Fever**.

The agent of yellow fever was identified as a filterable virus, transmitted by mosquitoes (*Aëdes aegypti* in particular), by W. Reed and colleagues, working in Havana for a United States Army Commission, at the beginning of the twentieth century. Yet it was to take more than two decades before controversies about its aetiology and problems regarding understanding of its pathogenesis and culture methods could result in production of a safe and fully effective, attenuated live virus vaccine, developed by Max Theiler and colleagues at the Rockefeller Institute over a period in the 1930s. By then, the disease had taken its toll among researchers of opposing views, among them Adrian Stokes, who definitively confirmed the agent as a virus, in 1927, and Hideyo Noguchi, who had defended his erroneous theory of a spirochaete, *Leptospira icteroides*, as the agent of yellow fever for a decade, in 1928. See also **Noguchi, Hideyo (1876–1928)**; **Reed, Walter (1851–1902)**; and **Theiler, Max (1899–1972)**.

During World War II Theiler's yellow fever vaccine saved countless lives among both troops and civilians. Jungle yellow fever on the other hand,

where the virus is part of a monkey–mosquito cycle involving different species of mosquito including *Haemagogus*, remains a problem which will prevent complete eradication of the disease for the foreseeable future.

Polio. Poliomyelitis may or may not have been present in antiquity; any evidence is largely pictorial or buried in hieroglyphic records and liable to other interpretations. Identifiable epidemics of paralytic polio begin to appear in the nineteenth century; and work with a bearing on prophylaxis, even after Karl Landsteiner's demonstration of filterability of the agent and its transmissibility to monkeys in 1909, had a number of obstacles to overcome before the long overdue successes of the 1950s. One obstacle was the complexity of the family of polioviruses; another the fact that Landsteiner's experimental animal, the rhesus monkey, is highly susceptible to infection with poliovirus, but only via the respiratory system. The latter fact appeared to support Simon Flexner of the Rockefeller Institute in his rigidly held and influential views, which totally ignored Swedish results, by Carl Kling and others, showing the presence of poliovirus in the intestinal wall and intestinal contents of victims of a severe outbreak in 1911. The work of J. F. Enders, T.H. Weller and F.C. Robbins, who in 1949 were able to grow the virus in cultures of human non-nervous embryonic tissues, finally opened the way to successful production of vaccines against polio. Between 1950 and 1960 three types of vaccine were produced: Jonas Salk used a chemically (formalin) killed vaccine; Albert Sabin and Hilary Koprowsky worked independently on live attenuated virus vaccines. Vast clinical trials were undertaken in the United States in the 1950s. There were disturbing incidents and disasters along the way, but from 1962 onwards, Sabin-type oral vaccines have been successfully used in the United States as well as in Britain and on the European continent. See also **Enders, John Franklin (1897–1985)**; **Flexner, Simon (1863–1946)**; **Landsteiner, Karl (1868–1943)**; and**Poliomyelitis**.

Emerging Viruses. The latest challenge to virologists is the 'emerging viruses'. Their story began in Marburg, Germany, in 1967 when 31 laboratory workers using African monkeys as a source of cells for tissue culture material were struck down by an acute infection. Seven died before the cause of the illness was identified as a hitherto unknown virus, carried by the monkeys, which are not affected by it. It became known as Marburg virus. Two years later, in 1969, Lassa fever was first observed in West Africa, when a nurse in a small mission hospital in Lassa, Nigeria, came down with a rapidly developing acute illness with alarming manifestations, from which she died two weeks later. A fellow nurse who had cared for her died in similar circumstances; a third nurse who had cared for both patients also caught the disease, but eventually recovered. The carrier of Lassa fever virus in these cases has been identified as the African rodent *Mastomys natalensis*, the multimammate mouse. See also **Lassa Fever (African Hemorrhagic Fever)**; and **Marburg Hemorrhagic Fever**.

A third African virus has become notorious since first observed in human infections in Zaire in 1976: Ebola. Again, the clinical picture is alarming, as is the fatality rate. In spite of the virus being identified in electron micrographs within 6 months of the initial outbreak, its natural reservoir and path of transmission to humans remain so far unknown. In 1989 there was a, fortunately rapidly contained, outbreak in the USA, when four human subjects caught the infection from monkeys imported from the Philippines. There was no further spread, and no fatalities; but the threat is still very much present in Africa, in Democratic Republic of the Congo (formerly Zaire) and Gabon, and on the Ivory Coast. See also **Ebola Hemorrhagic Fever**.

There are indications in early Chinese texts that Hantaviruses as causes of hemorrhagic fevers may have been present there during the first millennium AD. They reappeared as threats to both Eastern and Western societies in the mid-twentieth century as the cause of an outbreak of hemorrhagic fever in 2000 UN troops during the Korean War, preceded by minor ones in Japan, Russia, Scandinavia, and elsewhere on the European continent. Named after the Hantaan River in Korea, the Hantaviruses are carried by rodent vectors and their respective ectoparasites; in the USA by the deermouse and the cottontail rat. Like Lassa fever virus and Ebola and other RNA viruses, the Hantaviruses mutate frequently and use a wide range of hosts; consequently the emergence of new virulent types is an ever present possibility. Their history is open-ended.

HIV and AIDS. The human immunodeficiency virus–HIV, causing AIDS–was first observed in the USA in four homosexual men in 1981. The disease has since caused havoc, both in the Western world and in developing countries, where resurgence of tuberculosis is linked to its prevalence. The virus and the disease have been intensively studied by virologists and public health officials for the last two decades of the twentieth century. Its identification has even caused a latter-day priority dispute involving Luc Montagnier of the Paris Institut Pasteur and Robert Gallo, then at the National Institutes of Health and now at the University of Maryland in Baltimore, USA. In spite of much inspired work by virologists and other medical scientists on both sides of the Atlantic since 1981, and considerable progress made, there are still no long-term therapies or vaccines available in the fight against HIV and AIDS. If and when they are perfected, there will still remain enormous problems of financing and distribution before they can be effectively dispensed throughout developing countries, where prevention and control, and even containment, remain a long way off in an uncertain future, for cultural as well as scientific reasons. See also **Acquired Immune Deficiency Syndrome (AIDS)**; **Gallo, Robert Charles (1937–Present)**; **Human Immunodeficiency Viruses (HIV)**; **Immune System and Immunology**; and **Montagnier, Luc (1930–Present)**.

Influenza. In contrast to HIV and AIDS, the influenzas and their viruses have been with humankind for long periods of time. The problem here is that influenza–'flu'–viruses change continually; and although they were shown to be 'filterable', and at the same time infectious for both humans and ferrets in the Wellcome/MRC Mill Hill laboratories in the early 1930s, there can be no let-up in work to keep vaccine production abreast of the steady emergence of new types of influenza viruses. Ferrets initially presented a ready-made animal model for vaccine work, but the virus was gradually adapted to growth in the more convenient white laboratory mouse, and later in embryonated eggs and tissue culture. Influenza viruses are subject to antigenic drift and genetic recombination, as well as changes in host specificity (swine flu, avian (wild aquatic birds, and also domesticated ones) flu, etc.). Vaccines are effective, but must consequently be under constant review. See also **Influenza**.

From 'Slow Viruses' to Spongiform Encephalopathies. The *rickettsiae* were long ago shown to contain both DNA and RNA and be susceptible to the action of antibiotics, and hence better classified as small bacteria rather than true viruses. The spongiform encephalopathies present far more complex problems in this respect. In 1954 Björn Sigurdsson (1913–1959), outstanding Icelandic virologist and founder, with Rockefeller support, of Reykjavik's Institute for Experimental Pathology, published a classic paper on the sheep disease scrapie. He pointed out striking similarities between scrapie, known in European countries for more than 2 centuries, and a sheep disease called 'rida' in Iceland. It had been shown to be transmissible by injection of filtered material from the brain and spinal cord of affected animals by French researchers in 1936. Twenty-five years later J.T. Stamp in Edinburgh would confirm and extend the French results and draw attention to the unusual resistance of the unknown agent and the surprising length of the incubation period. Sigurdsson had introduced the term 'slow virus infections'; after Gajdusek's work on kuru and CJD (Creutzfeldt–Jakob disease) in the 1950s and 1960s they are now classed as spongiform encephalopathies. The recent furore in Britain over BSE (bovine spongiform encephalopathy) and its possible ability to cross species barriers and cause CJD, and new variant CJD, in humans, has renewed interest in Stanley Prusiner's work on the prion protein and the question of whether or not prions are the sole agents of these diseases, or whether an additional, possibly genetic, factor is involved in the pathogenesis of the spongiform encephalopathies. The identity of prions as small protein molecules with no nucleic acid component would distinguish them from all known viruses, viroids, and infectious agents in general. See also **Creutzfeldt-Jakob Disease and Related Diseases**; **Gajdusek, Daniel Carleton (1923–Present)**.

VIRTANEN, ARRTURI I. *(1895–1973)*. A Finnish biochemist that won the Nobel prize in 1945. His work was primarily concerned with research in nutrition and agriculture. He made important discoveries regarding prevention of fodder spoilage and bacterial fermentation as well as nitrogen metabolism in plants. His Ph.D. was awarded at the University of Helsinki and followed by an illustrious career that included awards throughout Scandanavia.

VIRTUAL POTENTIAL TEMPERATURE. The theoretical potential temperature of dry air that would have the same density as moist air. It is used as a convenient surrogate for density in buoyancy calculations. The virtual potential temperature θ_v is defined by

$$\theta_v = \theta(1 + 0.61r - r_L),$$

where θ is the actual potential temperature, r is the mixing ratio of water vapor, and r_L is the mixing ratio of liquid water in the air. Temperatures must be in units of Kelvin, and mixing ratios in units of $g_{water}/g_{dry\ air}$. Because water vapor is less dense than dry air, humid air has a warmer θ_v than dry air. Liquid water droplets, if falling at their terminal velocity in air, make the air heavier and are associated with colder θ_v. For saturated or cloudy air, use saturation mixing ratio in place of r, while for unsaturated air, use $r_L = 0$.

See also **Virtual Temperature**.

VIRTUAL TEMPERATURE. The virtual temperature $T_v = T(1 + r_v/\varepsilon)/(1 + r_v)$, where r_v is the mixing ratio and ε is the ratio of the gas constants of air and water vapor, ≈ 0.622. Also called density temperature.

The virtual temperature allows the use of the dry-air equation of state for moist air, except with T replaced by T_v. Hence the virtual temperature is the temperature that dry dry air would have if its pressure and density were equal to those of a given sample of moist air. For typical observed values of r_v, the virtual temperature may be approximated by $T_v = (1 + 0.61r_v)T$. Some authors incorporate the density increment due to liquid or solid water into virtual temperature, in which case the definition becomes $T_v = T(1 + r_v/\varepsilon)/(1 + r_v + r_l) \approx T(1 + 0.61r_v - r_l)$, where r_l is the liquid or liquid plus solid water mixing ratio.

VIRTUAL WORK. See **Work (Virtual)**.

VIRUS. Viruses are considered to be the smallest infectious agents capable of replicating themselves inside eukaryotic or prokaryotic cells. The majority of these extremely small infectious particles fall within a size range of about 0.02–0.25 micrometer and can only be visualized directly with the aid of an electron microscope.

In 1898, Loeffler and Frosch demonstrated that foot-and-mouth disease of cattle could be transferred by material passed through a filter capable of excluding bacteria. This new group of "organisms" subsequently became known as *filterable viruses*. Years of debate have centered around the question of whether viruses are living or nonliving and, although resolution of this is now considered to be simply a problem of semantics, several fundamental differences distinguish viruses from other organisms. Viruses, unlike true microorganisms, are not cells, do not replicate by binary fission, and contain a genome consisting of only one type of nucleic acid (DNA or RNA, double or single stranded). They contain no organelles, such as mitochondria or ribosomes (except for the Arena viruses, which contain cellular ribosomes). Some virions contain special enzymes, such as transcriptase required for initiation of the vital growth cycle, not present in host cells.

Smaller than viruses, however, are the particles known as *viroids*, which are nothing more than very short strands of RNA uncoated by protein as is a normal virus. Viroids are known to be responsible for several plant diseases and may also be involved in animal and rare human nerve diseases. Very little is known about viroids except that when they are introduced into a host cell they replicate without the assistance of a helper virus. They are not translated into proteins and, presumably, their replication must rely entirely upon the enzyme systems of the host.

Viruses are obligatory intracellular parasites and, as such, cannot replicate in cell-free media. Therefore, the study of viruses is normally carried out with cultured cells. These are classified as: (1) *Primary cell cultures*; (2) *diploid cell strains*; and (3) *continuous cell lines*. Primary cell cultures are developed on tissue freshly removed from a plant or animal, contain several cell types capable of supporting replication of a wide range of viruses, but are limited to only a few cycles of cell division in vitro. Diploid cell strains contain cells of a single type which retain their original diploid chromosome number and are capable of up to about 100 divisions in vitro. Continuous cell lines consist of transformed or dedifferentiated cells of a single type which bear little resemblance to normal cells of that type. Continuous cell lines are capable of indefinite propagation in vitro.

Viral Structure. The mature virus particle, referred to as the *virion*, consists of a nucleic acid molecule(s) surrounded by a protein coat, the *capsid*. The capsid is composed of a number of *capsomeres* comprising one or more polypeptide chains and in some viruses surrounds a protein *core*. The capsid and enclosed nucleic acid together constitute the *nucleocapsid*. The viral capsid symmetry is characteristic of groups of virus and may be icosahedral (cubic) or helical. The icosahedron has 12 vertices and 20 faces, each an equilateral triangle. Nucleocapsids exhibiting helical symmetry consist of capsomeres and nucleic acid wound together into a spiral or helix. However, regardless of capsid symmetry, the actual virion may appear to be round, brick, or bullet-shaped. Some icosahedral and all helical viruses are enclosed in an outer *envelope* composed of lipoprotein, which is derived directly from the virus-modified cellular membrane during release of the nucleocapsid from the infected cell by a process called *budding*. Enveloped viruses can usually be inactivated by ether, chloroform, or bile salts.

Nucleic acid extracted from purified virus using phenol or dodecyl sulfate is easily destroyed by the homologous nucleases present in normal sera or tissues. DNA is destroyed by the enzyme deoxyribonuclease; RNA by ribonucleases. This provides one means of identifying the type of nucleic acid. The intact virus is not affected by these enzymes.

Bacteriophage, a virus infecting bacterial cells, has a structure somewhat different from those previously described. A *head* contains the nucleic acid and the viral DNA passes through a *tail* during the infection process. In the T-even phages (Fig. 1), the tail consists of a tube surrounded by a *sheath* and is connected to a thin *collar* at the head end and a plate at the tip end. The sheath is capable of contraction and the plate possesses *pins* and *tail fibers*, which are the organs of attachment of the bacteriophage to the wall of the host cell.

Some strains of the bacterium *Escherichia coli* harbor a dormant virus called lambda, which consists of a long molecule of DNA enclosed in protein. Exposure of such infected bacteria to ultraviolet light suddenly "switches on" these inactive lambda. The viruses proliferate and some 45 minutes after irradiation the bacteria burst, yielding a crop of new virus particles. If the bacteria are not irradiated, they grow normally, and rarely give rise spontaneously to viruses.

Viral Replication. In contrast to eukaryotic and prokaryotic cells, which multiply by binary fission, viruses multiply by synthesis of their separate components, followed by assembly. Several stages are involved in viral replication:

1. **Attachment or adsorption.** The virus becomes attached to the cell via specific receptors. Thus, cells lacking the receptors are resistant to attack.
2. **Penetration.** With enveloped viruses, this step occurs when the virion's envelope fuses with the cellular membrane. Naked virions

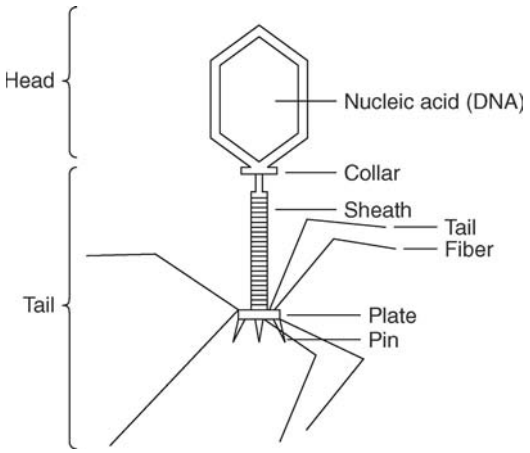

Fig. 1. T-even bacteriophage

penetrate intact through the cellular plasma membrane and into the cell cytoplasm. Viruses may also enter the cell by cellular phagocytosis. Ordinarily, without a protein coat, viral nucleic acid is incapable of entering a cell, showing the importance of the coat in infectivity. The efficiency of infection with naked nucleic acid can be increased by the presence of basic polymers, such as DEAE-dextran, or by pretreating cells with hypertonic salt solution. Even under the most favorable conditions, however, the efficiency of infection is not more than 1% that of the corresponding intact virions.

3. **Uncoating and eclipse.** Uncoating is detected by the lability of viral nucleic acids to nuclease after the artificial disruption of the cell. Eclipse is recognized by loss of infectivity of intracellular virions recovered from disrupted cells.

   Once inside the cell, virulent viruses turn off cellular macromolecular synthesis and disaggregate cellular polyribosomes, thus favoring a shift to viral synthesis. These viruses cause the ultimate destruction of the infected cell. In contrast, moderate viruses may stimulate host DNA, mRNA, and protein synthesis — a phenomenon which may be of considerable importance in viral carcinogenesis.

   In general, the DNA viruses multiply in the nucleus of the host cell. The viral DNA is transcribed in the nucleus and the resultant mRNA translated into proteins on cytoplasmic ribosomes. Depending upon the virus type, "early" or "late" proteins may be synthesized. These proteins may function as enzymes in replication of the viral DNA, as structural components of progeny virions, or as regulatory proteins. Replication of the viral DNA is semiconservative and, in general, depends upon viral proteins. RNA viruses usually replicate in the cytoplasm and can be divided into five classes according to the nature of the RNA in the virion. *Class I* viruses contain a molecule of single-stranded RNA which acts as mRNA to be translated into viral proteins. The RNA is said to have plus *strand polarity*. The picornaviruses are an example. *Class II* viruses (e.g., paramyxoviruses) have a molecule of single-stranded RNA which cannot act as mRNA (minus strand polarity). A virion transcriptase synthesizes several complementary messenger molecules from which viral proteins are translated. *Class III* viruses (e.g., myxoviruses) contain single-stranded RNA of minus strand polarity, present in seven or more segments. A virion transcriptase transcribes each segment into a complementary messenger. *Class IV* viruses contain ten segments of double-stranded RNA which is transcribed into mRNA by a viral transcriptase. Representative of this group are the reoviruses. *Class V* viruses (e.g., leukoviruses) contain segmented single-stranded RNA of messenger polarity. Each RNA segment is transcribed into DNA by a *reverse transcriptase* present in the virion; mRNA is then transcribed from the DNA.

4. **Assembly and release.** The assembly of the capsid and its association with nucleic acid is then followed by release of the virus from the cell. This may occur in different ways, depending upon the nature of the virus. Naked viruses may be released slowly and extruded without cell lysis, or released rapidly by disruption of the cell membrane. DNA viruses, which mature in the nucleus, tend to accumulate within infected cells over a long period. Enveloped viruses generally acquire their envelope and leave the cell by budding through the nuclear or cytoplasmic membrane at a point where virus-specified proteins have been inserted. The budding process is compatible with cell survival.

Viral Classification

Several methods of viral classification are in use. Classification based upon epidemiological criteria, such as enteric or respiratory viruses, is useful, but of more significance are schemes based upon the morphology of the virion (symmetry, envelope, etc.) and type of nucleic acid (DNA, RNA, number of strands, polarity, etc.).

The two groups of viruses, RNA and DNA, are further divided according to size, morphology, and biological and chemical properties. Thus, the icosahedral RNA viruses that are ether stable are divided into the picornaviruses and the reoviruses. The name picornavirus comes from *pico* (meaning very small) and *rna* (indicating the type of nucleic acid). Included in the group are enteroviruses, such as polio, Coxsackie, foot-and-mouth, and echoviruses, among others, and also the rhinoviruses. The picornavirus capsid consists of 60 subunits each made up of four proteins, which change by mutation to yield antibody-resistant strains of cold and polio viruses. The reoviruses (*r*espiratory *e*nteric *o*rphan virus) cause inapparent infection in humans and other animals, and their relationship to spontaneous disease is uncertain. They are morphologically similar to the wound-tumor virus of clover, and a small cross-activity with this virus by means of complement fixation has been reported.

The arboviruses are those which multiply in both vertebrates and arthropods. The former serve as reservoirs and the latter primarily as vectors. Arbovirus is a somewhat arbitrary epidemiological classification, which contains several heterogeneous groups. The togaviruses contain such entities as Eastern and Western equine encephalitis viruses (EEE and WEE) and dengue and yellow fever viruses, which have mosquitoes as vectors. The arenaviruses comprise such agents as Lassa, Tacaribe, and lymphocytic choriomeningitis viruses. Arboviruses are dangerous and difficult to study. They appear to contain single-stranded RNA (positive polarity), are ether sensitive, and are relatively unstable. The capsids are suggestive of icosahedral symmetry.

Myxoviruses, orthomyxovirus, and paramyxoviruses are spherical or filamentous, enveloped single-stranded RNA viruses. The myxovirus group contains the influenza viruses which, in turn, have been separated into three distinct antigenic types, designated A, B, and C. The genome of myxoviruses, unlike that of the paramyxoviruses, is segmented. It is this characteristic that is responsible for the devastating influenza pandemics which have occurred periodically. Influenza A viruses have undergone three major antigenic shifts since 1933, and each new variant is able to successfully infect populations of individuals immune only to preexisting types. In the influenza pandemic of the winter of 1917–1918, over 20 million persons died worldwide, with better than one-half million fatal cases in the United States. Over 50 million cases of influenza were reported in the United States in the 1968–1969 winter. These cases were attributed to a hitherto unknown variant, first isolated in Hong Kong (hence named "Hong Kong flu"). Some 20,000 and possibly as many as 80,000 deaths resulted from this influenza invasion and the side effects it produced. In the 1972–1973 winter season, a much milder and minor variant, called the "London flu," caused well over 2000 deaths in the United States, particularly from complications such as pneumonia. When combined with influenza, pneumonia is the fifth most serious public health problem in the United States. In terms of absenteeism, it is the number one problem.

Only Type A influenza virus has been found to be capable of producing *pandemics*. The influenza A virus is identified as a medium-size RNA virus, some 110 nanometers in diameter and delimited by a membrane of lipids and polysaccharides derived from the host cell and virus-specific protein. Five distinct proteins have been identified, three of which are inside the virion. A schematic representation of the influenza virus emerging from a cell is given in Fig. 2.

It has been reported that the antigenic shifts are manifested in hemagglutinin and neuraminidase, two glycoproteins found on the surface of the influenza virion. It is suggested that the hemagglutinin binds the virus to the target cell and when the hemagglutinin function is inhibited (as by an antibody), the virus is no longer infective. It is believed that the neuraminidase

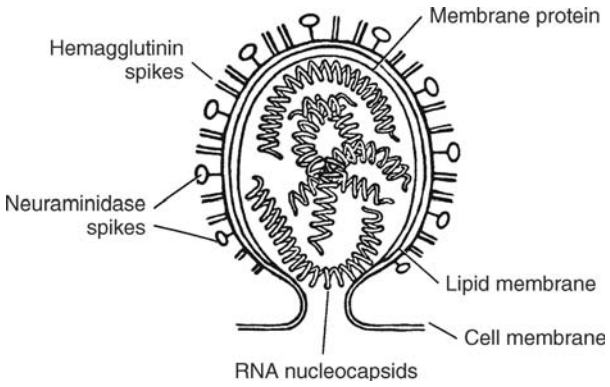

Fig. 2. Schematic representation of an influenza virus emerging from a cell. (*After Kilbourne*.

cleaves a glycoside bond in the host membrane. This action frees the newly formed virus from the cell and, if inhibited, will not reduce the infectivity of the virus, but will deter the spread of virus particles to other cells.

The emergence of new influenza subtypes appears to be too abrupt to be explained fully by conventional concepts of mutation and the full story may rest in the very nature of the segmented viral genome. If a host cell is infected by two different subtypes of influenza virus at the same time, the genes from the subtype may undergo random reassortment in the cell, resulting not only in production of the two original subtypes, but in production of one or several other subtypes as well. Each hybrid, of course, will have a different but full set of genes and recombination within the infected host can explain the large mutations that occur about once every decade. However, it is well established that only one influenza subtype can exist in humans at any given time. Also, that the emergence of a new subtype, such as the Hong Kong strain, is usually accompanied by the abrupt disappearance of the antecedent subtypes — thus allowing little, if any, opportunity for recombinations to occur within human cells. Of considerable interest, however, is the fact that several virus strains can exist simultaneously within animal hosts. In animals, the appearance of a new influenza virus strain is not necessarily accompanied by the disappearance of previously recognized strains. It has been established that there are at least two discrete subtypes of equine influenza, eight or more avian strains and two subtypes in swine. Thus, the postulation that recombination occurs in animals which share the general environs with humans. Some evidence of this may derive from the fact that most new subtypes appear to originate in Asia, where animals and humans commonly inhabit the same building.

The paramyxovirus group includes the causative viruses of mumps, measles, parainfluenza, Newcastle disease, canine distemper, and several other diseases. These viruses are generally larger than the myxoviruses, are enveloped and pleomorphic, and contain one molecule of single-stranded RNA.

The rhabdoviruses, causative agents of rabies in humans and other animals, are also enveloped and contain a single strand of RNA. A peculiar bullet-shaped morphology disguises the helical nucleocapsid.

The human immunodeficiency virus (HIV) which induces AIDS is a retrovirus. Its genetic material is RNA and it carries with it a reverse transcriptase which catalyzes transcription of viral RNA into double helical DNA that then integrates into the genome of the infected cell where it is known as a *provirus*. Transcription of this provirus produces new viral RNA and proteins. One characteristic of HIV is that its genome is significantly more complex than that of other known retroviruses; it possesses at least seven types of genes instead of the normal three. The virus replicates by budding off from a T lymphocyte to become a free infectious virus. See also **Immune System and Immunology**.

The chemical nature of many viruses, which either do not grow well or do not lend themselves to purification, is unknown. The Riley lactic dehydrogenase virus is a nonpathogenic virus, which is recognized only by an increase in lactic dehydrogenase in the blood of infected mice. A lipovirus described by Chang causes marked degradation of infected cells and releases a lipogenic toxin dissociable from infectivity, which is capable of inducing fatty degeneration in other uninfected cells. A marked increase in the gamma globulin fraction of blood serum of mink infected with Aleutian mink disease is an indication of infection with a virus which causes a color change in the fur and often sickness and death.

Several groups of viruses, of importance in human disease, contain DNA. The adenoviruses, named for their original isolation from adenoid tissue, contain double-stranded DNA, have icosahedral symmetry and lack and envelope. This group of viruses that multiply in the nucleus of infected cells is usually associated with respiratory tract and eye infections, although it is now apparent that adenoviruses are not the etiological agents for the majority of acute viral respiratory infections. Although adenoviruses exhibit marked oncogenic (tumor causing) potential in animals, they are probably not oncogenic for humans.

The adenoviruses contain at least three protein moieties, and certain types are capable of inducing one or more new host antigens, such as tumor (T) antigens, the chemistry of which is presently unknown. The viral proteins can be separated by gel diffusion and correlated with results obtained by complement fixation. One moiety is the toxic protein that causes the host cell to degenerate. Another corresponds to the group antigen common to all 31 types of adenoviruses and the third is the type-specific protein.

The papovaviruses (*pap*-illoma, *po*-lyoma, *va*-cuolating agent, SV40) are small, nonenveloped, icosahedral viruses which also replicate in the cell nucleus. The virion contains double-stranded DNA. Apart from causing several forms of warts, this group of viruses is of interest as models for understanding mechanisms of viral carcinogenesis.

The major herpesviruses (Gr: *herpein* =to creep) that infect humans are herpes simplex (Type I: fever blisters; Type II: genital lesions), varicella (chickenpox), zoster (shingles), cytomegalovirus, and Epstein-Bar viruses. A number of viruses that infect lower animals also belong to this group of enveloped, icosahedral, double-stranded DNA viruses. Most members of this group tend to produce latent infections with periodic recurrent disease. Two examples are fever blisters caused by herpes simplex I, and shingles, the recurrent form of chickenpox. Cytomegalovirus causes a severe, often fatal, illness of newborns, usually affecting the salivary glands, brain, lungs, kidneys, and liver. Surpassing rubella virus, this is the most common viral cause of mental retardation. It has been estimated that cytomegalovirus (CMV) causes serious mental retardation of more than 3000 infants annually in the United States alone. In addition to mental retardation, the disease in infants may cause blindness and deafness. In about 90% of infants infected with CMV, the disease can be detected only through urine examination. In about 10% of the cases, the disease is typified by enlargement of the spleen and liver, blood abnormalities, and hepatitis. Microcephaly (abnormally small head) is also sometimes an indication. CMV causes enlargement of the affected cells (cytomegaly). The disease is found throughout the world and it is believed that congenital infections result from a primary infection of the mother during pregnancy. CMV, like herpesviruses, probably persist in a latent stage for long spans of time. Immunosuppressed patients, such as those suffering from cancer or recipients of organ transplants, are also prone to infections with CMV.

The Epstein-Barr viruses play an etiological role in infectious mononucleosis, an acute infectious disease that affects lymphoid tissue throughout the body. A strong association of this virus with Burkitt's lymphoma and perhaps nasopharyngeal carcinoma also has been observed.

The poxviruses are the largest and most complex viruses of vertebrates and contain a large, double-stranded DNA molecule. The virions are complex, brick-shaped particles, covered by several membrane layers of viral origin. Unlike other DNA viruses of mammals, poxviruses multiply in the cell cytoplasm. They can be divided into several groups on the basis of specific antigens, morphology, and natural hosts. *Group I* consists of mammalian viruses, such as variola (smallpox), vaccinia, cowpox, ectromelia, and monkeypox. Of this group, variola or smallpox has caused the greatest human morbidity and mortality. However, because the virus has no animal reservoir, and is spread chiefly by human contact, the World Health Organization was able to announce in 1980 that, because of massive immunization campaigns, smallpox has been completely eradicated. Since that announcement, remaining stores of the virus have been destroyed to prevent laboratory accidents, such as the one in 1979, which took the life of a scientist. *Group II* comprises the tumor-producing viruses, the fibroma and myxoma viruses.

The hepatitic viruses appear to fall into two different groups of small, icosahedral DNA viruses. *Type A* causes infectious hepatitis and

is transmitted through the oral-intestinal route. *Type B* is transmitted by injection, usually of infected blood or its products.

Slow Viruses

During the last decade or two, there has been increasing speculation and some tentative evidence that so-called *slow viruses* may be operative and may be the underlying causes of a number of degenerative diseases, long poorly understood, such as multiple sclerosis and rheumatoid arthritis, among others. More recently, there have been increasing postulations of an association between viruses and diabetes. In fact, rather positive identification of slow viruses with some rare diseases has been established. Most investigators caution that the term "slow" should not necessarily be fully interpreted in terms of a virus per se, but equally if not completely with the manifestations of the virus. So-called slow virus infections are characterized by a long incubation period, followed by a protracted course of disease. The slowness may arise in some cases from the virus itself, but the slow pace also may be the result of weak but prolonged interactions between the virus and the host's immune system. It is also possible that these characterizations of slowness may not be attributable to viruses at all, but to some other unknown causative factors. Obviously as of this juncture, investigators are following a source of suspicion rather than a chain of hard evidence. Nevertheless, the case for the slow viruses is becoming increasingly convincing. The causative agents for at least four rare diseases, two in humans and two in animals, are sometimes referred to as "unconventional viruses."

One of these diseases in humans is *kuru*, encountered only in the Fore people and their neighbors in New Guinea. The disease for many years was considered a genetic disease. However, it has been established that the disease can be transmitted to chimpanzees by injection of extracts from the brains of human kuru victims into the brains of chimpanzees. Kuru is a neurological disease with brain lesions located mainly in the gray matter. The cerebral cortex takes on a spongy appearance. The other human disease is Creutzfeld-Jakob disease, rare but of worldwide distribution. It involves the premature development of the mental deterioration sometimes seen in old age. It also has been established that it is caused by a transmissible agent that can infect chimpanzees and lower primates. One of the animal diseases referred to is *scapie*, known for over two centuries as a fatal disease among sheep. The other animal disease is *transmissible mink encephalopathy*, first discovered in Wisconsin in the late 1940s. A puzzling aspect of the unconventional slow viruses is the fact that they cannot be observed with an electron microscope. Another puzzling aspect is their apparent lack of antigenicity. Although it has not been possible to demonstrate that any of these four "agents" will evoke production of antibodies, recent work has found fibrils in the brains of infected animals that are believed to be specific markers for the "unconventional" slow viruses and may indeed be the etiological agent. These unconventional slow viruses are not destroyed by ultraviolet radiation, and they are highly resistant to treatment with formalin or heat, but infectivity is destroyed by phenol or ether. Some investigators believe that these agents may incorporate a very small nucleus of the size range of the viroids (self-replicating infectious RNA molecules known to produce certain plant diseases).

Two slow infections of the human central nervous system—*progressive multifocal leukoencephalopathy* (PML) and *subacute sclerosing panencephalitis* (SSPE) are thought to be associated with conventional viruses. Although PML does not cause inflammation of the brain, it does produce demyelination, i.e., destruction of the layers of membranes surrounding nerve axons. Some investigators believe that the virus is a papovavirus (group of small viruses including human wart virus, simian virus 40, and the polyoma virus of mice). It is reasoned that in PML the virus destroys the cells needed for formation and maintenance of the myelin sheath. A conventional virus has been isolated from the brains of persons suffering from SSPE. An association between measles (in patients under two years of age) or immunization with a live measles virus vaccine and later development of SSPE has been shown. SSPE patients have unusually high titres of measles antibodies and affected brain cells have inclusions similar to those seen in measles infections.

Slow viruses are becoming increasingly suspect in the instances of much more common diseases, particularly the autoimmune diseases. An autoimmune disease may be defined as a disease wherein the immune system of the body does not direct its attack on an invading foreign substance, but instead at the body's own tissue. Many authorities consider rheumatoid arthritis and multiple sclerosis as autoimmune diseases. The precise causes of these diseases have remained obscure. Multiple sclerosis is a demyelinating disease and has variously been described as an autoimmune disease, a viral disease, or an autoimmune disease provoked by a virus. Epidemiological studies indicate that from 3 to 23 years may elapse between the time of exposure to the virus and the onset of symptoms. Further evidence points to involvement of a myxovirus. Measles virus is of this kind.

Possible Viral Connection to Diabetes. A Norwegian physician (J. Stang) in 1864 noted that diabetes developed in one of his patients within a short period after a mumps infection and was probably the first person to indicate a possible connection between viruses and diabetes. Over the years, numerous other connections have been attempted to relate diabetes with mumps, hepatitis, rubella, coxsackie, and influenza viruses, adenoviruses, enteroviruses, and cytomegalovirus. One of the presumptions made is that viruses are understood to replicate in the pancreas. Commencing in the late 1950s, more substantive evidence has been given. Reports from Sweden in 1958 link juvenile diabetes with mumps infection. Reports from New York State in 1974 relate closely the cycles of incidence of mumps and those of juvenile diabetes. The study was based upon investigation of records for the period 1946–1971. Tentative conclusions indicate an average lag period of about 3.8 years between onset of diabetes and exposure to mumps and it is reasoned that this represents the time required for the virus to produce permanent damage to the pancreas. Other investigators have statistically linked diabetes to rubella (German measles). Some authorities suggest that the pancreas, along with other embryonic organs, may be damaged by the virus that causes congenital rubella. The records of nearly 3,000 juvenile diabetics treated at King's College Hospital in London (1955–1968) have been studied, and they reveal a seasonal pattern on the onset of juvenile diabetes, striking a low incidence in June and a high incidence in October. Without presenting the details, conclusions are suggested that an association of viral infections with the juvenile form of diabetes is evident. However, the relationship, if any, has not been determined in the case of the maturity-onset form of diabetes.

Viral Diagnosis and Vaccination

Viral Diagnosis. Three major approaches to identification of viruses are commonly used: (1) *Microscopy*. Viruses may be observed directly by electron microscopy; viral antigens may be recognized in infected tissue by immunofluorescence, using virus-specific antisera; virus-induced pathology may be identified by light microscopy. (2) *Virus isolation*. Provisional viral identification may be based upon cytopathic effects produced in cell cultures infected with virus present in tissues or secretions of the patient. (3) *Serology*. Antibodies specific for a particular virus may be identified in a patient's serum. A very sensitive, accurate, and recently developed diagnostic approach is radioimmunoassay, which involves the use of an isotope-labelled antibody or antigen.

Viral Vaccination. Vaccines, agents that elicit a specific antiviral immune response, have been very successful against smallpox, measles, rubella, poliomyelitis, and yellow fever, all of which are generalized diseases. Vaccines against diseases caused by respiratory tract viruses, where great antigenic diversity is found, have been less effective.

Vaccines may be prepared by rendering viruses harmless without affecting their immunogenicity. This can be done by either inactivating the virus, or by selecting avirulent mutants. The most successful vaccines are "living" avirulent viruses, which possess the advantage of multiplying in the host and which usually require only a single dose to be effective. This leads to prolonged immunological stimulation similar to that which occurs in natural infection. Live vaccines, however, are subject to a number of problems, such as genetic instability and contamination by extraneous viruses. Inactivated viruses are usually produced by treatment with formaldehyde, which destroys their infectivity. The major difficulty with inactivated viruses is the administration of sufficient viral antigen to induce a lasting immunity. In many cases, several injections must be given over a substantial period of time. The only inactivated viral vaccine in widespread use in humans is the influenza vaccine. The inactivated Salk

polio vaccine has been largely replaced by the attenuated live-virus Sabin vaccine.

Interferon. Interferons (IFN) are proteins that evert virus nonspecific antiviral activities in cells through metabolic processes involving synthesis of both DNA and protein. The number of interferon-inducing substances has increased to include not only all of the major virus groups, but also bacterial and fungal products, nucleic acids, polymers, mitogens, and various low-molecular-weight substances. However, as interferons are induced by viruses and inhibit viral replication, viruses are usually considered to be natural inducers. The ability of viruses to induce interferon production depends upon the virus type. Some viruses, such as that responsible for Newcastle disease, are good inducers, while others, such as the adenoviruses, are regarded as poor inducers. Further, the type of cell used presents another factor in interferon production. In the whole animal, cells of the reticuloendothelial system are generally considered to be the major interferon producers. Recently, interferons have been classified into types on the basis of their antigenic specificities. Alpha and beta interferons (formerly called leukocyte and fibroblast, respectively) are acid stable and correspond to what have been called *Type I* IFNs (interferons). Gamma interferons (formerly called Immune) are acid labile and correspond to *Type II* IFNs.

Although interferon has been studied extensively for over a decade, the mechanism of its antiviral activity remains unclear. Considerable evidence exists to support the concept that interferon inhibits virus-specific protein synthesis, thus blocking viral replication in cells adjacent to the infected cell producing the interferon. There is no established reason to conclude, however, that interferon exerts antiviral action through a single mechanism. Interferon is probably one of the most important early determinants of recovery from a number of viral diseases.

Recent work has centered upon use of interferon as a therapeutic agent in humans and animals. In humans, local application of monkey interferon is effective in reducing the severity of vaccinia virus skin infections. Recent results with herpes keratitis and chronic hepatitis are promising. Interferon appears to be active against oncogenic viruses in the treatment of such cancers as osteogenic sarcoma, and at present it is only the limited availability of interferon that prevents more extensive testing.

A number of virus diseases and virus related topics are described in this encyclopedia. Check alphabetical index for antiviral drugs, cancer research, chickenpox, common cold; coxsackie virus, dengue (breakbone fever), hepatitis, infectious mononucleosis, influenza, measles, mumps, Norwalk virus, poliomyelitis, rabies, Rift Valley fever, vaccinia, virus diseases (plants), and yellow fever.

VISCERA. Organs lying more or less freely in the cavities of the body. Usually applied to the heart and lungs as thoracic viscera and to the stomach, intestines, spleen, liver and pancreas, and some of the reproductive organs as abdominal viscera.

VISCOELASTICITY. Mechanical behavior of material which exhibits viscous and delayed elastic response to stress in addition to instantaneous elasticity. Such properties can be considered to be associated with rate effects — time derivatives of arbitrary order of both stress and strain appearing in the constitutive equation — or hereditary or memory influences which include the history of the stress and strain variation from the undisturbed state. See also **Rheology**.

Early scientists defined matter as a solid, liquid, or gas. They found that some materials fit in more than one of these phases. Honey is a good example of a material with the physical properties of both a solid and a liquid. Allow honey to flow from a container and then quickly tip it up. A portion of the honey will be pulled back into the container. Liquids don't typically respond to tensile force or pulling force. Scientists defined this material as viscoelastic because it exhibited the characteristics of a viscous liquid and an elastomeric solid. Silly putty, chewing gum, and polyurethane memory foam are also examples of viscoelastic materials.

Almost all polymers exhibit viscoelastic behavior. Polymers (and other viscoelastic materials) behave more like solids at low temperatures and at fast deformation speeds. They are more like liquids at high temperatures and slow deformation speeds.

Viscoelastic material models are frequently used to describe the behaviour of (soft) human tissue, plastics, soil, etc. Commonly used viscoelastic models are the Kelvin material and Maxwell material. Each model can be represented by springs and dashpots set in combinations of series and parallel elements.

Linear viscoelasticity is when the function is separable in both creep response and load. All linear viscoelastic models can be represented by a Volterra equation connecting stress and strain. Like:

$$\varepsilon(t) = \frac{\sigma(t)}{E_{inst,creep}} + \int_0^t K(t-t')\sigma(t')dt'$$

or

$$\sigma(t) = E_{inst,relax}\,\varepsilon(t) + \int_0^t F(t-t')\varepsilon(t')dt'$$

where t - time, $\sigma(t)$ - stress, $\varepsilon(t)$ - strain, $E_{inst,creep}$ and $E_{inst,relax}$ - instantaneous elastic moduluses for creep and relaxation, $K(t)$ - creep function, $F(t)$ - relaxation function.

Nonlinear viscoelasticity is when the function is not separable. It is usually happens when the deformations are large or if the material changes its properties under deformations.

VISCOMETER (or Viscosimeter). A device for measuring the viscosity of a liquid. The types most widely used are the Engler, Saybolt, and Redwood, which indicate viscosity by the rate of flow of the test liquid through an orifice of standard diameter of the flow rate of a metal ball through a column of the liquid. Other types utilize the speed of a rotating spindle or vane immersed in the test liquid. The liquids commonly measured are lubricating oils and the like; heavier (non-Newtonian) liquids such as paints and paper coatings require more complex devices, e.g., Brookfield and Krebs-Stormer.

See also **Viscosity**.

VISCOSE PROCESS. The best-known process for making regenerated cellulose (rayon) by converting cellulose to the soluble xanthate, which can be spun into fibers and then reconverted to cellulose by treatment with acid. Wood pulp is steeped with 17–20% caustic soda; the resulting alkali cellulose is pressed to remove excess liquor and the soluble β-and γ-cellulose, and then shredded and aged. It is then treated with carbon disulfide and sodium hydroxide to form an orange, viscous solution of cellulose xanthate. After filtration and deaeration, this solution (viscose) is forced through minute spinnerette openings (or long slit dies in the case of cellophane) into a bath containing sulfuric acid and various salts such as sodium and zinc sulfate. The salts cause the viscose to gel immediately, forming a fiber or film of sufficient strength to permit it to be drawn through the bath under tension. At the same time the sulfuric acid decomposes the

xanthate, converting the fibers to cellulose, in which form they are washed and dried.

See also **Xanthates**.

VISCOSITY. A property of fluids, which appears as a dissipative resistance to flow. A solid subjected to external forces can attain a condition of elastic equilibrium with elastic stresses balancing the applied forces. A fluid subject to external forces can be in static equilibrium only if the forces are derivable from a potential function and the usual result is steady flow resisted by viscous stresses set up by distortion of fluid elements. The mechanism and nature of the viscous effect may be very different in gases and in liquids.

In a gas, viscous stresses arise from migration of molecules, which carry with them momentum relative to their starting-points. To the extent that the gas may be treated as a continuous fluid, i.e., on scales large compared with the mean free path and for time intervals large compared with the collision frequency, Newton's law of fluid friction is obeyed. The elementary form of the law is that, in simple shearing motion, the shear stress is proportional to the rate of shear. More generally, the stress tensor p_{ij} is linearly related to the rate of deformation tensor

$$S_{ij} = \frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}.$$

The kinetic theory of gases leads to

$$p_{ij} = \eta\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \delta_{ij}\left(\frac{1}{3}\eta\frac{\partial u_j}{\partial x_j} + p\right)$$

where

u_i is the velocity at position x_i
p is the hydrostatic pressure
$\eta = A\rho\tilde{c}\lambda$ is the coefficient of (dynamic) viscosity
ρ is the density
$\tilde{c}$ is the mean speed of the molecules
λ is the mean free path

The constant A depends on the forces between the molecules and is nearly 0.5 for hard spherical molecules. For low densities, the viscosity is independent of pressure and proportional to the square root of the absolute temperature. For large densities, the Enskog relation describes the variation with density,

$$\frac{\eta}{\rho} = \frac{1}{2545}\left|\frac{v}{b} + 0.8000 + 0.7614\frac{b}{v}\right|\left(\frac{\eta}{\rho}\right)_{\min}$$

where v and b mean the same as in van der Waals equation. The variation with temperature is given by Sutherland's formula,

$$\eta = \eta_0\left(\frac{T}{273.2}\right)^{3/2}\frac{c + 273.2}{c + T}$$

where c is a constant and η_0 is the viscosity at 0 °C.

The viscous stresses in liquids arise more from intermolecular attraction than from molecular migration and more complicated kinds of behavior are found. The concept of a liquid as an imperfect solid suggests that a liquid behaves as an elastic solid with considerable thermal creep. A simple model has a relaxation time λ, and relates stress to strain by

$$p_{ij} + \lambda\frac{\partial p_{ij}}{\partial r} = \eta_1\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) - \delta_{ij}\left(\frac{1}{3}\eta_1\frac{\partial u_j}{\partial x_j} - p\right)$$

describing a simple visco-elastic fluid. For some liquids, the relaxation time is small compared with time scales of ordinary flows, and the liquid exhibits Newtonian behavior. Many liquids, such as solutions of proteins and polymers, are non-Newtonian in behavior and show relaxation effects and even nonlinear response to deformation. The variation of viscosity of Newtonian liquids with temperature and pressure is described by the Arrhenius formulas. Characteristically, the viscosity of a liquid decreases rapidly with increase of temperature and increases with pressure. An exception is liquid helium I whose viscosity at its own vapor pressure increases with temperature.

The Newtonian coefficient of viscosity has dimensions $ML^{-1}T^{-1}$ and the cgs unit is the poise (after Poiseuille). The centipoise is frequently used for mobile liquids. English units are lbm ft^{-1} sec^{-1} and lbf ft^{-2} sec. Special units are used in engineering practice, related to specific instruments for the measurement of viscosity. For problems involving the action of viscous stresses on the fluid itself, it is convenient to use the kinematic viscosity, $v = \eta/\rho$. It may be regarded as the diffusivity of momentum.

See also **Units and Standards**.

In view of the importance of viscosity as an index of the suitability of liquids for practical purposes such as lubrication, many methods of measurement have been devised. There are four chief kinds of absolute methods, as follows:

1. *Stokes' law methods*. These involve measurement of the rate of fall of a small sphere in the liquid. The viscosity is given by

$$\eta = \frac{2gr^2(\rho - \rho_l)}{qV}$$

where r is the radius of the sphere, ρ is the density of the sphere, ρ_l is the density of the fluid and V the rate of fall. It is essential that the Reynolds number of flow $V + \rho/\eta$ should not exceed 0.1, i.e.,

$$V^2 < 0.02\frac{\rho - \rho_l}{\rho}gr$$

2. *Capillary tube methods*. These apply the Poiseuille equation to the measurement of viscosity. Allowance must be made for end effects, and the Reynolds number of flow must be small enough to ensure laminar flow.

3. *Rotating cylinder methods*. The torque transmitted to a stationary inner cylinder when the outer one is rotated at constant speed is given by a simple equation involving the viscosity, provided the speed of rotation is not too high. The method is wellsuited for precision measurement as end-effects may be eliminated by guard-rings.

4. *Oscillating disk method*. A disk oscillating in a plane parallel and close to a plane surface undergoes a damping due to the viscosity of the intervening fluid. From the dimensions of the apparatus and the rate of damping, the viscosity may be calculated.

Most of the absolute methods have been applied in simplified form, i.e., operationally convenient but subject to corrections that must be determined by use with a fluid of known viscosity. Thus, the Engler and Saybolt viscosimeters use the time taken for a sample of liquid to flow past a constriction in a tube as a measure of its viscosity. See also **Rheology**.

VISIBILITY. In United States weather-observing practice, the greatest distance in a given direction at which it is just possible to see and identify with the unaided eye (a) in the daytime, a prominent dark object against the sky at the horizon, and (b) at night, a known, preferably unfocused, moderately intense light source. Daytime estimates of visibility are subjective evaluations of atmospheric attenuation of contrast, while nighttime estimates represent attempts to evaluate something quite different, namely attenuation of flux density.

According to United States weather-observing practice, after visibilities have been determined around the entire horizon, they are resolved into a single value of *prevailing visibility*, which is the greatest horizontal visibility equaled or surpassed throughout half, though not necessarily a continuous half, of the horizon circle. Visibility determined from a point on the ground is *surface visibility*, as opposed to *control tower visibility* observed from an airport control tower. *Vertical visibility* is the distance that can be seen vertically into a surface-based obscuring phenomenon such as fog, rain, or snow.

Transmissometers are used to measure visibility at airports along the active runway. A transmissometer consists of a narrow light beam focused into a photoelectric cell 250 feet (75 meters) away. The output of the photocell is a measure of the light received from the spotlight, i.e. the amount of light transmitted. The attenuation of the light beam is a measure of the transmissivity of the atmosphere and is related to what the human eye (aircraft pilot's) can see. If there is no attenuation the visibility is "unlimited." If there is 100% attenuation the visibility is less than 250 feet (75 meters), the baseline distance.

Visibility obtained by the use of a transmissometer is called *Runway Visual Range* and it is intended to be the distance a pilot can see at touchdown for landing.

See also **Fog and Fog Clearing**; and **Weather Technology**.

VISION AND THE EYE. The complete visual system requires light, the eye, and a conscious observer. In its gross aspects, the visual system includes the eyes, the *extraocular muscles* which control eye position in the *bony orbit* (eye socket), the optic and other nerves that connect the eyes to the brain, and those several areas of the brain that are in neural communication with the eyes. This summary will stress the informational aspects of human vision. It should be realized, however, that no visual system could function without its *protective mechanisms* (tears and eyelids, especially) or if its normal metabolism (mediated through the vascular supply of eye and brain) should malfunction.

The visual system is particularly well adapted for the rapid and precise extraction of spatial information from a more-or-less remote external world. It does this by analyzing, in ways that are as yet imperfectly understood, the continuously changing patterns of radiant flux impinging upon the surfaces of the eyes. Much of this light is reflected from objects that must be discriminated, recognized, attended to, and/or avoided in the environment. This ability transcends enormous variations in intensity, quality, and geometry of illumination as well as vantage point of the observer. A block diagram of the visual system is given in Fig. 1.

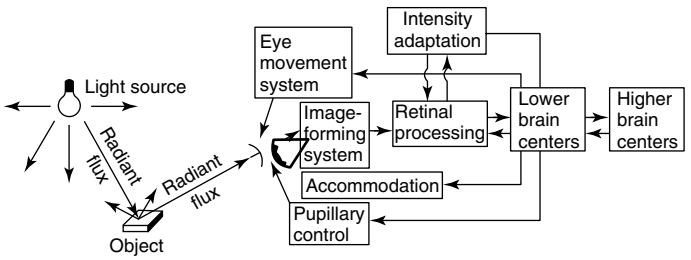

Fig. 1. Functional components of the visual system.

Although image formation in the eye is importantly involved, the analogy between eye and photographic camera has been badly overworked and tends to create the erroneous impression that little else is needed to explain how we see. Image formation is greatly complicated by the movement of the eyes within the head, and of both eyes and head relative to the external sea of radiant energy. Such visual input is ordinarily sampled by discrete momentary pauses of the eyes called *fixations*, interrupted by very rapid ballistic motions known as *saccades* which bring the eyes from one fixation position to the next. Smooth movements of the eyes can occur when an object having a predictable motion is available to be followed. A large body of evidence suggests that the visual input is processed by the brain in "time frames" of about 100 milliseconds, although the peripheral parts of the visual system operate with much shorter time constants than this.

Each eye controls many important functions within one mobile housing; it is a device to form an image upon a vast array of light sensitive *photoreceptors*, but it also contains systems to dissect, encode, and transmit information derived therefrom. A cross section of the human eye is shown in Fig. 2. The primary refracting surface is the *cornea*, a complex yet transparent structure, which admits light through the anterior part of the outer surface of the eye. The *iris* contains muscles that alter the size of the entrance port of the eye, the *pupil*. The *crystalline lens* has a variable shape, under the indirect control of the ciliary muscle. Since it has a refractive index higher than the surrounding media, it gives the eye a variable focal length, allowing *accommodation* to objects at varying distances from the eye. The iris muscles and the ciliary muscle, known collectively as the *intraocular* muscles of the eye, are controlled by impulses having their origins in separate but interacting centers in the brain stem. These brain centers also receive nerve impulses from the eye. These loops, and those involving the extraocular musculature and thus eye position, have some of the properties of nonlinear servosystems, and have been actively investigated as such.

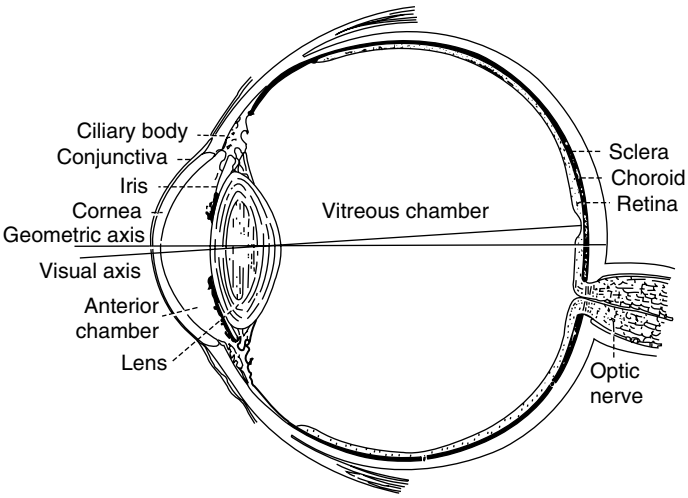

Fig. 2. Horizontal cross section of the right eye of the human.

Much of the remainder of the eye is filled with fluids and materials under pressure, which help the eye maintain its shape. The *aqueous humor* — thin, watery, and continuously being replaced — fills the *anterior chamber* between cornea and lens. The *vitreous humor* — thinly jellylike and of very low metabolism — fills the majority of the eye's volume. The image produced through these structures is formed upon the *retina* at the back of the eye. The retinal image is very small, because the eye itself is small and has a short posterior focal length of about 19 to 23 millimeters, depending upon accommodative state. The retinal image has a point-spread function on the order of two to three minutes of arc, corresponding to about 10 micrometers on the retina for ideal conditions. These conditions include a 2 to 3 millimeters pupil, monochromatic light, optimal accommodation and a normal, young, and healthy eye. This quality approaches, but is somewhat worse, than that produced by diffraction-limited imagery in an ideal optical system. The retinal image is always in motion. Even during the best efforts at steady fixation, there exists an irreducible tremor of the eye whose high-frequency components are in the 20 to 30 second-of-arc range, with larger drifting and saccadic movements up to 5 minutes of arc. It is possible to eliminate this residual motion by various optical techniques. Such stabilization usually results in a total loss of vision, providing an elegant demonstration that the visual system responds primarily to *changes* in light patterns, rather than to steady states. Electrophysiological evidence from animals amply confirms this.

The retina is a thin structure of extreme complexity. It is considered embryologically to be a displaced part of the brain, and it is of clinical importance as the only part of the central nervous system that can be directly observed in the intact living subject. The receptors, the *rods* and *cones*, line the back surface of the retina, in immediate contact with a dark layer (the choroid) which helps to nourish the receptors and to prevent multiple reflection of light. There are about 125,000,000 receptors in each human eye, of which only about 5% are cones. The cones are, however, of an importance disproportionate to their relative number. In particular, there is a small central bouquet of about 2,000 cones located in a rod-free depression of the retina known as the *fovea centralis*. There, they are packed together into a hexagonal array having a density of about 150,000/square millimeter. These are capable of dissecting the finest details of the optimal retinal image. This process is aided by the lateral displacement of other retinal structures through which light must pass to reach the cone receptors. Moreover, this is the area of the retina where images have the highest attention value and which "projects" to a disproportionately huge area of the visual brain. The extraocular muscles move the eye more or less automatically, in the act of fixation, to put object of interest into this region, where their details can be most critically appreciated, while the accommodative mechanism alters the shape of the lens to produce the sharpest possible image in this region. The cones, including those in the fovea, function only at high luminance levels (approximately, above .01 candela/square meter), below which are functionally blind and the rods take over. Thus the retina contains two systems intermixed: (a) the cone system (photopic), good for high-acuity

vision, which also mediates all color vision; (b) the achromatic rod system, which has relatively poor spatial resolving power, but very high sensitivity.

The rods and cones are synaptically connected to the *bipolar cells*, which in turn relate to the *ganglion cells*, whose axons constitute the optic nerve fibers. There are also rich horizontal connections among the receptors, among the bipolar cells, and among the ganglion cells. In addition, there is a high degree of convergence: the 125,000,000 receptors ultimately feed into only 1,000,000 nerve fibers of the flexible optic nerve, which therefore constitutes the principal "bottleneck" of information flow in the visual system. The convergence ratio for the fovea is about 1:1, helping to preserve the high-detail vision of this region, while in the peripheral retina this ratio is many thousands to one, leading to high sensitivity at the sacrifice of resolving power.

The pathways from retina to brain are by no means independent, including those emerging from the central fovea. The horizontal interconnections are utilized to allow inhibitory processes to sharpen the "neural image" by a process of border enhancement, but much more complicated preprocessing of information occurs also. It is abundantly clear that the brain does not receive a replica of what is on the retina, although a spatial isomorphism between retina and brain does exist. Rather, the messages sent to the brain tend to carry information that is already processed in complex ways to make efficient use of the limited communications pathways between eye and brain in an adaptively significant manner.

Because the two eyes are located in slightly different places in space, a disparity of the two retinal images results. Rather than to produce a blurred or confused picture, this *retinal disparity* results in the appearance of *stereoscopic depth*. Such depth judgments are remarkably precise, consistent with the findings that all but the smallest eye movements and accommodative adjustments are highly correlated between the two eyes, and that neural units in the visual brain are precisely connected, by way of intermediate synapses, to optically corresponding areas.

The normal eye exhibits a large amount of chromatic aberration, which is not normally noticeable. There are at least two reasons for this: (a) the cone receptors exhibit a directional sensitivity, which reduces the visual effectiveness of light entering the marginal zones of the pupil; (b) the visual system has a remarkable capacity to adapt to systematic distortions, of almost any kind, which do not carry useful information from the external world. For example, observers learn with practice to compensate for the effects of gross visual displacement caused by prisms placed before the eyes, and are not longer able to see the chromatic fringes produced by such prisms. Removal of the prisms produce reappearance of chromatic fringes and an apparent displacement in the opposite direction. The explanation of such effects is not simple: in this example, the adaptation to displacement is probably kinesthetic rather than visual, but the adaptation to fringes is almost certainly confined to the visual system. Related to this are many entoptic phenomena that are seldom perceived: (a) the shadows of the retinal blood vessels, which are in front of the receptors; (b) the blind spot in the visual field, caused by the receptor-free optic disc, large enough to contain 200 images of the moon; (c) "floaters," usually shadows of debris in the vitreous humor, clearly visible if attended to against bright, uniform surfaces such as the sky; (d) fleeting specks of light probably caused by the movements of corpuscles within the retinal blood vessels; (e) Maxwell's spot, probably corresponding to the region of the macular pigment, and many others.

The initial nonoptical event in the visual process is the absorption of single light quanta by single molecules of visual photopigment, of which millions are located in each rod or cone. Under ideal conditions, as few as a half-dozen of these elemental events within fairly broad bounds of time and area, are sufficient to lead to a visual sensation. The visual photopigment contained in the rods is *rhodopsin*, having a peak sensitivity at about 505 nanometers. It has been much studied and is found in most animals including man. Absorption of light by rhodopsin probably produces graded potentials at the receptors that trigger all-or-none nerve impulses by the time the ganglion cells are activated, if not before. The exact mechanisms whereby light absorption gives rise to receptor potentials (and these to nerve impulses), although under active investigation, cannot be said yet to be satisfactorily understood.

Modern neurophysiology has learned much about the operation of the individual nerve cell, but rather little about the meaning of the circuits they compose in the brain. An initial approach to visual information processing is described by these authors. See also the entry on **Central and Peripheral Nervous Systems**.

Color vision depends upon the existence of three classes of visual photopigment, all different from rhodopsin, housed in different proportions in different classes of cone receptors. When two fields of light that are physically different look exactly alike in color (*metameric* matches), it is probable that the rate at which light is being absorbed in the three classes of cone photopigment is the same from both fields, although this is not yet definitely established. The perception of color clearly involves the higher levels of the visual system as well.

Another important property of the eye is its adaptation to intensity by means of which the eye changes its gain and other characteristics, enabling it to respond discriminatively over a stimulus intensity range of about ten billion to one. At one time, it was felt that the bleaching of photopigments was primarily involved in this process. Recent evidence indicates, however, that this plays only a minor role and the true mechanisms are numerous and include changes in the organizational properties of retinal networks.

Physical Disorders of the Eye

Near-and Farsightedness. Ideally, the lens of the eye receives light from the outside and bends it in such a way that an image is resolved upon a small point of the retina. In order to maintain focus on the retina, the lens must change its shape when objects are viewed from different distances. However, the cornea has more than twice the focusing power of the lens. If the cornea-lens combination focuses the light rays at a point in *front of the retina*, the person is *near-sighted* (myopia) and *cannot see distant objects* clearly without glasses. If, on the other hand, the light rays are focused at a point *behind the retina*, the person is *farsighted* (*hyperopia*). *Presbyopea*, a decrease in the ability of the eye to accommodate to various distances, is a normal concomitant of the aging process. It is common in persons over 40 years. Unless caused by disease, accommodation is afforded by the use of glasses.

The manner in which light rays from distant objects are focused on the retina in a normal eye is shown in Fig. 3. *Myopia* may occur when the eyeball has grown too long for the normal focus of the cornea and the lens, so that the image projected onto the retina is blurred and out of focus. See Fig. 4. An eye of normal size can also develop the problem if the curvature of the cornea and lens increase, causing greater refractive (bending of light) power. The focus falls short and a blurred image is transmitted to the retina. See Fig. 5.

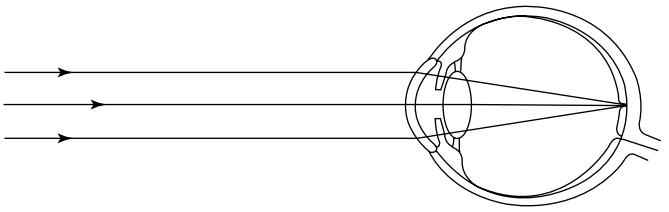

Fig. 3. Pattern of light rays from distant objects as focused on the retina of a normal eye. (*American Association of Ophthalmology*.)

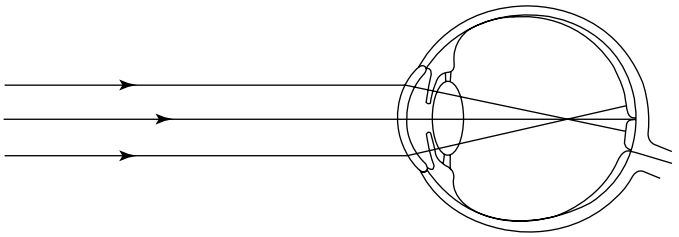

Fig. 4. Pattern of light rays from distant objects as focused in a myopic eye due to abnormal length of the eyeball. The rays are focused short of the retina by the normal curvatures of the cornea and lens. (*American Association of Ophthalmology*.)

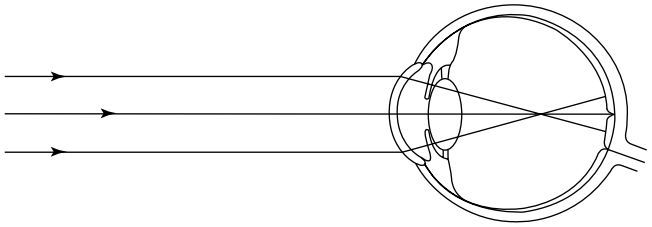

Fig. 5. Pattern of light rays from distant objects as focused in a myopic eye due to increased curvatures of the cornea and lens. The rays are focused short of the retina. (*American Association of Ophthalmology*.)

A distinction is usually made between *simple* and *pathologic myopia*. Simple myopia is the most common form and is not attributable to eye disease. The cause of pathologic myopia is not well understood. Various hypotheses, including deficiency of vitamins and eyestrain due to reading, have been put forth. There is no evidence that reading (even in poor light) will influence myopia, or that it can be changed by eye exercises. The myopic person can have vision as sharp and clear as anyone by wearing the proper eyeglasses or contact lenses. See Fig. 6. A surgical procedure for correcting nearsightedness in some patients was introduced a few years ago. Known as *radial keratotomy*, the procedure involves making radial incisions in the cornea, permitting peripheral bowing which causes central flattening of the cornea.[1]

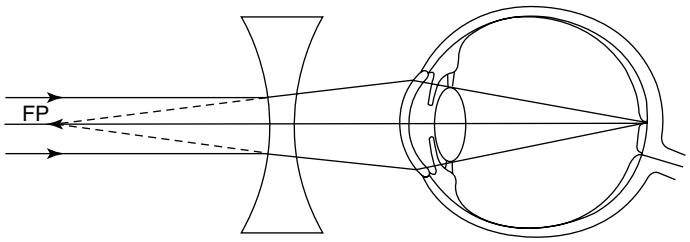

Fig. 6. The myopic eye has a fixed far point (F.P.) beyond which objects cannot be seen clearly. To correct this problem, the proper diverging lens placed before the eye will permit light rays from distant objects to be focused sharply on the retina. (*American Association of Ophthalmology*.)

In *hyperopia* (*hypermetropia* or *farsightedness*), there is a defect in refraction of light into the eye which diminishes the ability to see at close range. Rays of light coming from nearby objects cannot be focused on the retina, but those coming from distant objects can be properly refracted. As a result, close images are blurred, while distant ones are clear. The cause may be too shallow an eyeball, or insufficient convexity of the lens, or changes in the refractive media of the eye with increasing age of the individual. The condition usually is easily correctible by use of glasses having convex lenses, or the equivalent contact lenses. See Fig. 7. A surgical procedure for correcting farsightedness in some patients is also relatively new. Known as *epikeratophakia*, the procedure involves suturing a corneal button to the front of the eye. If unsuccessful, the lens (intended to serve as a permanent contact lens, in essence) can be removed and vision returned to preoperative levels.

Astigmatism. This is a common optical defect, but in most cases it is so slight as to go completely unnoticed. It is manifested by a distortion of vision. Thus, in looking at an object, a straight line in the vicinity of the object may appear curved. When the eyes are moved, a motionless object may seem to move as it passes through the distorted area of the field of vision. See also **Astimagtism**.

Nystagmus. This is an involuntary rapid movement of the eyeball, which may be from side to side, up and down, circular, or a combination of these movements. It may be due to incoordination of the eye muscles, disturbances of the nerves of the eye, or to disturbances of the vestibular canals in the ear.

[1] Some of the more recent surgical procedures described have stirred sone controversy among experts. (See *Science*, **35**, February 1, 1985.)

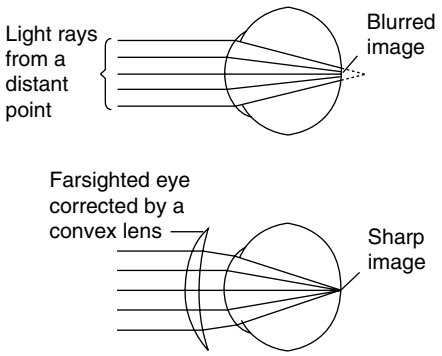

Fig. 7. Path of light rays (above) in farsighted eye, in normal eye (below).

Night Blindness. The greatest concentration of nerve endings in the retina is found in a particular area called the *fovea*, which is located near the center of the retina. The nerve endings in this area are called *cones* and are responsible for direct vision and detection of both intensity and color of light. Scattered near the fovea and distributed in greater numbers elsewhere in the retina are other types of nerve endings called rods. These nerves have little ability to detect color, but are extremely sensitive to light. In daylight, they are almost unable to operate, but when the light is dimmed, their sensory ability returns (*dark adaptation*). The inability to see in dim light is called night blindness. About 30 minutes are required for dark adaptation to reach its maximum. Since only a few of the rods are located in the foveal region, one does not look directly at objects to view them in the dark; instead, the individual looks slightly to the side or just above or below the object.

Color-Blindness. There are several hereditary conditions that may cause an individual to be color-blind. In most instances, the cones of the fovea are operative, but do not distinguish colors. The most common type of color-blindness is termed "red-green" color-blindness. The individual has defective recognition of reds and greens. Rarer types prevent differentiation of other pairs of colors. Total color blindness is the rarest type; the individual can distinguish only shadings of gray and black. The inheritance of red-green color blindness usually follows a sex-linked pattern. Briefly, the disability appears more frequently in men than in women; although only one girl in 100 will be color-blind, the disability will appear in one out of every 10 or 12 boys. The disorder will not appear in a color-blind man's son unless the boy's mother is either color-blind, or is a carrier of the gene for color-blindness. Consequently, the disorder only rarely is transmitted from father to son. More commonly, color-blindness is transmitted from an affected man through his daughters (in whom the condition usually is not expressed) to about one-half of his grandsons. Color-blindness also can be caused by disease or injury of the retina, the optic nerve, or the conduction paths of the eye to the brain. See also **Color Blindness**.

Strabismus. Normal binocular vision is the ability of each eye to look at the same point in distance. It is the result of balanced muscular coordination, allowing proper convergence of the eyes to take place. When one eye cannot achieve binocular vision with the other because it deviates inward ("cross-eyes"), outward ("wall-eyes"), upward, or downward, strabismus is said to be present. Strabismus may be caused by paralysis of one or more ocular muscles, or by congenital imbalance of the muscles. See also **Strabismus (Cross-Eyes)**.

Retinal Disorders. The retina is a delicate sheet of tissue made up of ten layers. The pigmented outermost layer normally lies snug against the back wall of the eye. The nine inner layers, which pick up light rays, have in front of them a semi-solid transparent gel called the *vitreous*. This vitreous gel occupies most of the eye cavity. See Fig. 8. The retina's function is like that of film in a camera. By means of a complex chemical process it transforms light into electrical energy and transmits it to the brain. The brain, in turn, interprets these electrical impulses as visual images. Only when the retina is intact and in proper position can vision be normal.

During normal aging, the gel becomes liquified. It collapses in a significant percentage of the total population by the age of 65 years. The breakdown of the gel or liquification is a prolonged process rather than

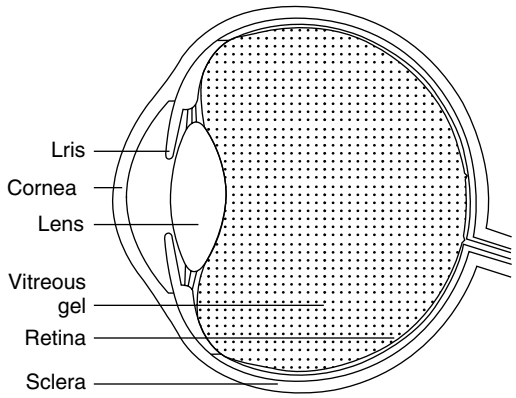

Fig. 8. Sectional view of human eye showing large amount of space taken up by vitreous gel between the lens and the retina. The retina, made up of ten layers of delicate tissue, may be torn, develop holes, and sometimes become detached. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

a single episode in the patient's life. During the collapse of the gel, if a retinal adhesion is present, it creates a traction force tearing a hole in the retina. The patient may be aware of flashing lights and a shower of spots during this period. The vitreous collapse continues and fluid may seep through the hole in the retina, lifting or detaching the retina, much as wallpaper falling from a ceiling when there is a leak in the roof. A black visual curtain results, with the loss of sight. See Fig. 9.

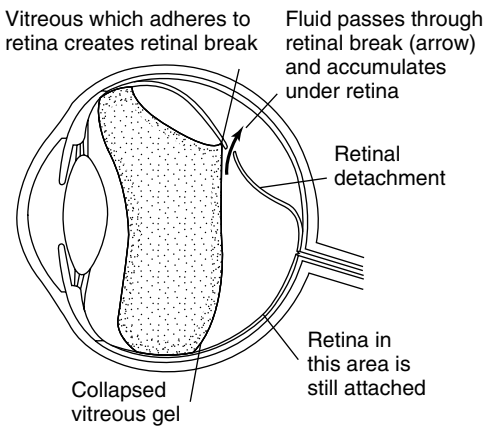

Fig. 9. When the retina detaches it becomes separated from the eye wall by a layer of fluid. Most retinal detachments occur spontaneously when the vitreous gel shrinks and tugs on the retina causing one or more holes or tears to occur. Liquefied vitreous fluid then seeps through the hole and accumulates behind the retina, detaching it from the back wall of the eye. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

Careful examination with the use of a bright light of the binocular ophthalmoscope will reveal a tear before the detachment occurs. In some cases, when tears and holes are detected before the retina actually detaches, the ophthalmologist may be able to seal them by means of laser photocoagulation or cryotherapy. Both of these methods are relatively simple and safe, requiring no general anesthetic, and are usually performed on an outpatient basis. See Figs. 10 and 11.

Early diagnosis and treatment of retinal problems is very important because the progression from hole to *actual detachment* may be rapid and, once detachment occurs, major eye surgery is required. Recent advances in diagnostic and surgical techniques, coupled with improved silicone supporting materials, have significantly increased the success rate in detachment surgery and decreased the period of hospitalization.

Surgical repair of retinal detachment involves sealing the hole or holes so that the retina can return to its normal position. Scarring is produced by freezing or heating the tissue around the hole. A patch is sewn on the sclera over the hole to support the tear by reducing vitreous traction. In some

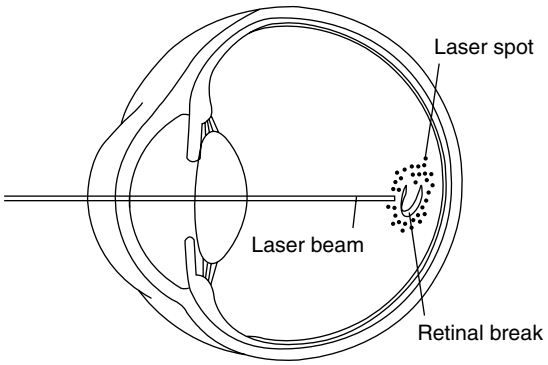

Fig. 10. Laser photocoagulation is a process in which split-second bursts of intense, precisely focused light are directed through the pupil onto the retina. This procedure is successfully used to repair the retina prior to it becoming fully detached. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

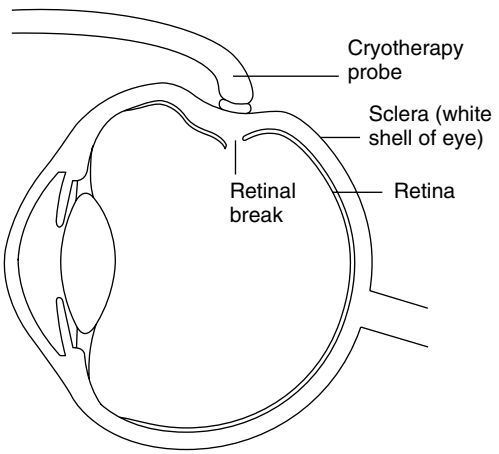

Fig. 11. Cryotherapy is a process in which a freezing probe (which looks similar to a ballpoint pen) is applied briefly to the outside of the eye wall. The probe freezes through to the retinal hole and promotes growth of sealing scar tissue.

cases, a silicone rubber sponge is used. In other cases, solid silicone rubber patches are used. An encircling band of silicone rubber also may be used to provide support during the period of scar formation. See Fig. 12. As a rule, the band remains permanently in place, in the hopeful expectation that it will prevent a recurrence of the detachment.

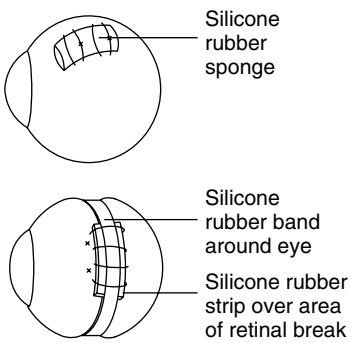

Fig. 12. Surgical repair of retinal detachment. Holes in the retina are sealed by scarring produced by freezing or heating the tissue around the hole to support the tear by reducing vitreous traction. In some cases, a silicone rubber sponge is used, as shown in top of diagram. In other cases, an encircling band of silicone rubber may be used to provide support during the period of scar formation. as shown in bottom of diagram. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

Vitrectomy. The vitreous gel may undergo various other changes which will cause a decrease or loss of vision. These changes may or may not be

related to retinal detachment. In some patients, especially diabetics, the vitreous may become permanently filled with blood, which acts like a cloud, preventing light from reaching the thin, sensitive retinal layer. In one type of surgery, instruments that look like small metal straws are inserted into the vitreous cavity. See Fig. 13. Bloody vitreous is removed by suction, in a procedure called vitrectomy. As the flood-filled vitreous is withdrawn, a clear fluid is automatically infused through a third opening in the eye. This exchange of clear fluid for opaque fluid permits light to reach the retina, returning improved vision.

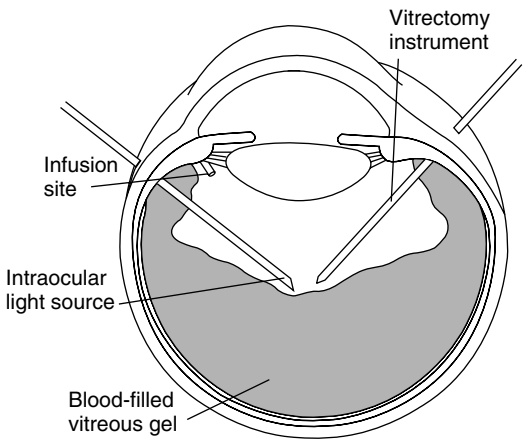

Fig. 13. Vitrectomy, a surgical procedure for exchanging blood-filled vitreous with a clear fluid. Instruments that look like small metal straws are inserted into the vitreous cavity and the blood vitreous is removed by suction, after which a clear fluid is automatically infused through a third opening in the eye. (*Wills Eye Hospital, Philadelphia, Pennsylvania*.)

In some patients, scar tissue may develop in the vitreous gel. As the vitreous shrinks, this scar tissue pulls on the retina and causes it to separate from the eye wall. This is known as *traction retinal detachment*. See Fig. 14. In this complex situation, vitrectomy is combined with retinal detachment surgery. The scar tissue is first removed with the vitrectomy instrument and automated scissors to release traction on the retina.

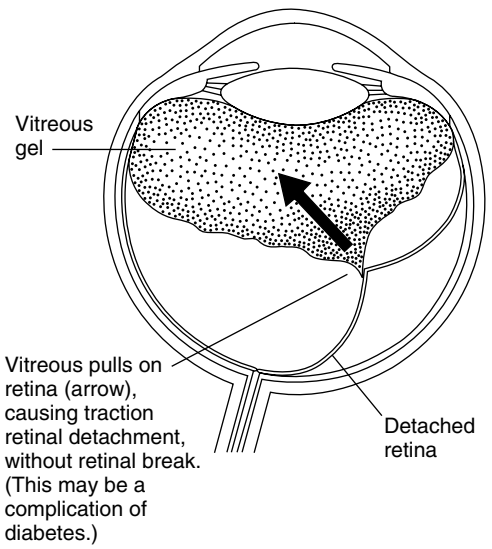

Fig. 14. Complex eye surgery in which vitrectomy is combined with retinal detachment surgery. Scar tissue is first removed with the vitrectomy instrument and automated scissors to release traction on the retina. (*Wills Eye Hospital, Philadelphia, Pennsylvania*.)

Cataract. The loss of sight due to cataract has been known since antiquity. Cataract is defined as any opacity (clouding) of the lens of the eye that alters or blocks the passage of rays of light through it, and thus interferes with vision. The lens of the eye is normally a transparent body that lies directly behind the iris and pupil. Cataract is not a film that grows over the lens, but a cloudiness of the lens itself. Cataracts are not growths and are not contagious. Among known causes of cataract are some general diseases, such as diabetes. A child may be born with cataract from hereditary influences or because the mother had rubella (German measles) during the first trimester of pregnancy. Radiation and dietary deficiencies also may produce cataract, as can chemical camage or mechanical injury.

In some cases, a cataract may not necessarily become progressively worse and visual acuity can be improved by specially prescribed spectacles. Occasionally, when the cataract is small and centrally located, drops can be given to keep the pupil dilated and allow the person to see around the cataract, thus making surgery unnecessary, or at least postpone it. An individual should not self-diagnose a cataract and allow it to "ripen" prior to consulting a physician. However, the majority of cataracts are progressive and eventually require surgery. Development of advanced surgical techniques during the last several years for removing the lens have resulted in a very high percentage of successful cataract surgeries. At one time, the natural lens of the eye was "replaced" by wearing aphakic glasses with very thick lenses. With few exceptions, these glasses have been replaced either by wearing contact lenses or by implanting an intraocular lens at the time of surgery. The current major trend is toward the latter procedure. The intraocular lens is a clear plastic implant, which is placed either posteriorly (behind the iris) or anteriorly (in front of the iris).

Most lens research pertaining to cataract formation in the past has concentrated on the biochemistry of the processes that may be causative factors. More recently, groups of investigators have also been concentrating on the biophysics of the problem. For example, scientists at Rush University (Chicago) have reported on a new and functional theory of how the lens can maintain its volume and transparency. These investigators found that the lens has a highly unusual structure — the fiber cells in its interior have extremely impermeable membranes. The researchers have proposed that impermeability is a rigid requirement if small ions are not to penetrate the lens and cause cataract. Other scientists as well have been constructing mathematical models of the electrical properties of the lens. Out of this work came the concept that the lens has two kinds of cells — epithelial cells on the outer surface and fiber cells on the interior. It has been shown that the membranes of most cells of the body are far more permeable to sodium than are lens fiber cell membranes. The concept of a "sodium pump" in the lens, which would extrude any sodium ions that might wander into the lens, has been ruled out, because such pumps require energy, and because the lens does not provide facilities for metabolic energy input. Hence the concept that the membranes must be absolutely impermeable. When that permeability deteriorates, a cataract forms according to this hypothesis. See also **Central and Peripheral Nervous Systems**; and **Cataract**.

Diseases of the Eye

A number of eye problems and defects result from various diseases, which affect vital parts of the eye. Some of these conditions are described in separate entries in this encyclopedia. Thus, see **Conjunctivitis**; and **Glaucoma**. For diseases affecting the eyelids, see also **Eyelid** and the glossary at the end of the entry.

Corneal Diseases. *Corneal ulcer* usually starts as a small, gray area of localized necrosis (tissue death). Corneal ulcer is considered a medical emergency because of its tendency to widen and deepen rapidly, until much of the cornea is destroyed. Causes include trauma (usually a foreign body in the eye), infection, and allergy. The most common infectious agent is the herpes simplex virus. Characteristic symptoms are reddened eyes, discharge and lacrimation, pain, blurred vision, and photophobia, but individual symptoms vary. Infections are treated with specific antibiotic therapy, and steroid compounds may be prescribed.

Keratitis is inflammation of the cornea caused by infection, trauma, or chemical irritation. There are many types of keratitis. *Interstitial keratitis* is an inflammation of the deep layers of the cornea, and it occurs most commonly among children afflicted with congenital syphilis, and appears between the ages of 5 and 15. The cornea becomes progressively grayish and opaque. Eventually, both eyes are usually involved. If drug therapy fails, corneal transplantation may be considered in suitable cases. *Industrial*

keratitis takes many forms. Almost always, the source of inflammation is physical trauma or chemical irritation. See also **Keratitis**.

Keratopathy is deterioration of the cornea with aging, or in the presence of other eye diseases, the production of outgrowths of hyaline tissue on the back surface of the cornea. These transparent growths interfere with vision by scattering incident light. The condition is called *guttate keratopathy*. The cornea also may develop blisters on its front surface (*bullous keratopathy*) which interfere with vision and may be very painful.

Corneal Transplantation. Surgical techniques make it possible to replace all or part of a diseased human cornea by a corresponding segment of a clear human cornea obtained from another individual. In addition to damage from corneal diseases, the transparency of the cornea may have been scarred by injury or burn. For the corneal transplant to be successful in restoring sight, the other parts of the eye must be in good condition. Because of difficulties of acquiring healthy corneas for transplantation when needed, eye banks have been established. Persons wishing to donate the eyes immediately after death should best contact an eye bank or inform a physician. Simply mentioning this desire in one's will is not sufficient because of the long time factor involved.

Donor corneas can be frozen for long periods of time without apparent damage of any kind of the corneal tissue. Significant advances have been made toward the development and ultimately common use of artificial corneas. Problems involve rejection of foreign substances, such as silicone rubber, synthetic polymers, and plastics from which artificial corneas have been constructed.

Retinitis. This is inflammation or edema of the retina, often associated with inflammation of the choroid coat, in which case the term *choroiditis* may be used.

Uveitis. The eye has three coats — an outer, tough protecting layer called the *cornea/sclera*; an inner, light-sensitive layer called the retina; and a middle, pigmented, nourishing layer called the *choroid*. See Fig. 15. If the outer and inner layers of the eye are removed, the remaining tissue — darker and full of blood vessels — resembles a grape. If this is inflamed, the condition is called *uveitis*. This is a fairly common condition and results in approximately 10% of all blindness.

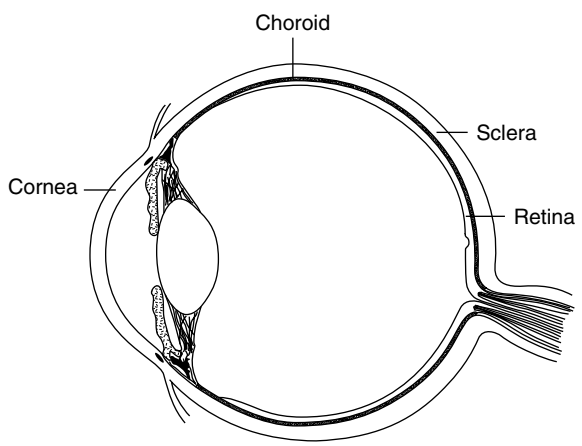

Fig. 15. Coats of the eye. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

Many systemic diseases cause uveitis. More frequently, an attack of inflammation in the uvea is not attributable to any known disease and is believed to be immunologic in nature. In this case, the uvea reacts in a highly sensitized fashion to some abnormal or foreign protein within the body.

Uveitis is a general term referring to the entire uveal tract, but usually this condition is localized or confined to areas that are more often involved, such as the iris (iritis), the ciliary body (cyclitis), or the choroid (choroiditis), depending on whether the inflammation is in the front, middle, or back of the eye. See Fig. 16.

Diseases in which uveitis may be present include ankylosing spondylitis, Behcet's syndrome (rare), epidemic typhus, erythema multiforme, gonorrhea, leptospirosis, meningococcal disease, Reiter's syndrome (rare), and Whipple's disease (rare), among others. See also **Uveitis**.

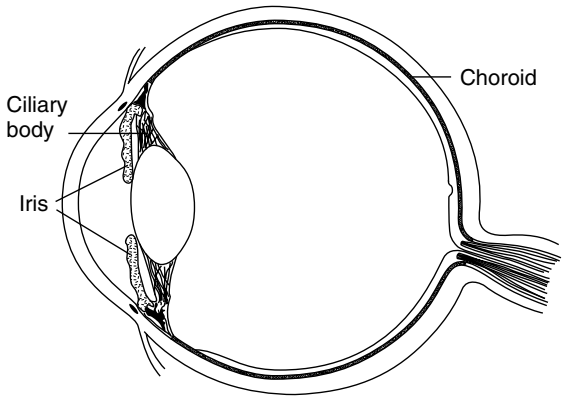

Fig. 16. Areas of the eye that may be involved in uveitis. (*Wills Eye Hospital, Philadelphia, Pennsylvania.*)

Disorders of the Iris. Other than certain congenital malformations, *iritis* is the most common condition affecting the iris. This is an acute or chronic inflammation of the iris, due to any of a variety of causes. When the ciliary body, which lies behind the iris, is also involved, the condition is termed *iridocylitis*. In iritis, the iris looks muddy, dull, and swollen. Symptoms usually include throbbing eye pain, blurred vision, photophobia, and sometimes swelling of the upper lid. Prompt medical care is essential because of the danger of secondary glaucoma ending in blindness. Often atropine drops are prescribed to keep the pupil dilated and adrenocorticoid steroids to shorten the course of the disease.

Tumors of the Eye. These may be benign or malignant. They can involve outer or inner ocular structures. Although they seldom occur, benign tumors can cause serious eye damage and malignant tumors are a threat to life. Tumors of the eyelids closely resemble tumors of the skin elsewhere. However, they may interfere with vision and irritate the eyeball by friction or pressure. Tumors that arise within the eyeball may cause increased ocular pressure (glaucoma), bulging of the affected eye from its socket (exophthalmos), pain, defects in vision, and other symptoms. In the early stages of tumor growth, the patient may experience no symptoms. The two principal malignant tumors are *malignant melanoma* and *retinoblastoma*. Melanoma occurs almost exclusively in adults, usually between the ages of 40 and 60 and involves only one eye and is first noticed as a defect in the visual field. Eventually, retinal detachment takes place around the tumor.

Retinoblastoma is a congenitally acquired cancer. It occurs in children under five years of age, usually in one eye, but sometimes in both. Occasionally several children in the same family have the condition. It has been known to occur in the offspring of adults who were cured of retinoblastoma in childhood.

Researchers at the Massachusetts Eye and Ear Infirmary and the Whitehead Institute announced in 1986 the isolation of the entire retinoblastoma gene. The retinoblastoma gene is thought to be a rare mutation of a normal gene. Children develop retinoblastoma when they inherit one copy of the gene and then, by chance, the homologous segment of their other chromosome in one or more of their retinal cells is deleted or mutated. The result of this sequence is that the individual has no normal gene to counter the effects of the retinoblastoma gene and cancer develops. Search for the retinoblastoma gene stems back to the 1960s to a researcher at the University of Minnesota who reported a patient with an eye tumor who also had a deletion on chromosome 13. This case provided the first hint of where the retinoblastoma gene might be located. Researchers are now searching for the protein that the gene normally codes for. This finding also has a broader implications. It is the first recessive cancer-causing gene ever isolated. All other oncogenes are dominant, that is, one copy of the gene leads to cancer. Researchers at the Muscular Dystrophy Association observe that the dominant genes code for products that apparently direct cells to grow uncontrollably. Because a recessive gene only causes cancer where there is no good copy of the homologous gene present, the interpretation is that these genes may be coding for substances that tell a cell to stop proliferating.

Blindness

Blindness may be caused by any of a number of conditions, including severe instances of the various diseases and disorders previously described. Emotional upsets and hysteria may produce temporary blindness. In addition to the conditions described, permanent blindness can be caused by pressure on the optic nerve by tumors, brain damage by skull fracture or loss of adequate blood supply, and, of course, eye injuries. Comparatively few years ago, most blind persons were considered incurable, but rapid advancements in medical science have greatly altered the situation.

Blindness affects all age groups, but most of those so afflicted are elderly, although about 60% of the blind are not sightless in the real sense of the word. In some states, a person is considered "industrially blind" when the visual acuity is less than 20/200 in the better eye with properly fitted glasses. These Figures mean that the person taking the test for visual acuity can only see at 20 feet (6 meters) what one with normal vision can see at 200 feet (60 meters). Normal vision is defined as 20/20 vision or better. Some persons classified as blind can see clearly, but over only a small area. That is, their vision may be limited to an area approximately the size of that to be seen by looking through the barrel of a gun.

Reading Aids. The usual reading aids for the blind will not be discussed here, but a few of the electronic reading aids will be described briefly.

1. A letter-recognition device for reading short sections of print to make it possible to check bank statements, proof typed letters, or recognize a particular book or magazine by reading its title. The device consists of a probe with 8 to 11 photocells arranged in a linear array, each individually connected to an oscillator the frequency of which increases in pitch from the bottom to the top of the array. When a photocell "sees" dark, it keys on its oscillator. Thus, as the probe is moved along a line of letters, each letter generates a characteristic sequence of chords, which can be learned, but with considerable difficulty.

2. A character recognition device which takes the outputs from an array of specially placed photocells, puts them through a recognition matrix, and triggers a section of magnetic tape that speaks the appropriate letter. Because of slow speed, such a device is not geared to reading for pleasure, but can facilitate reading for information.

3. A device that is a complete automatic computer-controlled print-to-speech converter, which does the equivalent of a human being reading printed material onto magnetic tape. The device is costly and before available on a mass basis, the logistics of a communication and distribution system will have to be worked out, probably utilizing local libraries and telephone lines.

Although in development for a number of years, convenient, low cost reading aids remain to be marketed. Since programs of this type are of a dynamic nature, details cannot be presented here. The Veterans Administration, which has sponsored much development along these lines, is an appropriate contact for additional information.

See also **Braille System**; **Lasers (Eye Surgery)**; and **Retina**.

An abridged glossary of terms used to describe all aspects of vision and the eye would include:

Aberration. Blurred or distorted image quality that results from inherent physical properties (shape, curvature, density) of an optical device such as a lens or prism.

Accommodation. The ability of the eye to change its focus from distant to near objects as well as from near to distance objects. This process is achieved by the crystalline lens changing its shape.

Achromatopsia. Congenital absence of the ability to see colors. Caused by absence or defects in light-sensitive retinal receptor cells (cones) that provide sharp visual acuity and color discrimination. See also **Achromatopsia**; and **Color Blindness**.

Afterimage. A sensation of seeing an object that is no longer in your sight. Also called *after sensation, after vision*.

Age-related macular degeneration (AMD). Degeneration of the photoreceptors in the macula or central region of the retina. This area of the retina is responsible for central vision, used for reading, seeing faces, and so on. Often associated with aging. See also **Age-Related Macular Degeneration**; and **Macula**.

AIDS-related eye disorders. Anyone who is HIV positive should have regular eye examinations by an ophthalmologist, especially if their T-cell count falls under 250 or if vision changes are obvious. The most common eye problem from AIDS is called Cotton Wool Spots. A more serious problem is an eye infection caused by cytomegalovirus (CMV) which can permanently impair vision. Other AIDS-related eye disorders include red eye, shingles, detached retina and Kaposi's sarcoma, a slow growing tumor on the eyelid or spot on the white of the eye.

See also **AIDS-Related Eye Disorders**.

AK. Acronym for Astigmatic Keratotomy. A surgical procedure used to correct moderate cases of astigmatism. Often performed at the same time as the Radial Keratotomy (RK) procedure for correcting nearsightedness. Both AK and RK have been largely replaced by newer refractive surgery procedures. See also **Astigmatic Keratotomy (AK)**; and **Refractive Eye Surgery**.

ALK. Automated Lamellar Keratoplasty. See also **Automated Lamellar Keratoplasty (ALK)**; and **Refractive Eye Surgery**.

Allergies of the eye. Allergic reactions triggered by the body's immune system to protect eyes from injury. Ocular allergies can be seasonal, such as those caused by pollens, or caused by bacteria's, food sensitivities, cosmetics, fabrics, soaps and other substances. Visible symptoms of eye allergies may include swelling, hives, itching, watering, eye pain and sensitivity to light.

Allyl resin plastic lens. The lightest of all vision-correction lenses. But they are thicker than other plastic lenses, are less scratch resistant, and do not block as much ultraviolet light as polycarbonate and glass lenses.

Amacrine cell. A type of neuron seen in the retina.

Amblyopia. Also called lazy eye, this is a condition of decreased vision in one or both eyes that occurs without detectable structural abnormalities or disease in the eye or visual pathways. See also **Amblyopia**.

Amsler grid. Home eye test featuring equally spaced horizontal and vertical lines in a grid pattern. Used for determining the presence of macular degeneration and other defects that affect central vision. See also **Age-related Macular Degeneration**; and **Amsler Grid**.

Angiography. Test used to examine blood vessels in the retina, choroid and iris of the eye. See also **Fluorescein Angiography**.

Angioma. Benign tumor consisting of small blood vessels. Can affect eye with tumors beneath or on top of the retina, which may lead to blood leakage and possible retinal detachment. See also **Von Hippel-Lindau Disease (VHL)**.

Aniridia. A birth defect, in which a child is born without an iris, so there is no way to control the amount of light that enters the eye. The only treatment is to use colored eye lenses to reduce the amount of light entering the eye.

Anisometropia. A condition that occurs when each of a person's eyes have a different refractive power.

Anterior segment. Front third of eyeball, including the cornea, anterior chamber, iris and ciliary body.

Anterior capsulotomy. Cataract surgery technique used to make a round opening in the front (anterior) of the capsule, which encases the eye's natural lens.

Aphakia. Absence of the eye's natural crystalline lens, usually after cataract extraction.

Astigmatism. Uneven curvature of the cornea in which refractive light rays are bent out of focus resulting in distorted vision. Those people with astigmatism are usually born with the disorder and it does not worsen with age. Often occurs in conjunction with nearsightedness or farsightedness. See also **Astigmatism**.

Asthenopia. The term for eye strain.

Automatic keratometer. Instrument used to measure curvature of the front surface of the cornea.

Automatic refractor. Electro mechanical device, that provides an "objective" measurement of an eye's refractive error.

Bardet-Biedl Syndrome. A genetic disorder characterized by degeneration of the light sensitive cells in the periphery of the retina causing night blindness, tunnel vision, decreased visual acuity, and photophobia. Other conditions include obesity, developmental delays, spastic paraplegia and renal disorders. See also **Bardet-Biedl Syndrome (BBS)**.

Basil cell nevus syndrome. An inherited group of multiple defects that result in an unusual facial appearance and a predisposition for skin cancer. The disorder affects the eyes as well as the skin, nervous system, endocrine glands and bones. Children with the disease have wide-set eyes, a broad nose and heavy protruding brow. The disorder results in the appearance of skin cancers, particularly around the cheekbones, upper lip and eyes. See also **Basal Cell Nevus Syndrome**.

Batten Disease. A group of inherited neurological disorders that affect children and are marked by progressive vision failure and other disorders that affect the brain. Most prominent in families of Northern European-Scandinavian ancestry. See also **Batten Disease**.

Bell's Palsy and the eye. Paralysis of muscles controlled by the facial cranial nerve. Eyelid on affected side does not close properly, so corneal drying may become a problem.

Binocular vision. The ability to maintain visual focus on an object with both eyes, creating a single visual image. Lack of binocular vision is normal in infants. Adults without binocular vision experience distortions in depth perception and visual measurement of distance.

Blepharitis. Common, persistent and sometimes chronic inflammation of the eyelids, resulting from bacteria, that reside on the skin. In certain individuals, these bacteria thrive in the skin at the base of the eyelashes or even in the oil glands near the eyelid, resulting in dandruff-like scales and particles. See also **Blepharitis**.

Blepheroplasty. Surgery to improve the appearance of the eyelids. In addition to detracting from overall appearance, drooping eyelids may cause functional problems such as impaired field of vision or difficulty wearing glasses. See also **Blepharoplasty**.

Blepharospasm. Condition characterized by uncontrollable, forcible closure of the eyelids caused by a progressive dysfunction of the nerve that controls muscles around the eye. Less serious form may cause eyelid twitches or tics. See also **Blepharospasm**.

Blind spot. 1. A small area of the retina where the optic nerve enters the eye, this type of blind spot occurs normally in all eyes. Also called optic disk. 2. Any gap in the visual field corresponding to an area of the retina where no visual cells are present; this type of blind spot is associated with eye disease.

Blindsight. A phenomenon reported in individuals who have damage to the primary visual cortex resulting in blindness. Individuals with blindsight report that they are unable to see, yet when examined are able to indicate the presence and location of objects.

Braille. A system of raised-dot writing devised by Louis Braille (1809–1852). Each braille character or "cell" is made up of 6 dot positions that are arranged in a rectangle comprising 2 columns of 3 dots each. A dot may be raised at any of the 6 positions, and each combination of raised dots corresponds to a letter of the alphabet, a punctuation mark, and another symbol. See also Braille **System**.

B-Scan. Ultrasound procedure in which high frequency waves are reflected by eye tissues and orbital structures and then converted into electrical pulses, which are displaced as bright spots on a black background. Provides a cross-sectional view of tissues used for evaluating structures that cannot be seen directly.

Calcarine sulcus. The portion of the occipital lobe of the brain where sight takes place. The central visual field is represented in the posterior calcarine sulcus. The peripheral visual field is represented in the anterior portion of the calcarine sulcus.

Cauterization. The use of heat to destroy abnormal cells. Also called *diathermy* or *electrodiathermy*.

Chalazion of the eyelid. Inflammatory lump in a meibomian gland of the eyelid. This gland, located just inside the eyelid, supplies the outer portion of the tear film, preventing rapid tear evaporation and overflow and providing airtight eyelid closure.

Choroid. Layer of major blood vessels, which lies between the retina and the sclera (white of the eye), that provides oxygen and nutrients to the retina.

Choroidal hemangioma. A noncancerous growth within the "choroid" blood vessel layer, which lies beneath the retina. Many choroidal hemangiomas never grow or leak fluid, and the ophthalmologist observes them without treatment. However, if the growth is located in the macula (center of vision) or if it leaks fluid, it requires treatment because it can cause a retinal detachment or other vision problem.

Choroidal melanoma. Relatively rare malignant melanomas that form in the choroid, the blood vessel layer beneath the retina. Small melanomas can be treated and are usually watched for growth prior to treatment Medium to large sized melanomas are usually treated with either radiation therapy or removal of the eye.

Choroidal metastasis. Sometimes, malignant tumors from other parts of the body can spread to areas in and around the eye. In women, these are usually from the breast, while in men they are more often from the lung. Chemotherapy can sometimes be used to treat these tumors, although radiation is usually a more definitive treatment.

Choroidal nevus. Rare tumors that can grow into a malignant melanoma. Like a raised freckle on the skin, nevi can occur inside the eye and should be seen by an eye doctor.

Choroidal osteoma. Benign bony tumors that can arise within the choroid blood vessel layer beneath the retina. They are usually located near the optic nerve and can cause vision loss.

Closed-angle glaucoma. Serious form of glaucoma, that can result in a sudden rise in intraocular pressure. Condition develops when the drainage angle, which allows the aqueous (fluid behind the iris) to flow out of the eye, is suddenly blocked. Symptoms of a partial blockage can include blurred vision, halos around lights, pain and redness of the eye. A sudden blockage can result in severe pain. To avoid permanent damage to the eyes, an ophthalmologist should treat the symptoms immediately. See also **Glaucoma**.

Collagen. In referring to the eye, collagen is the protein fibrils within the corneal tissue that help sustain its shape. Some new refractive vision correction procedures heat these fibrils with a special laser causing them to shrink and change the shape of the cornea.

CO_2 laser. High-energy laser, that can be used for making surgical incisions and for skin resurfacing. Emits short, intense bursts of energy that vaporize the outer layer of skin without damage to the underlying skin. See also **Lasers (Eye Surgery)**.

Color deficiency. Partial or total inability to distinguish specific colors. See also **Color Blindness**.

Computer vision syndrome (CVS). Collection of symptoms brought about by eyestrain associated with prolonged use of the computer. Symptoms include eyestrain, blurred vision, headaches, flickering or flashing sensations, loss of appetite, nausea and dry or irritated eyes. See also **Computer Vision Syndrome (CVS)**.

Cone. A type of specialized light-sensitive cell (photoreceptor) in the retina that provides sharp central vision and color vision. Highly concentrated in fovea. Three classes of cones exist: short, medium, and long wavelength cones.

Conjunctiva. Thin, transparent membrane that lines the inner surface of the eyelid and covers the sclera where it becomes the white of the eye. See also **Conjunctiva**.

Conjunctival tumor. Malignant cancers, that grow on the surface of the eye. The most common conjunctival cancers are squamous carcinoma, malignant melanoma and lymphoma. See also **Conjunctival Tumors**.

Conjunctivitis. Inflammation of conjunctiva or membrane, that covers the white of the eye and inner surfaces of the eyelid. Characterized by discharge, grittiness, redness and swelling. May result from virus, bacteria, allergens, chemical exposure or ultraviolet light exposure and, depending on cause, can be contagious. Sometimes called *pink eye*. See also **Conjunctiva**; and **Conjunctivitis**.

Contact lens. Thin plastic or glass lens designed to fit over the surface of the cornea, usually for correction of a refractive error, but can also be cosmetic. See also **Contact Lenses**.

Contrast sensitivity. Measure of visual ability to distinguish details between an object and its background under varying degrees of contrast.

Convergence. Coordinated movement of the two eyes so that the images of a single point fall on corresponding points of the two retinas.

Cornea. Clear structure that covers the front part of the eye including the iris and pupil. The cornea provides most of the eye's optical power, while the crystalline inner lens, located behind the iris serves to "fine tune" the focus of the images. When both are working properly, a sharp image is focused on the retina and transmitted through the optic nerve to the brain. See also **Cornea**.

Corneal abrasion. A tearing, scrape or puncture of the cornea, sometimes accompanied by a loss of epithelium, the outer tissue layer of the cornea. Although a corneal abrasion can be very painful, the corneal layer of the eye heals more quickly than most other tissues in the human body. See also **Corneal Abrasion**.

Corneal dystrophy. Any of a number of rare hereditary abnormalities, that are characterized by an accumulation of abnormal material in the cornea. This accumulation may occur later in life and result in cloudiness of the cornea and reduction in vision. See also **Corneal Dystrophy**.

Corneal mapping. Procedure whereby a detailed map of the corneal surface is drawn by a corneal topography instrument. Maps are used to evaluate the cornea prior to treatment and are especially valuable as a tool in preparing for refractive vision correction.

Corneal ring. Plastic half-ring segments used in a particular type of refractive surgery. This procedure involves implantation of the ring segments in the peripheral area of the cornea in order to change its contour to the shape desired to correct cases of nearsightedness. These rings may later be removed or replaced.

Corneal topography. Procedure that creates detailed maps of the surface of the eye using an instrument that combines a computer and video camera. The maps are used to evaluate the cornea prior to treatment and are especially valuable as a tool in preparing for refractive vision correction. See also **Corneal Topography (Videokeratography)**.

Corneal ulcers. Wound on the surface of the eye similar to a scrape or cut on the skin. The cornea is covered by a layer of tissue called the epithelium which, when damaged can result in infection if left untreated. Corneal ulcers have many causes including injury, abnormal eyelashes, absence of tear production and infections. Persistent irritation or redness is reason to see an eye doctor.

Cylindrical surface. With respect to eyeglass lenses, is not evenly curved, but more like an egg or a football.

Diabetic retinopathy. Potentially serious complication of diabetes that results in the weakening of tiny blood vessels that nourish the retina. See also **Diabetic Retinopathy**.

Diopter. Unit that measures the degree of refractive error in an eye or the light-bending power of a lens. In an eyeglass or contact lens prescription, a negative number refers to nearsightedness, while a positive number refers to farsightedness. For instance, a -8.00 diopter lens is very nearsighted, while a $+0.75$ is slightly farsighted. Astigmatism can be measured as either a positive $(+)$ or a negative $(-)$ but will be accompanied by another number such as "@ 90" indicating the direction (axis) of the astigmatism.

Diplopia. The condition whereby a single object appears as two objects. Occurs because the eye muscles do not act equally. Also called double vision.

Drooping eyelids. Condition (usually hereditary), in which the upper eyelid(s) sag. May be congenital or caused by a later problem associated with a nonfunctioning levator muscle.

Drusen. Tiny yellow or white deposits in the retina of the eye or on the optic nerve head, visible to an eye care specialist during an eye examination. One of the most common early signs of age-related macular degeneration (ARMD). The presence of drusen alone does not indicate disease, but it may mean that the eye is at risk for developing more severe ARMD.

Dry eye. Condition due to a deficiency in the production and/or composition of tears by the eye's lacrimal glands. Symptoms are redness, swelling and irritation, often accompanied by excessive watering of the affected eye. See also **Dry Eye**.

Ectropion. An abnormal turning out of an eyelid.

Electro-oculogram. A record of the standing voltage between the front and back of the eye that is correlated with eyeball movement, as in rapid eye movement (REM) sleep, and obtained by electrodes suitably placed on the skin near the eye.

Electroretinography. A test that measures the electrical impulses of the retina when the eye is exposed to light. For an ERG, an electrode is placed on the cornea at the front of the eye. The electrode measures the electrical response of the rods and cones, the visual cells in the retina at the back of the eye. An abnormal ERG is found in conditions such as arteriosclerosis of the retina, detachment of the retina, and temporal arteritis with eye involvement. The instrument used to do electroretinography is an electroretinograph, and the resultant recording is called an *electroretinogram*.

Emmetropia. Refractive condition, in which no refractive error is present. In other words, perfect 20/20 vision. Distant images are focused sharply on the retina without the need for corrective lenses.

Enucleation. Surgical removal of a diseased or damaged eyeball, leaving eye muscles and remaining orbital contents intact. See also **Enucleation**.

Epiphora. Overflow of tears down the cheek caused by defective tear drainage system or by excessive flow of tears. See also **Epiphora**.

Erbium laser. Laser developed as a refinement to the CO_2 laser used in skin resurfacing for acne removal and removal of shallow wrinkles. Erbium laser shows promise in a new procedure to emulsify the lens nucleus during cataract surgery.

Esophoria. A tendency of one eye to turn inward.

Esotropia. Misalignment of the eyes in which one eye deviates inward toward the nose while the other fixates normally. See also **Esotropia**.

Exophoria. A tendency of one eye to turn outward from the nose.

Exotropia. Misalignment of the eyes in which one eye deviates outward away from the nose while the other fixates normally. See also **Exotropia**.

Extracapsular cataract extraction. A surgical procedure that involves removing a cloudy or opaque lens (cataract) while leaving the back lens capsule intact. See also **Extracapsular Cataract Extraction (ECCE)**.

Field analyzer. Automated projection perimeter instrument, which uses projected points of light to determine central or peripheral field of vision. Used for early diagnosis, treatment and management of diseases resulting in visual field loss.

Fixation. The act, or an instance of focusing the eyes on an object.

Fixation point. The point in the visual field on which the two eyes focus in normal vision, and for each eye is the point that directly stimulates the fovea of the retina.

Flashers. Bright bursts of light, that are sometimes seen when the eyes are closed. These occur normally as the eye ages and the vitreous humor, which is jelly-like substance that fills center cavity of eye, begins pulling away from the retina. The flashes can appear off and on for several weeks or months. If there is a sudden appearance of many light flashes, an ophthalmologist should be consulted immediately to see if the retina has been torn.

Floaters. Particles that float in the vitreous, which is jelly-like substance that fills center cavity of eye, and cast shadows on the retina. The particles appear to be strung together with a web-like thread. See also **Floaters**.

Fluorescein angiography. Test used to examine blood vessels in the retina, choroid and iris of the eye. Fluorescein dye is injected into an arm vein and rapid, sequential photographs are taken of the eye as the dye circulates. See also **Fluorescein Angiography**.

Fovea. A small rodless area of the retina that affords the sharpest vision because the layers of the retina spread aside to let light fall directly on the cones, which are the cells that give the clearest vision.

Glaucoma. Condition caused by excessive buildup of fluid inside the eye putting pressure on the retina. Glaucoma is the leading cause of blindness among adults in the United States. There are two types of glaucoma; the most common being open angle and the less common, but more serious, called *narrow angle*. Glaucoma has few if any symptoms, but a simple, painless eye test detects the problem. If untreated, glaucoma can result in gradual, painless, irreversible loss of vision. See also **Glaucoma**.

Graves disease. Condition caused by over activity of the thyroid gland. Patients with Graves disease may experience these eye symptoms:

inflammation of the eyes, swelling of the tissues around the eyes, and protrusion of the eyes. See also **Thyroid Gland**.

Heterophobia. A constant tendency of one eye to deviate in one or another direction due to imperfect balance of ocular muscles.

Histoplasmosis. Disease caused when airborne spores of the fungus Histoplasma Capsulatum are inhaled into the lungs. This fungus is found throughout the world where bird or bat droppings accumulate. Initial symptoms are usually mild, similar to a common cold. Even mild cases can later cause a serious eye disease called ocular histoplasmosis syndrome, a leading cause of vision loss in Americans ages 20 to 40. Although most people infected with the fungus never develop the disease, people who have lived in an area with a high rate of histoplasmosis should have their eyes examined regularly. See also **Histoplasmosis**.

Horopter. For a given fixation point, the set of points on the retina that are perceived to have zero retinal disparity. The points sweep out an arc in space that intersects a fixated point in space.

Hyperopia (farsightedness). Vision that results when there is too short a distance from the cornea to the retina. See also **Hyperopia (Farsightedness)**.

Infant vision development. At birth, infants can see patterns of light and dark but have blurred vision of specific objects. During the first 4 months, the two eyes will begin working together, with visual horizon expanding, vision becoming clearer and color vision developing. It is believed that by 4 months, an infant's color vision is similar to an adult's. By 6 months of age, babies acquire eye movement control and eye-hand coordination skills. It is normal at this stage for an infant's eyes to appear at times as crossed or out of alignment. Persistent misalignment should be reported to an eye care professional.

Inferior. In eyecare terminology, referring to the lower half of the eye.

Intracapsular Cataract Extraction (ICCE). Older method of cataract surgery, that involves removal of the entire lens. Some surgeons may still use this method in selected cases. See also **Intracapsular Cataract Extraction (ICCE)**.

Intraocular lens (IOL). Plastic lens surgically implanted to replace the focusing power of the natural crystalline lens following cataract extraction or during a refractive surgery procedure called Clear Lens Extraction. See also **Intraocular Lenses (IOLs)**.

Intraocular pressure (IOP). Measurement of fluid pressure inside the eye. All eye exams include a measurement of this eye pressure with an instrument called a tonometer. Glaucoma, the leading cause of blindness in adults, is caused by a buildup of pressure inside the eye and often occurs without noticeable symptoms. This buildup puts pressure on the optic nerve, which can permanently damage eyesight or even cause blindness. See also **Tonometer**.

Iritis. Inflammation of the iris causing pain, tearing, blurred vision, small pupil, and a red congested eye. See also **Iritis**.

Isopter. A contour line in a representation of the visual field around the points representing the macula lutea that passes through the points of equal visual acuity.

Itchy eyes. Condition that can be caused by many factors such as pollutants in the air, allergies, chemical exposure (swimming pool for instance), sun glare, viral and bacterial infections and conjunctivitis (pink eye). See also **Itchy Eyes**.

Keratitis. Infection or inflammation of the cornea which can be caused by a variety of conditions, including infections, dry eyes, foreign objects, contact lenses, intense light, vitamin A deficiency or allergies. Usual treatment is with antibiotic or anti-viral eye drops and ointments. See also **Keratitis**.

Keratoconus. Hereditary, degenerative corneal disease characterized by generalized thinning and cone-shaped protrusion of the corneal area usually affecting the vision of both eyes. See also **Keratoconus**.

Keratometer. Device for measuring the curvature of the cornea and for detecting and measuring astigmatism. The keratometer measures the frontal curvature, or steepness, of the cornea and compares high and low points to determine if a refractive problem exists.

Keratometry. Measurement of the form and curvature of the cornea.

Lacrimal system. Orbital structures of the eye responsible for tear production and drainage. Tears are produced in the lacrimal gland above the outer corner of the eye. See also **Lacrimal System**; and **Tears**.

Laser. Acronym for Light Amplification by Simulated Emission of Radiation. A very narrow, hi-intensity light, which can vaporize tissue and/or join structures.

Laser: Excimer. A high-energy, cold laser that is used in the Photorefractive Keratectomy (PRK) and Laser In-Situ Keratomileusis (LASIK) procedures to sculpt the central zone of the cornea to correct nearsightedness, farsightedness or astigmatism. See also **Laser In-situ Keratomileusis (LASIK)**; **Photoreactive Keratectomy (PRK)**; and **Refractive Eye Surgery**.

Laser: CO_2. High-energy laser that can be used for making surgical incisions and for skin resurfacing. Emits short, intense bursts of energy that vaporize the outer layer of skin without damage to the underlying skin.

Laser: Erbium. Laser developed as a refinement to the CO_2 laser used in skin resurfacing for acne scarring and wrinkle removal for shallow wrinkles. Erbium laser shows promise in a new procedure to emulsify the lens nucleus during cataract surgery.

Laser: Holmium. Infrared (thermal) laser developed in the late 1980s. The laser's beam is cool and can remove small areas of tissue without affecting surrounding tissue. In a refractive surgery procedure called Laser Thermal Keratoplasty (LTK), the Holmium laser is used to shrink the peripheral area of the cornea. See also **Laser Thermal Keratoplasty (LTK)**; and **Refractive Eye Surgery**.

Laser In-Situ Keratomileusis (LASIK). Currently the most widely used refractive eye surgery procedure. Combines the minimal post-operative discomfort of Automated Lamellar Keratoplasty (ALK) with the computer-controlled precision of Photorefractive Keratectomy (PRK). See **Automated Lamellar Keratoplasty (ALK)**; **Laser In-situ Keratomileusis (LASIK)**; **Photoreactive Keratectomy (PRK)**; and **Refractive Eye Surgery**.

Laser pointers. Pointing devices that use a laser beam. Light energy that some laser pointers can deliver into the eye may be more damaging than staring directly into the sun. Even momentary exposure can cause discomfort and temporary vision impairment.

Laser Vision Correction. Any of several surgical vision correction techniques that use a computer-controlled laser to gently sculpt the corneal tissue to correct vision error caused by corneas that are too steep (nearsighted), too flat (farsighted) or uneven (astigmatic). See also **Refractive Eye Surgery**.

Laser: Yag. Short pulsed, high-energy light beam that can be precisely focused by computer to optically cut, perforate, or fragment tissue.

Lateral. In eye care terminology, denoting a position farther from the median plane or midline of the eye.

Lateral geniculate nucleus. Structure in the thalamus, which is a major recipient of axons from the retina.

Lazy eye. Condition of decreased vision in one or both eyes without detectable structural abnormalities or disease in the eye or visual pathways. Also known as amblyopia. See also **Amblyopia**.

Lens: aspheric. Premium contact lens for borderline astigmatic patients and emerging presbyopes.

Lens: bifocal. Eyeglass lens made up of a main lens on top for distance vision and an additional lens on the bottom for near vision.

Lens: bitoric. Toric contact lens used to correct residual astigmatism.

Lens: crystalline. Natural lens of the eye that lies behind the iris and helps bring light rays to focus on the retina. Muscular elastic fibers contract or expand the lens so that it can focus on objects at varying distances. In this manner, the lens fine-tunes the focus of the light rays refracted by the cornea so that a sharp, clear and colorful image is focused on the retina. The lens of the eye is often compared to the lens of a camera.

Lens: meter. Device used for determining the refractive power of an eyeglass or contact lens.

Lens: multifocal. Eyeglasses or contact lenses, that enable the wearer to focus through two or more prescriptions for different distances on one lens. Bifocals have two points of focus, one for distance and the other for

near, while trifocals have three points of focus — distance, intermediate and near. Progressive "no-line" eyeglass lenses offer a continuous range of focus from top to bottom.

Lens: progressive. "No-line" multi-focal eyeglass lenses with progressive powers that graduate from distance to reading power. Although progressive lenses often require a greater period of adjustment, these are the most versatile of all multi-focal designs because of the continuous range of focus.

Lens: spheric. Eyeglass or contact lens with a single continuous curve across the entire front surface.

Lens: toric. Contact lens that contains both a spherical and cylinder component to correct astigmatism. Thickness of lens may be modified from one meridian to another, thereby enabling the lens to maintain correct orientation on the eye.

Lens: trifocal. Eyeglass or contact lens design that includes three focal areas: usually a reading lens, a lens for faraway viewing, and a lens for mid-distance viewing.

Lensectomy. Surgery to remove the natural crystalline lens of the eye. During most cataract surgery, the cloudy cataract lens is removed and replaced with a plastic prescription lens. In a procedure called "Clear Lens Extraction" or "Clear Lensectomy," the eye's natural lens is also removed and replaced with a plastic prescription lens in order to correct refractive disorders. The word "clear" denotes that the natural lens that is removed is clear, rather than a cloudy cataract lens. See also **Cataract**.

Lensometer. Device used for determining the refractive power of an eyeglass or contact lens.

Lenticular. Special noncataract lenses for patients who have cataracts.

Light adaptation. The automatic adjustment of the pupil or the retina to the amount of light that is present at any given time.

Low vision. The condition that exists when ordinary eyeglasses, contact lenses, intraocular lens implants or refractive surgery do not provide clear vision. Should not be confused with blindness. People with low vision have useful vision that can be improved with vision devices. The terms "legally blind" or "partially sighted" are often used in association with low vision. A person is considered legally blind when the best-corrected vision in the better eye is no more than 20/200 and/or the field of view is less than 20 degrees. A person with best-corrected vision of no more than 20/70 in the better eye is considered partially sighted or visually impaired.

Lutein. Yellow carotenoid pigment found in body fats, egg yolks and green plants that promotes healthy eyes. One of two primary pigments found in the central part of the retina which helps filter out damaging light. See also **Lutein**.

Lysozyme. A basic protein that is present in egg white, saliva, and tears.

Macula. Small centralized area of the retina responsible for acute central vision. Damage to this portion of the retina severely limits a patient's ability to read, recognize faces and perform any other task that requires straight-ahead vision. See also **Macula**.

Macula lutea. The cone-rich area of the human eye, that contains the fovea. Also called yellow spot.

Macular degeneration. Degeneration of the photoreceptors in the macula or central region of the retina. This area of the retina is responsible for central vision, used for reading, seeing faces, and so on. Often associated with aging. See also **Age-related Macular Degeneration**.

Meibomian gland. Little glands in the eyelids, that make a fatty lubricant which they discharge through tiny openings in the edges of the lids. The meibomian glands can become inflamed, a condition termed meibomianitis or meibomitis. Chronic inflammation of the meibomian glands leads to a cyst, also called *chalazion*, which is a pimple in the margin of the eyelid. The meibomian glands are also known as the *palpebral glands, tarsal glands*, or *tarsoconjunctival glands*.

Melanin. Black pigment in the pigment epithelium cells that absorbs light not captured by the retina, thereby preventing the light from being reflected off the back of the eye.

Microkeratome. Sophisticated surgical device used to shave a very thin amount of the cornea at a predetermined depth. Used in LASIK refractive vision correction procedure to create the corneal "flap" which is lifted. Then the Excimer laser sculpts the underlying corneal tissue See also **Laser In-situ Keratomileusis (LAISK)**.

Microspectrophotometry. A procedure that involves passing a narrow measuring beam through the outer segments of individual photoreceptors to measure absorbancy in excised retinas.

Miosis. Condition in which the pupil is constricted. Occurs as a normal response to a bright light stimulus, to focusing on a near object (known as accommodation), or to administer certain drugs.

Monochromat. An individual who is completely color-blind.

Multi-focal. Eyeglasses or contact lenses, that allow the wearer to focus through different prescriptions for different distances on the same lens. Bifocals have two points of focus, one for distance and the other for near, while trifocals have three points of focus — distance, intermediate and near. Progressive "no-line" eyeglass lenses offer a continuous range of focus from top to bottom.

Multiple sclerosis. Chronic central nervous system disorder in which there is loss of the protective myelin sheath surrounding nerve tissue. Effects on the eye include optic nerve inflammation with reduced vision, double vision and involuntary eye oscillations.

Mydriasis. Increase in pupil size (dilation) occurring normally in the dark. May occur artificially through the use of drugs.

Mydriatic. A drop that dilates the pupil.

Myope. Medical term for nearsighted person. A person with good reading vision, but who has difficulty seeing distant objects.

Myopia. Also called nearsightedness. The front curvature of the cornea is too steep in a nearsighted person, causing good reading vision but poor distance vision. See also **Myopia (Nearsightedness)**.

Nasal. When referring to the eye, this term indicates inward direction toward the nose. Also refers to that half of the eye or visual field from the middle of the eye inward.

Nasal lacrimal system. That portion of the lacrimal (tear producing) system that includes ducts which drain tears from the eye into the nose.

Nasal lacrimal duct. Tear drainage channel that extends from lacrimal sac to opening in mucous membrane of nose.

Occlusion. The transient approximation of the edges of a natural opening, i.e, occlusion of the eyelids.

Ocular. Of, pertaining to, or affecting the eye.

Ocular hypertension. Condition in which the intraocular pressure of the eye is elevated above normal without any obvious optic nerve damage or visual field defects. Over time, ocular hypertension may develop into glaucoma.

See also **Ocular Hypertension**.

Ocular motility. The movement of the eye.

Onchocerciasis. River blindness, a disease caused by a parasitic worm (Onchocerca volvulus) transmitted by biting blackflies (buffalo gnats) that breed in fast-flowing rivers. The adult worms can live for up to 15 years in nodules beneath the skin and in the muscles of infected persons, where they produce millions of worm embryos (microfilariae) that invade the skin and other tissues including the eyes. About 18 million persons are affected, mostly in Africa and also in Yemen and Latin America. Both living and dead microfilariae cause severe itching in the skin and sometimes blindness after many years. Since1987, the drug ivermectin (brand name: Stromectol) has been provided by the manufacturer (Merck) free of charge. A single oral dose administered once a year prevents the accumulation of microfilariae in persons at risk. No drug suitable for mass treatment can kill the adult worms in the body, and therefore, onchocerciasis cannot be wiped out. The blindness, however, can be eliminated.

Open-angle glaucoma. The less serious of two types of glaucoma, a condition caused by excessive buildup of fluid inside the eye putting pressure on the retina. Sometimes called chronic glaucoma, it is caused by a gradual blocking of aqueous outflow from the eye. It can develop slowly with no noticeable symptoms. If untreated, open-angle glaucoma results in a gradual, painless, irreversible loss of vision. See also **Glaucoma**.

Ophthalmologist. A medical doctor (M.D.) with education, training and experience in medical and surgical treatment of eye diseases and disorders.

Ophthalmoscope. An instrument for viewing the interior of the eye. It comprises a concave mirror with a hole in the center through which the observer examines the eye, a source of light that is reflected into the eye by the mirror, and lenses in the mirror that can be rotated into the opening in the mirror to neutralize the refracting power of the eye being examined. It makes the image of the retina clear.

Ophthalmology. Branch of medical science that deals with the structure, functions and diseases of the human eye.

Optic disc. The circular area in the back of the inside of the eye where the optic nerve connects to the retina. Also called the optic nerve head. Contains no photoreceptors and therefore creates a blind spot in the visual field.

Optic nerve. Connects the eye to the brain. It carries the impulses formed by the retina, the nerve layer that lines the back of the eye and senses light and creates impulses. The brain interprets the images. Using an ophthalmoscope, the head of the optic nerve can be seen. It can be viewed as the only visible part of the brain (or extension of it).

Optic nerve head. The circular area in the back of the inside of the eye where the optic nerve connects to the retina.

Optic nerve pathways. The left and right branches of the optic nerves join behind the eyes, just in front of the pituitary gland, to form a cross-shaped structure called the *optic chiasma*. Within the optic chiasma, some of the nerve fibers cross. The fibers from the nasal (inside) half of each retina cross over, but those from the temporal (outside) half do not. Specifically, the fibers from the nasal half of the left eye and the temporal half of the right eye form the right optic tract; and the fibers from the nasal half of the right eye and the temporal half of the left form the left optic tract. The nerve fibers then continue along in the optic tracts. Just before they reach the thalamus of the brain, a few of the nerve fibers leave to enter nerve nuclei that function in visual reflexes. Most of the nerve fibers enter the thalamus, forming a junction (synapse) in the back of the thalamus. From there the visual impulses enter nerve pathways called the optic radiations, which lead to the visual (sight) cortex of the occipital (back) lobes of the brain.

Optic neuritis. Inflammation of the optic nerve. Characterized by rapid onset of decreased vision and usually accompanied by discomfort upon eye movement and central visual field defect. See also **Optic Neuritis**.

Optic neuroma. A benign tumor of the optic nerve.

Optic tract. The portion of each optic nerve between the optic chiasma and the diencephalon proper.

Optometrist. Doctors of Optometry (O.D.) are primary health care providers who examine, diagnose, treat and manage diseases and disorders of the eye and associated structures. In accordance with state law, optometrists prescribe, fit and dispense ocular medications, glasses and contact lenses. An optometrist cannot perform surgery but often works with an ophthalmologist on pre-and post-surgical care.

Optometry. The profession of examining the eyes, measuring vision and prescribing corrective lenses, diagnosing diseases of the eye and treating certain conditions that do not require license as a medical doctor.

Orbit. Pyramid-shaped cavity in the skull containing the eyeball, its muscles, blood supply, nerve supply and fat.

Orbital tumor. Process by which a living organism assimilates food and uses it for growth and tissue replacement. In the prevention of ocular disease, the role of vitamins and minerals has taken on a major role. To maintain the health of the eye, a high-fiber, high-carbohydrate, high-antioxidant, low-fat, low-protein diet is best.

Orthokeratology. Controversial nonsurgical contact lens procedure designed to eliminate nearsightedness and astigmatism. See also **Orthokeratology**.

Overconvergence. Condition in which the eyes come too far inward when focusing on a near object, resulting in blurring.

Pachymeter. Ultrasound machine used in measuring thickness of the cornea. Especially important in determining treatment depth in refractive surgery.

Pachometer. Instrument that uses optical principle of split images to measure corneal thickness or anterior chamber depth.

Palpebral glands Little glands in the eyelids, that make a fatty lubricant which they discharge through tiny openings in the edges of the lids. The meibomian glands can become inflamed, a condition termed meibomianitis or meibomitis. Chronic inflammation of the meibomian glands lead to a cyst, also called *chalazion*, which is a pimple in the margin of the eyelid. The meibomian glands are also known as the *meibomian glands, tarsa*l *glands*, or *tarsoconjunctival glands*.

Perimeter. Instrument used for determining central or peripheral field of vision.

Perimetry. Method of charting extent of visual field as seen by the stationary eye. Aids in the detection of damage to the sensory visual pathways. See also **Perimetry**.

Peripheral vision. Side vision; vision not in the straight-ahead direction.

Phacoemulsification. Technique for removing eye's natural crystalline lens in cataract surgery or clear lens extraction. See also **Pacoemulsification**.

Phaco machine. Ultrasonic instrument used in phacoemulsification technique for removing the natural lens of the eye during cataract or clear lens extraction surgery. Using a hand piece connected to the phaco machine, the surgeon dissolves the lens into small fragments, aspirates the contents and irrigates the eye.

Phoropter. An instrument used by the eye doctor to determine the degree of myopia (nearsightedness), hyperopia (farsightedness) or astigmatism that is present in the patient's eye.

Photocoagulation. A surgical process of sealing off, or clotting, tissue by means of a laser beam. It is used in cancer treatment to destroy blood vessels entering a tumor and deprive it of nutrients, in the treatment of a detached retina, to destroy abnormal blood vessels in the retina, to treat tumors in the eye; etc.

Photophobia. Abnormal sensitivity to, and discomfort from, light. Frequently associated with excessive tearing and often due to inflammation of iris or cornea.

Photorefractive Keratectomy (PRK). Refractive eye surgery procedure that employs a computer-controlled Excimer laser system to sculpt by ablation (vaporize) the central corneal zone, or visual axis. By changing the shape of the patient's cornea, the eye care surgeon can correct some cases of nearsightedness, farsightedness and astigmatism. See **Photorefractive Keratectomy (PRK)**; and **Refractive Eye Surgery**.

Pigmentary retinopathy. Any of several hereditary progressive degenerative diseases of the eye marked by night blindness in the early stages, atrophy and pigment changes in the retina, constriction of the visual field, and eventual blindness. Also called *retinis pigmentosa*.

Pink eye. Also known as conjunctivitis. Inflammation of conjunctiva or membrane that covers the white of the eye and inner surfaces of the eyelid. Characterized by discharge, grittiness, redness and swelling. May result from virus, bacteria, allergens, chemical exposure, or ultraviolet light exposure. Can be contagious. See also **Conjunctiva**; and **Conjunctivitis**.

Plano. Term used by eye care professionals to describe lenses with no focusing power. The term is most often applied to nonprescription sunglasses or contact lenses that are worn for cosmetic purposes only.

Polarized lenses. Eyeglass lenses designed to protect the eye against UV rays and reduce the glare of reflected light. May be constructed of glass, plastic or lightweight, hi-index plastic.

Pole. Posterior pole refers to back curvature of eyeballs, usually to the retina between optic nerve and macular area. Anterior pole refers to center of front surface of cornea.

Posterior chamber. In referring to the eye, that space between the back which is filled with aqueous fluid between the iris and front face of the vitreous.

Presbyope. Person who has difficulty reading print and seeing nearby objects because of age-related loss of elasticity of the eye's natural crystalline lens.

Presbyopia. Deterioration in the ability of the eye's natural crystalline lens to expand or contract in order to focus on close objects. See also **Presbyopia**.

Prosopagnosia. The inability to recognize faces.

Ptosis. Condition in which, the upper eyelid(s) sag. May be congenital or caused by a later problem associated with a nonfunctioning levator muscle. Usually hereditary.

Punctum plug. Small, nondissolvable silicone plugs inserted in the tear draining ducts to close the openings of the tear draining system in order to slow drainage and loss of tears. Used to provide dry eye relief and/or reduce or eliminate the major cause of contact lens discomfort. See also **Tears**.

Pupil dilation. Enlarged pupil resulting from contraction of dilator muscle or relaxation of iris sphincter. Normally occurs in dim illumination conditions. Comprehensive examination of the interior of the eye requires pupil dilation through the administration of appropriate eye drops by the examining eye professional. Dilation can also be caused by injuries, including blunt trauma.

Radial Keratotomy (RK). Surgical procedure where patterned surgical incisions are made in the peripheral area of the cornea. As these incisions heal, the cornea is flattened to the degree required to make the desired refractive error correction. This early refractive vision correction procedure has been largely replaced by newer, more accurate procedures such as LASIK. See also **Refractive Eye Surgery**.

Red eye. Any condition, that causes the white part of the eye to look red. Redness usually is because of engorged blood vessels on the surface of the eye or hemorrhaging on the surface. In making a diagnosis, an eye doctor will pay close attention to the location and pattern of redness.

Refraction: objective. Eye test utilizing an automated device called an Auto Refractor that instantly measures the power of the eye and the outer shape of the eye. The device needs no input from the patient such as that required by the "Which is better? 1 or 2" question used in a phoropter exam.

Refraction: subjective. Eye test using a phoropter where patient is given choices between lens 1 and 2, providing the examining eye doctor with "subjective" information regarding which prescription will make the patient more comfortable.

Refractive error. Optical defect of the eye that causes light rays to focus in front of the retina (nearsighted), behind the retina (farsighted), or in several different places on the retina (astigmatic), resulting in less than perfect vision. These defects can normally be corrected with eyeglasses, contact lenses or refractive eye surgery.

Refractive surgery. Elective eye surgery which corrects optical defects of the eye by either changing the shape of the cornea or by inserting a plastic lens to supplement the eye's natural focusing ability. See also **Refractive Eye Surgery**.

Refractor. Instrument that aids an eyecare professional in determining the proper corrective prescription for a patient with less-than-perfect vision.

Retinal detachment. Painless disorder, where patient may notice gradual raising or lowering of a curtain over the visual field of the affected eye. See also **Retinal Detachment**.

Retinal hole. With age, the retina starts to thin and weaken especially near its attachments with the front of the eye (periphery). In addition, the jelly-like ball that fills most of the eye behind the lens, called the *vitreous*, changes from a firm substance to a loose fluid. When the vitreous becomes fluid, it can easily move and tug on its attachments and become detached, pulling a small bit of retina with it. When this happens, a hole is left in the retina.

Retinal rivalry. The perception of first one then the other of two visual stimuli, which differ in color or form when they are presented at the same time to congruent areas of both eyes.

Retinitis pigmentosa. Any of several hereditary progressive degenerative diseases of the eye marked by night blindness in the early stages, atrophy and pigment changes in the retina, constriction of the visual field, and eventual blindness. Also called *pigmentary retinopathy*. See also **Retinitis Pigmentosa**.

Retinoblastoma. Hereditary, malignant intraocular tumor, that develops from retinal cells. See also **Retinoblastoma**.

Rhabdomyosarcoma. A malignant tumor composed of striated muscle fibers.

Rhodopsin. The visual pigment in rod cells. Also called visual purple.

Sclera. Tough outermost layer of the eye, that is visible as the white of the eye.

Scleral buckle. Surgical procedure that repairs a retinal detachment by indenting, or buckling the sclera inward, usually by sewing a piece of preserved sclera or silicone rubber to the scleral surface. This pushes choroid and pigment epithelium closer to the retina and helps relax the vitreous tug on the retinal surface. See also **Scleral Buckle**.

Scotoma. Nonseeing area, or blind spot, within visual field, resulting from damage to visual pathways or to the retina. Blind spots exist normally in all eyes and mark the site of the optic nerve.

Scotopic vision. Dim light conditions where only rods are functional. Also called *twilight vision*.

Slit lamp. Microscope used in eye examination that projects a thin, intense beam of light into the eye through a controlled diaphragm. Aids in the diagnosis of diseases or trauma, which affect the structural properties of the anterior eye segment. See also **Slit Lamp**.

Snellen Eye Chart. Test chart for assessing visual acuity. Rows of letters, numbers and symbols in standardized graded sizes, with a designated distance at which each row should be legible to a normal eye. See also **Snellen Eye Chart**.

Spherical. Single prescription contact lenses with smooth spherical surfaces that bend light rays equally in all directions (360 degrees).

Sports vision. Growing specialty in many eye care offices, usually focusing on the safety aspects of sports, but may also include vision therapy designed to strengthen eye coordination and/or overcome congenital weaknesses. Sports safety usually includes ultra-violet and sun protection, glare protection and safety from direct impact.

Spots. Particles that float in the vitreous, which is jelly-like substance, that fills the center cavity of the eye, and cast shadows on the retina. Some spots are formed before birth while others occur normally with aging. The sudden appearance of many spots can be an indication of a serious eye disorder and should be checked by your eye doctor.

Stereopsis. Perception of depth, depending on the differences in the images projected on the retinas of the two eyes.

Stye. Inflammation of one or more sebaceous, or fluid-producing, glands of an eyelid. See also **Stye (Hordeolum)**.

Stiles-Crawford effect. An optical phenomenon in which light passing through the center of the pupil is perceived as more intense than light passing through the periphery of the pupil.

Superior. In eye care terminology, referring to the upper half of the eye.

Superior colliculus. Part of the brain that constitutes a primitive center for vision. Also called *optic lobe, optic tectu m*.

Sympathetic ophthalmia. Inflammation of one eye following inflammation in the other eye.

Tapetum. Silvery lining behind the retina in some animals active in dim light. Reflects light back through the eye and allows the photoreceptors a second chance to absorb photons.

Tarsoconjunctival glands. Little glands in the eyelids, that make a fatty lubricant which they discharge through tiny openings in the edges of the lids. The meibomian glands can become inflamed, a condition termed *meibomianitis* or *meibomitis*. Chronic inflammation of the meibomian glands lead to a cyst, also called *chalazion*, which is a pimple in the margin of the eyelid. The meibomian glands are also known as the *meibomian glands*, or *palpebral glands*.

Tay-Sachs disease (TSD). A progressive neurodegenerative disorder affecting babies. The child with TSD usually develops normally for the first few months of life. Then the baby gets an exaggerated startle reaction, and loses head control by 6 to 8 months of age. The infant cannot roll over or sit up, spasticity and rigidity develop, and excessive drooling and convulsions become evident. Blindness and head enlargement set in by the second year. It is fatal by age 5. TSD results from an enzyme deficiency, which in turn allows a fat, named lipid, to be deposited in the brain. It occurs primarily in Ashkenazi Jews of European origin, a group comprising 95 percent of the Jews in the United States.

Tears. Watery, slightly salty secretion of the lacrimal glands that serve to lubricate the front of the eye and wash away particles and foreign bodies. Natural tears are composed of three layers: the outer oily layer, the middle watery layer, and the inner mucus layer. See also **Tears**.

Thermokeratoplasty. Refractive eye surgery procedure that involves use of the Holmium laser to heat and shrink tissues in the peripheral area of the cornea in order to change the shape of the cornea to correct farsightedness and/or some cases of astigmatism. See also **Refractive Eye Surgery**.

Tonometer. Instrument used by the eye care professional to determine the intraocular or internal pressure of the eye. See also **Tonometer**.

Toric. Contact lenses that contain a cylinder component to correct astigmatism by bearing two different optical powers at right angles to each other. These lenses may be thicker in one meridian to enable the lens to maintain proper orientation on the eye. See also **Contact Lenses**.

Trachoma. Severe, chronic, contagious conjunctival eyelid and corneal infection caused by a virus. Leads to corneal blood vessel formation, corneal clouding, conjunctival and eyelid scarring and dry eyes. Leading cause of blindness in the world. See also **Trachoma**.

Trifocals. Eyeglass or contact lens design that includes three focal areas: usually a reading lens, a lens for faraway viewing, and a lens for mid-distance viewing.

Ultrasound: A-Scan. Type of ultrasound device that emits very high frequency waves that are reflected by the ocular structures and converted into electrical impulses. Used for differentiating normal and abnormal eye tissue or for measuring length of eyeball.

Ultrasound: B-Scan. Ultrasound procedure in which high frequency waves are reflected by eye tissues and orbital structures and then converted into electrical pulses that are displaced as bright spots on a black background. Provides a cross-sectional view of tissues used for evaluating structures that cannot be seen directly.

Ultrasound: eye. Transmission into the eye of high frequency sound waves that are reflected by ocular tissues and displayed on a screen so the internal structures can be visualized. Aids in diagnosis of eye and orbital problems.

Visual acuity. Measure of eye's ability to distinguish object details and shape. Assessed by smallest identifiable object that can be seen at a specified distance, usually 20 feet for distance vision and 16 inches for near vision. See also **Visual Acuity**.

Visual field. Extent of space visible to an eye as it looks (fixates) straight ahead. Measured in degrees away from fixation. See also **Visual Field**.

Vitreous. A clear, jelly-like liquid, that fills the middle of the eye. Also called the *vitreous humor*.

Vitreous detachment. Separation of vitreous, which is the jelly-like substance that fills the eye behind the lens, from the retinal surface. Frequently occurs with aging, but may occur in diseases such as diabetes and severe myopia. Usually harmless, but can create retinal tears, which may in turn lead to retinal detachment. See also **Vitreous Detachment**.

Von Hippel's angioma. Also known as Von Hippel-Lindau disease, this hereditary disorder is characterized by tumors of the retina, central nervous system, and visceral organs. See also **Von Hippel-Lindau Disease (VHL)**.

VISUAL ACUITY. Visual acuity is the medical term for sharpness of vision. It deals with the sharpness, or discrimination, of central vision, rather than the extent or clarity of peripheral vision. Refractive errors, which can be corrected with eyeglasses, are the most common cause of poor visual acuity. These include myopia, or nearsightedness; hyperopia, or farsightedness; and astigmatism. Myopia is a reduced ability to see distant objects clearly, hyperopia is a condition that initially causes difficulty in seeing nearby objects and progresses to affect distance vision, and astigmatism is blurred vision caused by abnormal curvature of the front surface of the cornea.

Overall visual acuity is measured by using the Snellen Eye Chart, with the large E at the top followed by rows of letters where each row is smaller than the previous one. A chart using the letter E facing up, down, left, and right is used for children and those who do not read. A person whose vision can be corrected to 20/200 vision in the better eye is considered legally blind.

Near visual acuity is measured with the Jaeger card, which has print samples of different sizes. The card is held 14 inches from the person's eye for the test. A result of 14/20 means that the person can read at 14 inches what someone with normal vision can read at 20 inches. The results of visual acuity tests are used to prescribe eyeglasses or other corrective measures. See also **Snellen Eye Chart**.

Vision Rx, Inc., Elmsford, NY

VISUAL BINARIES. The visual binary is a pair of stars (i.e., a double star that can be separated in a telescope). The larger the aperture of a telescope, the greater the resolving power and hence the greater the ability to see two point sources as separated. The limiting factor in observing visual binaries is not the aperture of the telescope, but the unsteadiness of the Earth's atmosphere, a phenomenon called "seeing."

Algol (Beta Persei), also known as the winking demon star, is one of the best observed of the visual binaries. See also **Algol (β Persei)**.

VISUAL FIELD. The visual field is the total area in which perception is possible while an individual is looking straight ahead. For a person with normal vision, the visual field usually extends outward over an approximately 90-degree angle on each side of the vertical midline of the face. But the angle is smaller above and below the midline, especially for a person whose eyes are deep-set or who has prominent eyebrows. Because the visual fields of the two eyes overlap to a large extent, a defect in the field of one eye may not be evident when both eyes are open. Thus, the visual field can be divided into the area that is visible only to the right eye, the area that is visible to the left eye, and the middle region of binocular vision.

All the light from the visual fields that are left of center of both eyes falls on the right sides of the retinas of both eyes. This information is transmitted by the optic nerves to the right visual cortex of the brain. Information about the right fields of vision is transmitted to the left cortex, and information about the region of binocular vision is transmitted to both the right and left cortex.

An examination of the visual field measures the responsiveness of the peripheral area of the retina. That area does not have as many information-carrying nerve fibers as the center of the retina. The photoreceptors in the peripheral part of the retina are rods, which are less sensitive to light than the cones in the center of the retina, and so only larger and brighter objects are seen on the periphery of the field of vision. It is impossible to read fine print that is as little as 5 degrees to one side of a point on which the vision is fixed. The visual field examination generally is done by using electronic equipment that prints a computerized reading of an individual's field of vision and that can measure an individual's attention span and the consistency, accuracy and pattern of his or her responses to visual stimuli.

Peripheral vision can be lost because of glaucoma or a stroke. Although the loss caused by a stroke is sudden and obvious, the damage done by chronic glaucoma usually is gradual. Therefore, it is not apparent to the affected individual until considerable vision has been lost. Periodic tests of the visual field thus are important as people mature, because the incidence of glaucoma increases with age.

Loss of peripheral vision is obvious to anyone with macular degeneration, a progressive condition in which deterioration of the macula, the central part of the retina, produces a growing blind spot in the center of the field of vision.

Vision Rx, Inc., Elmsford, NY

VISUAL FUNCTION (Eye). The eye works like a camera with two lenses. The first lens is the cornea, a clear membrane that covers the front of the eye. The second lens is the eye's natural crystalline lens, which is located behind the pupil. The cornea is responsible for about 70% of the eye's focusing power, while the natural lens fine-tunes the image before it is focused on the retina, at the back of the eye. The retina works like the film in a camera, receiving light images and sending them through the optic nerve to the brain. If both lenses are working properly, the image is focused precisely on the surface of the retina and the result is perfect 20/20 vision.

Just as people are born with different sizes and shapes of hands, their eyes also vary in form and proportion. A perfect eye has an evenly rounded cornea that allows light to fall exactly on the retina resulting in perfect vision.

VITAMINS. Vitamins are specific organic compounds that are essential for normal metabolism. Many participate as cofactors or coenzymes in mammalian biochemical reactions. The common thread for the diverse chemical structures of the vitamins is that they are micronutrients. Micronutrients are compounds that are required in only small amounts and are not synthesized by humans, either at all or, at least, in sufficient quantity for metabolic needs. Vitamins are obtained from the diet or as synthetic preparations used in food fortification or supplements. The term vitamin is derived from *vitamine*, a word created by Polish biochemist (Casimir Funk) in 1911 when it was believed that the antiberiberi factor (thiamine) was an amine essential to the maintenance of life (*vita*). Later discoveries showed that not all vitamins are amines. However, a form of the name has remained.

Nearly all vitamins are associated in some way with the normal growth function as well as with the maintenance and efficiency of living things. Various species are capable of synthesizing some of the vitamins from precursors that are present in the body. Synthesis is frequently by way of intestinal bacteria. In the case of vitamin D, substances in the skin combine with ultraviolet radiation from sunlight to yield the essential substance. Some vitamins, such as vitamin C, are specific, singular substances — in this case ascorbic acid. With other vitamins, there is a range of related compounds, as exemplified by the D, E, and K vitamins.

Because of inconsistencies in nomenclature, the B vitamins are not closely related as one might suspect. The B vitamins are different specific substances, and the use of the letter B to designate them indicates a degree of commonality that actually is not the case. Vitamin B_1 is thiamine, vitamin B_2 is riboflavin, vitamin B_6 is pyridoxine, vitamin B_{12} is cobalamin. Vitamins B_6 and B_{12}, for example differ markedly in function and structure. The alphabetical method of designation became complex and somewhat confusing as the various vitamins were recognized and studied over many years. During this period some substances were found to be identical with previously announced and described vitamins; or some substances were found not to be vitamins at all. Thus, over the years, the International Union of Pure and Applied Chemistry (I.U.P.A.C.) assigned new names to several of the vitamins.

The major vitamins are described in separate alphabetical entries in this book. Titles used for these entries have been selected on the basis of the most frequently used designations as of the early 1980s. In alphabetical order, the vitamins described in this book are: **Ascorbic Acid (Vitamin C)**; **Biotin**; **Choline**; **Folic Acid**; **Insitol**; **Niacin**; **Pantothenic Acid**; **Riboflavin (Vitamin B_2)**; **Thiamine (Vitamin B_1)**; **Vitamin A**;

Vitamin B_6(Pyridoxine); **Vitamin B_{12}(Cobalamin)**; **Vitamin D**; **Vitamin E**; and **Vitamin K**.

History

The history of the vitamins can be divided into five major, overlapping periods.

Prehistory to ca 1990. The value of eating certain foods to maintain health was recognized long before vitamins were identified. The ancient Egyptians knew that feeding a patient liver would help cure night blindness, now known to be caused by a vitamin A deficiency. In 1747, the Scottish surgeon James Lind discovered that citrus foods helped prevent scurvy, a particularly deadly disease in which collagen is not properly formed, and characterized by poor wound healing, bleeding of the gums, and severe pain. In 1753, Lind published his *Treatise on the Scurvy*. His discovery, however, was not widely accepted. In the Royal Navy's Arctic expeditions in the 19th century, for example, it was widely believed that scurvy was prevented by good hygiene on board ship, regular exercise, and maintaining the morale of the crew, rather than by a diet of fresh food, so that Navy expeditions continued to be plagued by scurvy. At the time Robert Falcon Scott made his two expeditions to the Antarctic in the early 20th century, the prevailing medical theory was that scurvy was caused by "tainted" canned food.

In 1881, Russian surgeon Nikolai Lunin fed mice upon an artificial mixture of all the separate constituents of milk known at that time, namely the proteins, fats, carbohydrates, and salts. They died, while the mice fed by milk itself developed normally. He made a conclusion that "a natural food such as milk must therefore contain besides these known principal ingredients small quantities of unknown substances essential to life". However, his conclusion was rejected by other researchers who were unable to reproduce his results. One difference was that he used table sugar (sucrose), while other researchers used milk sugar (lactose) which still contained small amounts of vitamin B.

1880–1905. The ability to induce disease states in animals by manipulation of the diet was established in this period. The classical work by Eijkman, in which a beriberi-like condition was induced in chickens fed on polished rice, was significant. These findings led to the concept by Hopkins that small amounts of accessory growth factors are necessary for survival and growth.

1900–1972. During this 70 year period, all 13 of the substances now recognized as vitamins were discovered and isolated in pure form. Structure elucidation for each vitamin was completed, as was its total synthesis (Table 1).

TABLE 1. HISTORY OF THE VITAMINS[a]

Vitamin	Discovery	Isolation	Chemical structure	Synthesis
A	1909	1931	1931	1947
D	1918	1932	1936	1959
E	1922	1936	1938	1938
K	1929	1939	1939	1939

[a] Adapted from Isler, O., and G. Brubacher, *Vitamine I: Fettlösliche Vitamine*, Georg Thieme Verlag, Stuttgart, Germany, 1982.

1933–Present. The first commercial synthesis of a vitamin occurred in 1933 when the Reichstein approach was employed to manufacture vitamin C. All 13 vitamins are available in commercial quantities, and their biological functions have largely been established. A list of Nobel prize winners associated with vitamin research is given in Table 2.

1955–Present. The possibility that vitamins might have physiological functions beyond the prevention of deficiency diseases was first recognized in 1955 with the finding that niacin can affect serum cholesterol levels in humans. An explosion of research in the intervening years has been aimed at establishing optimal vitamin levels and anticipating the health consequences.

Structure

Common names, chemical structure, and synonyms for the vitamins are given in Table 3. The names given to the vitamins and/or their letter designations do not follow a logical pattern and are of historical significance only. Despite this, the nomenclature is in common use.

Vitamins are classified by their solubility characteristics into fat-soluble and water-soluble groups. The fat-soluble vitamins A, E, D_3 and K result from the isoprenoid biosynthetic pathway. Vitamin A is derived by enzymic cleavage of the symmetrical C_{40} beta-carotene, also

TABLE 3. VITAMIN NAMES AND STRUCTURES

Vitamin	Structure	CAS Registry Number	Common name and synonyms
A		[68-26-8]	Retinol, axerophthol
D		[520-91-2]	Vitamin D_3, cholecalciferol, antirachitic vitamin
E		[59-02-9]	α-Tocopherol, (*RRR*)- α-tocopherol, antisterility vitamin
K		[84-80-0]	Vitamin K_1, phylloquinome, coagulation vitamin, antihemorrhagic vitamin, phytonadione
B_1		[67-03-8]	Thiamine, aneurin
B_2		[83-88-5]	Riboflavin, vitamin G, lactoflavin, hepatoflavin, Ovoflavin, verdoflavin
Niacin		[59-67-6]	Vitamin B_3, nicotinic acid

B_6		[58-56-0]	Pyridoxine, pyridoxol, antiacrodynia factor
B_{12}		[68-19-9]	Cobalamin, cyano-cobalamin
Folic acid		[59-30-3]	Folacin, pteroylglutamic acid, antianemia factor, fermentation *L. casei* factor
Pantothenic acid		[79-83-4]	Chick antidermatitis factor
Biotin		[58-85-5]	*d*-Biotin, vitamin H, anti-egg-white-injury factor, bios II, coenzyme R
C		[520-91-2]	Ascorbic acid, antiscorbutic vitamin

known as pro-vitamin A. Vitamins E and K result from condensations of phytyldiphosphate (C_{20}) with aromatic components derived from shikimic acid. Vitamin D results from photochemical ring opening of 7-dehydrocholesterol, itself derived from squalene (C_{30}).

The water-soluble vitamins, B_1, B_2, B_6, B_{12}, niacin, folic acid, pantothenic acid, biotin, and C, have a much less common biosynthetic heritage. Furthermore, multiple biosynthetic paths exist for several of the vitamins. Thus vitamins B_1, B_2 and folic acid are derived from purines, with components coming from carbohydrates. Portions of vitamins B_1 and folic acid also originate in amino acids. One biosynthesis of niacin and that of vitamin B_6 are derived from glycerin. AcetylCoA serves as common precursor, in extremely complex processes, to biotin (via pimelic acid) and vitamin B_{12} (through 5-aminolevulinic acid). Pantothenic acid is constructed from glyoxylic acid and beta-alanine, itself derived from several pathways. Vitamin C, a carbohydrate, is biosynthesized from glucose or galactose.

Vitamers

Although the 13 substances described in Table 3 are commonly recognized as the vitamins, significant complexities exist because of the following factors. (*1*) A number of similar chemical structures can exhibit, at least qualitatively, the biological activity of the vitamin. (*2*) The biological activity can vary by organism type, eg, in microorganisms vs humans. (*3*) The physiologically active form of the vitamin may be other than that indicated; for example, several water-soluble vitamins are active in co-enzyme form. (*4*) A metabolite may be the active form of the vitamin, as in the case of 1-α-25-dihydroxy-vitamin D_3. (*5*) Biochemical interconversion of several forms of the vitamins can occur. The best studied example is pyridoxine, pyridoxal, pyridoxamine, and their 5′-phosphates. (*6*) Synthetic commercial forms, often manufactured and sold because of their increased stability, are convertible in the target organism to the vitamin. Esters of α-tocopherol and retinol are the most prominent examples. These compounds are known as vitamers. Specifically segmented are the major commercial forms of the vitamin.

Properties

Because of their diverse structures, there are few common threads to vitamin chemical properties aside from their fat or water solubility. Of general concern in all applications, however, is vitamin stability. Table 4 provides generic information regarding stability under several conditions. Levels of stability vary greatly and are impacted by acid or base strength, light intensity, etc.

TABLE 4. VITAMIN STABILITY[a]

Vitamin	Oxygen	Light	100 °C[b]	Acids[b]	Bases[b]
A	U	U	S	U	S
D	U	U	U	U	U
E	U	U	S	S	S
K	S	U	S	S	U
B_1	U	U	U	S	U
B_2	S	U	U	S	U
Niacin	S	S	S	S	S
B_6	S	U	U	S	S
B_{12}	U	U	U	S	S
Folic acid	U	U	U	U	S
Pantothenic acid	S	S	U	U	U
Biotin	S	S	U	S	S
C	U	U	U	S	U

[a] S = stable U = unstable.
[b] In absence of oxygen.

The relative instability of many of the vitamins has led to the creation of derivatives and stabilized product forms capable of withstanding the rigors of food, animal feed, and pharmaceutical process conditions. See also **Pharmaceuticals**.

Depending on the vitamin and application, stabilized forms may involve spray drying in a suitable matrix (eg, gelatin), encapsulation (beadletting), or coating with fats or waxes.

Analysis

Analytical methods for the vitamins involve physical and chemical, chromatographic, microbiological, and biological methods. The method of choice for a particular vitamin depends on the substance being measured, as well as its concentration. For example, detection of biotin, folic acid, and vitamin B_{12} is accurately achieved by high pressure liquid chromatography (hplc) or gas–liquid chromatography (glc). However, chromatographic methods often are not sufficiently sensitive for the low levels at which these vitamins usually are found. Microbiological methods, though slower, more expensive, and usually less accurate, are then employed for these low level assays. Biological assays, although extremely significant in the history of the vitamins, are rarely used in the 1990s.

Physiological Function

It is becoming more authenticated that vitamins have additional potential health benefits when administered, via the diet or by supplementation, at levels above those required for obviating deficiency. Although for most vitamins the optimal levels are not yet established, some of the potential health benefits to be derived from vitamins are indicated. In one case, the level of scientific proof is such that the U.S. FDA has allowed "a health claim that women who are capable of becoming pregnant and who consume adequate amounts of folate daily during their childbearing years may reduce their risk of having a pregnancy affected by spina bifida or other neural tube defects".

The Recommended Dietary Allowances (RDA) of the National Academy of Sciences are intended as daily intake guidelines for preventing deficiencies and maintaining reasonable reserves among most healthy people. These recommendations, revised every 5 to 10 years, are made by a committee of the U.S. Food and Nutrition Board and are based on scientific information that is available at the time of the review. This includes studies on subjects on deficient diets, nutrient balance studies, measures of tissue saturation, normal intakes of the nutrient, and extrapolation from animal data. The 1989 RDA has a special requirement of 100 mg of vitamin C for cigarette smokers. Otherwise, there is no recognition of special needs for specific groups such as those using certain drugs chronically, people with disease, or the elderly (eg, over 65 years). Neither does it address the needs for the prevention of any of the chronic diseases.

Production

Preparation of the vitamins in commercial quantities can involve isolation, chemical synthesis, fermentation, and mixed processes, including chemical and fermentation steps. The choice of process is economic, dictated by the need to obtain materials meeting specifications at the lowest cost.

More than one process is available for some of the vitamins. Further, manufacturers have developed variants of the classical syntheses during optimization. Whereas some of this information is available, as described in the individual sections on vitamins, much is closely held as trade secrets. Judging from the more recent patent literature, the assessment can be made that vitamin production technologies are in general mature. However, the economic value of these products drives continuing research aimed at breakthrough processes.

Applications

It is generally assumed that adequate vitamin levels in humans can be obtained through a balanced diet. However, ongoing studies continue to indicate that the majority of the U.S. population is not receiving even the RDA through diet. Supplementary vitamins are thus provided for fortification of foods and as oral or parenteral dosage forms.

The use of vitamins in humans consumes ca 40% of vitamins made worldwide. The majority of the vitamins, particularly in countries outside the United States, are used in animal husbandry. It is well established that vitamins are critical to animal productivity, especially under confined, rapid growth conditions. Newer information has shown that vitamin E added to cattle feed has the additional effect of significantly prolonging beef shelf life in stores. Additional applications of vitamins exist. A small but growing market segment involves cosmetics. The use of the chemical properties of the vitamins, particularly as antioxidants in foods and, more recently, in plastics (vitamin E), has emerged as a growing trend. See also **Antioxidant**.

TABLE 5. COMPARATIVE LOSSES OF VITAMINS FROM VEGETABLES (CANNING AND FREEZE PROCESSING)

Method of preservation	Loss of vitamins as compared with values of fresh cooke				
	Vitamin Value A	Thiamine (B_1)	Riboflavin (B_2)	Niacin	Ascorbic acid (C)
Frozen, cooked (boiled), drained	mean 12%	20%	24%	24%	26%
	range 0–50%	0–61%	0–45%	0–56%	0–78%
Canned, drained solids	mean 10%	67%	42%	49%	51%

Method of preservation	Loss of vitamins as compared with values of fresh products				
	vitamin Value A	Thiamine (B_1)	Riboflavin (B_2)	Niacin	Ascorbic acid (C)
Frozen (not thawed)	mean 37%	29%	17%	16%	18%
	range 0–78%	0–66%	0–67%	0–33%	0–50%
Canned, solids and liquids	mean 39%	47%	57%	42%	56%
	range 0–68%	22–67%	33–83%	25–60%	11–86%

The daily requirements of vitamins by humans are summarized in the entry on ***Diet***. The relationship between hormones and vitamins is described in the entry on ***Hormones***. Vitamins also are mentioned frequently in descriptions of various fruits, vegetables, and other foodstuffs throughout the book. Vitamins also figure prominently in discussions of some of the diseases, scores of which are described in this book.

Loss of Vitamins in Processing

During the last several years, much research has gone into determining the loss in effectiveness of vitamins as various foods are processed. It is a common tendency on the part of consumers to regard any fresh food as representing perfection in terms of nutritive, including vitamin, value and, conversely, to regard processed foods as nutritionally inferior. Under normal circumstances, these observations are true. Because fresh foods frequently are stored for several days at temperatures well above their freezing points, there are vitamin losses in unprocessed produce. Ascorbic acid content in vegetables, for example, can severely degrade during improper storage. The degradation of vitamin values depends a great deal upon the type of food substance, the particular vitamin, and the manner in which the raw food is processed. The consumer today also is protected by vitamin-fortified foods, where vitamins have been added to compensate for losses during processing, or, in some cases, to generally enrich the foods nutritionally. Losses of vitamins from fruits and vegetables during processing are tabulated in Tables 5 and 6.

Vitamin-Like Compounds

Although it is a general consensus that these 13 substances represent the known vitamins, other compounds upon which there is less agreement often enter the vitamin discussion. Included in this group are choline, myo-inositol (Bios I), vitamin F (essential fatty acids including linoleic acid, γ-linolenic acid, and arachidonic acid), α-lipoic acid, ubiquinones, plastoquinone, vitamin P (bioflavonoids), vitamin L (*o*-aminobenzoic acid), vitamin T (mixture including folic acid and vitamin B_{12}), vitamin U (L-methioninylmethylsulfonium chloride), orotic acid (vitamin B_{13}), and pyrroloquinoline quinone.

VITAMIN A. This substance also has been referred to as retinol, axerophthol, biosterol, vitamin A_1, anti-xerophthalmic vitamin, and anti-infective vitamin. The physiological forms of the vitamin include: Retinol (vitamin A_1) and esters; 3-dehydroretinol (vitamin A_2) and esters; 3-dehydroretinal (retinine-2); retinoic acid; neovitamin A; neo-b-vitamin A_1. The vitamin is required by numerous animal species. All vertebrates and some invertebrates convert plant dietary carotenoids in gut to vitamin A_1, which is absorbed. Most animal species store appreciable amounts of the vitamin in their livers, have low concentrations in the blood, and undetectable quantities in most other tissues. A deficiency of the vitamin produces a variety of symptoms, the most uniform being eye lesions, nerve degeneration, bone abnormalities, membrane keratinization, reproductive failure, and congenital abnormalities. Toxic symptoms from large doses of vitamin A are readily produced in animals and humans. Overdosage may cause irritability, nerve lesions, fatigue, insomnia, pain in bones and joints, exophthalmia, and mucous cell formation in keratinized membranes.

The principal physiological functions of this vitamin include growth, production of visual purple, maintenance of skin and epithelial cells, resistance to infection, gluconeogenesis, mucopolysaccharide synthesis, bone development, maintenance of myelin and membranes, maintenance of color and peripheral vision, maintenance of adrenal cortex and steroid hormone synthesis. Specific vitamin A deficiency diseases include xerophthalmia, nyctalopia, hemeralopia, keratomalacia, and hyperkeratosis.

The structure of vitamin A [CAS: 11103-57-4] and some of the important derivatives are shown in Figure 1. The parent structure is all-*trans*-retinol [CAS: 68-26-8] and its IUPAC name is (all-*E*)-3,7-dimethyl-9-(2,6,6-trimethyl-1-cyclohexen-1-yl)-2,4,6,8-nonatetraen-1-ol. The numbering system for vitamin A derivatives parallels the system used for the carotenoids. In older literature, vitamin A compounds are named as derivatives of trimethyl cyclohexene and the side chain is named as a substituent. For retinoic acid derivatives, the carboxyl group is denoted as C-1 and the trimethyl cyclohexane ring as a substituent on C-9. The structures of vitamin A and β-carotene were elucidated by Karrer in 1930 and several derivatives of the vitamin were prepared by this group. In 1935, Wald isolated a substance found in the visual pigments of the eye and was able

to show that this material was identical with Karrer's retinaldehyde [CAS: 116-31-4].

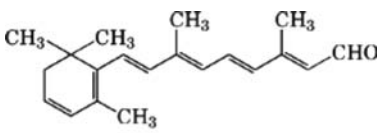
Fig. 1. Vitamin A and derivatives: retinol (**1**), retinyl acetate [CAS: 127-47-9] (**2**), retinyl palmitate [CAS: 79-81-2] (**3**), and retinyl propionate [CAS: 7069-42-3] (**4**).

Vitamin A_2 [CAS: 79-80-1] (**6**) is structurally similar to vitamin A_1 [CAS: 68-26-8] and is also found in fish oils. This compound is important biologically for fish and other lower animals. Interestingly, tadpoles require vitamin A_2 but after metamorphosis require vitamin A_1.



(**6**)

Vitamin A constitutes the most significant sector of the commercial retinoid market and is used primarily in the feed area. In the pharmaceutical area, there are several important therapeutic dermatologic agents which structurally resemble vitamin A and they are depicted in Figure 2. See also **Pharmaceuticals**. The carotenoids as provitamin A compounds also represent an important commercial class of compounds with β-carotene [CAS: 7235-40-7] occupying the central role (Fig. 3).

Chemical and Physical Properties

Because of the presence of an extended polyene chain, the chemical and physical properties of the retinoids and carotenoids are dominated by this feature. Vitamin A and related substances are yellow compounds which are unstable in the presence of oxygen and light. This decay can be accelerated by heat and trace metals. Retinol is stable to base but is subject to acid-catalyzed dehydration in the presence of dilute acids to yield anhydrovitamin A [CAS: 1224-18-8] **(16)**. Retro-vitamin A [CAS: 16729-22-9] **(17)** is obtained by treatment of retinol in the presence of concentrated hydrobromic acid. In the case of retinoic acid and retinal, reisomerization is possible after conversion to appropriate derivatives such as the acid chloride or the hydroquinone adduct. Table 1 lists the physical properties of β-carotene [CAS: 7235-40-7] and vitamin A.

TABLE 1. PROPERTIES OF β-CAROTENE AND VITAMIN A DERIVATIVES

Property	Retinol[a]	Retinyl acetate[a]	Retinyl palmitate[a]	Retinyl propionate[b]	β-carotene[a]

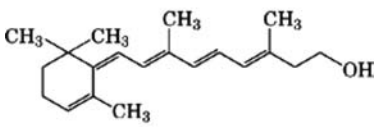
(16)



(17)

Of the 16 possible geometric isomers of vitamin A, only the all-trans form has full vitamin A activity and these compounds are commonly named according to the older, nonsystematic nomenclature (Table 2). From a biological standpoint, 11-*cis*-retinal plays a critical role in vision (*vide infra*). As earlier described, 13-*cis*-retinoic acid is important as a dermatological agent. Recently, 9-*cis*-retinoic acid has also been shown to be an important biological isomer and has been identified as a novel endogenous hormone in mammalian tissues. The other 13 isomers have no biological or commercial significance. Isolation, characterization, and synthesis of these isomers have been reported.

The most conspicuous physical feature of the retinoids and of the carotenoids is the uv spectrum. In the case of the carotenoids, this coloration property is one reason for their commercial significance.

Analytical Methods

Biological, spectroscopic, and chromatographic methods have been used to assay vitamin A and the carotenoids. Biological methods have traditionally been based on the growth response of vitamin A–deficient rats. The utility and shortcomings of this test have been reviewed. This test has found applicability for analogues of retinol. Carotenoids that function as provitamin A precursors can also be assayed by this test.

Spectroscopic methods such as uv and fluorescence have relied on the polyene chromophore of vitamin A as a basis for analysis. Indirectly, the classical Carr-Price colorimetric test also exploits this feature and measures the amount of a transient blue complex at 620 nm which is formed when vitamin A is dehydrated in the presence of Lewis acids. For uv measurements of retinol, retinyl acetate, and retinyl palmitate, analysis is done at 325 nm. More sensitive measurements can be obtained by fluorescence. Excitation is done at 325 nm and emission at 470 nm. Although useful, all of these methods suffer from the fact that the method is not specific and any compound which has spectral characteristics similar to vitamin A will assay like the vitamin.

Owing to the light and air sensitivity of the carotenoids and retinoids, sample handling is a critical issue. It is recommended to conduct extraction of these materials with peroxide-free solvents, to store biological samples at −70 °C under argon and in the dark, to perform the analysis under yellow light, and to use reference compounds of high purity.

In the *United States Pharmacopeia* (USP), vitamin A content is determined by the ratio of the corrected absorbance to the observed absorbance and is not to be less than 0.85 at 325 nm. Total vitamin A content is to be 95% of label claim. For β-carotene, the assay is performed

TABLE 2. PHYSICAL PROPERTIES OF STEREOISOMERS OF VITAMIN A

Isomer	Alcohol mp, °C	λ_{max}, nm	E_{max}	Vitamin A potency, %	Aldehyde mp, °C	λ_{max}, nm	E_{max}	Vitamin A potency, %
all-*trans*-vitamin A	62–64	325	1832	100	57/65	381	1530	91
13-*cis*-vitamin A	58–60	328	1686	75	77	375	1250	93
11-*cis*-vitamin A	oil	319	1220	23	63.5–64.7	376.5	878	48
11,13-di-*cis*-vitamin A	86–88	311	1024	15	oil	373	700	31
9-*cis*-vitamin A	81.5–82.5	323	1477	22	64	373	1270	19
9,13-di-*cis*-vitamin A	58–59	324	1379	24	49/85	368	1140	17

using uv spectroscopy and is determined by the absorbance at 455 nm. The range of the assay should be from 96.0 to 101.0%.

Occurrence

Rich sources of vitamin A include dairy products such as milk, cheese, butter, and ice cream. Eggs as well as internal organs such as the liver, kidney, and heart also represent good sources. In addition, fish such as herring, sardines, and tuna, and in particular the liver oil from certain marine organisms, are excellent sources. Because the vitamin A in these food products is derived from dietary carotenoids, vitamin A content can vary considerably. Variation of vitamin A content in food can also result from food processing and in particular, oxidation processes.

Fertile sources of carotenoids include carrots and leafy green vegetables such as spinach. Tomatoes contain significant amounts of the red carotenoid, lycopene. Although lycopene has no vitamin A activity, it is a particularly efficient antioxidant. See also **Antioxidants**. Oxidation of carotenoids to biologically inactive xanthophylls represents an important degradation pathway for these compounds.

In 1912, Hopkins reported a factor in milk needed for the growth of rats. In 1913, Osborne and Mendel demonstrated that milk factor is fat soluble, and present in other fats also. McCollum and Davis, in 1913–1915, identified milk factor (fat-soluble A) in butter and egg yolk. In 1917, McCollum and Simmonds found xerophthalmia in rats due to lack of fat-soluble A. In 1920, Drummond renamed fat-soluble A, vitamin A. In 1930, Moore determined that carotene is a precursor of vitamin A. See also **Carotenoids**. During 1930–1937, Karrer et al. isolated and synthesized vitamin A. In 1935, Wald reported visual purple in retina to be a complex of protein and vitamin A.

Distribution and Sources. Provitamin carotenoids are contained in numerous foods, but of varying concentrations.

High vitamin A and procarotenoids content (*10,000–76,000 I.U./100 grams*).[1] Carrot, dandelion green, kohlrabi, liver (beef, calf, chicken, pig, sheep), liver oil (cod, halibut, salmon, shark, sperm whale), mint, palm oil, parsley, spinach, turnip greens.

Medium vitamin A and procarotenoids content (*1,000–10,000 I.U./100 grams*). Apricot, beet greens, broccoli, butter, chard, cheese (except cottage), cherry (sour), chicory, chives, collards, cream, eel, egg yolk, endive, fennel, kale, kidney (beef, pig, sheep), leek greens, lettuce (butterhead and romaine), liver (pork), mango, margarine, melons (yellow), milk (dried), mustard, nectarine, peach, pumpkin, squash (acorn, butternut, hubbard), sweet potato, tomato, watercress, whitefish.

Low vitamin A and procarotenoids content (*100–1,000 I.U./100 grams*). Artichoke, asparagus, avocado, banana, bean (except kidney), berry (black-, blue-, boysen-, goose-, logan-, rasp-), Brussels sprouts, cabbage, carp, cashew, celery, cherry (sweet), clam, corn (maize), cowpea, cucumber, currant (red), grape, groundnut (peanut), hazelnut, herring, kumquat, leek, lentil (dry), lettuce, milk, okra, olive, orange, oyster, pea, pecan, pepper (sweet), pineapple, pistachio, plum, prune, rhubarb, rutabaga, salmon, sardine, squash (summer and zucchini), tangerine, walnut (black).

In higher plants, carotenoids are produced in green leaves. In animals, conversion of carotenoids to vitamin A occurs in the intestinal wall. Storage is in the liver; also kidney in rat and cat. Target tissues are retina, skin, bone, liver, adrenals, germinal epithelium. Commercial Vitamin A supplements are obtained chemically by extraction of fish liver; or synthetically from citral or β-ionone.

Biological Functions

In humans, vitamin A has important functions in vision, growth, and tissue differentiation. Its role in vision is fairly well understood and involves initial absorption of all-*trans*-retinol by the pigment epithelium cells of the eye. This event is followed by isomerization to11-*cis*-retinol by all-*trans*-11-*cis*-retinol isomerase. After conversion of 11-*cis*-retinol to 11-*cis*-retinal, reaction with opsin forms rhodopsin. Absorption of light by this pigment generates the visual signal by cis/trans isomerization. After release of *trans*-retinal from the pigment, *trans*-retinal is rapidly reduced to all-*trans*-retinol and the cycle repeats itself. Consequently, vitamin A is not consumed in the process. One feature of this system is that the basic chemistry is common to many photosensitive systems from such diverse species as halophilic bacteria to higher organisms such as vertebrates.

As previously described, the biological assay for vitamin A was based on the growth response of rats fed a vitamin A-deficient diet. Vitamin A is necessary for normal bone growth and remodeling and is required for the activity of epiphyseal cartilage. Retinoic acid is the active form of vitamin A for this function and it has been observed that ingestion of retinoic acid restores growth but cannot maintain vision. In animals cycled on retinoic acid, ie, fed a retinoic acid-containing diet then deprived of a retinoic acid-containing diet, these animals become sensitive to the removal of retinoic acid. This condition is characterized by a loss in appetite followed by a depression in growth. As a result, loss of appetite is one of the first symptoms of a vitamin A-deficient animal.

The specific role of vitamin A in tissue differentiation has been an active area of research. The current thinking, developed in 1979, involves initial delivery of retinol by *holo*-RBP (retinol-binding protein) to the cell cytosol. Retinol is then ultimately oxidized to retinoic acid and binds to a specific cellular retinoid-binding protein and is transported to the nucleus. Retinoic acid is then transferred to a nuclear retinoic acid receptor (RAR), which enhances the expression of a specific region of the genome. Transcription occurs and new proteins appear during the retinoic acid-induced differentiation of cells.

In contrast to vitamin A, the carotenoids are important in both plant and animal kingdoms. In plants, carotenoids are associated with photosynthetic structures. The function of these pigments is twofold: (*1*) the pigments serve as acceptors and act as energy-transfer agents and allow for excitation energy to be transferred from the carotenoid to the porphyrin; (*2*) the pigments protect the organism from light-induced photooxidative damage. In this regard, protection is achieved by two mechanisms: quenching of the excited triplet state of chlorophyll (itself a producer of singlet oxygen), and quenching of singlet oxygen. In both cases, a triplet excited state of the carotenoid, which decays back to the ground state by a radiationless conversion, is produced.

Many carotenoids function in humans as vitamin A precursors; however, not all carotenoids have provitamin A activity (Table 3). Of the biologically active carotenoids, β-carotene has the greatest activity. Despite the fact that theoretically one molecule of β-carotene is a biological source of two molecules of vitamin A, this relationship is not observed and 6 μg β-carotene is equivalent to 1 μ vitamin A. Although β-carotene and vitamin A have complementary activities, they cannot totally replace each other. Because the conversion of β-carotene to vitamin A is highly regulated, toxic quantities of vitamin A cannot accumulate and β-carotene can be considered as a safe form of vitamin A.

TABLE 3. PROVITAMIN A ACTIVITY OF SELECTED CAROTENOIDS

Provitamin A activity	No provitamin A activity
β-carotene	astaxanthin
α-carotene	canthaxanthin
γ-carotene	lutein
β-crypotoxanthin	lycopene
β-zeacarotene	zeaxanthin

Owing to the presence of an extended polyene chain, all carotenoids are effective single-oxygen quenchers and antioxidants. In addition, they can stimulate the immune response and, as a result, may protect against certain forms of cancer. These separate functions, ie, vitamin A equivalents or antioxidants, have allowed for carotenoids to be classified according to whether they are nutritionally or biologically active. For example, β-carotene is both nutritionally and biologically active whereas 14′-β-apocarotenal is nutritionally active but biologically inactive. Lycopene is nutritionally inactive but biologically active, whereas phytoene, the natural precursor to β-carotene, is both nutritionally and biologically inactive.

[1] One I.U. = 0.344 microgram vitamin A acetate = 0.3 microgram retinol.

Deficiency

In humans, vitamin A deficiency manifests itself in the following ways: night blindness, xerophthalmia, Bitot's spots, and corneal involvement and ulceration. Changes in the skin have also been observed. Although vitamin A deficiency is seen in adults, the condition is particularly harmful in the very young. Often, this results from malnutrition.

On a vitamin A-deficient diet, mucus-secreting tissues become keratinized. This condition tends to occur in the trachea, the skin, the salivary glands, the cornea, and the testes. When this occurs in the cornea, it can be followed by blindness. Vitamin A deficiency is the principal cause of blindness in the very young. This problem is particularly acute in the third world

Bioavailability of Vitamin A. Factors which may cause a decrease in the availability of vitamin A include: (1) liver damage; (2) impaired intestinal conversion of carotenes; (3) impaired absorption (low bile); (4) loss in food preparation (cooking and frying — heat oxidation); (5) presence of antagonists; (6) illness, causing increased destruction and excretion of the vitamin. Increases in availability may result from: (1) storage in body (liver); (2) factors which stimulate intestinal conversion of carotenes — tetraiodothyronine (thyroxine), insulin; (3) absorption aids — bile, fat; and (4) dietary protein which mobilizes vitamin A from storage in liver.

Antagonists of vitamin A include sodium benzoate, bromobenzene, citral, oxidized derivatives of vitamin A, excessive concentrations of thyroxine, estrogens, vitamin E (as regards membrane permeability). Synergists include vitamins B_2, B_{12}, and E, ascorbic acid, thyroxine, testosterone, melanocyte-stimulating hormone (MSH), and somatotrophin growth hormone.

Unusual features of vitamin A as observed by some investigators include: (1) decreases serum cholesterol in large-quantity administration (chicks); (2) dietary protein required to mobilize liver reserves of vitamin A; (3) decreased quantities in tumors; (4) coenzyme Q_{10} accumulates in A-deficient rat liver; (5) Ubichromenol-50 accumulation in A-deficient rat liver; (6) retinoic acid functions as vitamin A except for visual and reproductive functions; (7) anti-infection properties and anti-allergic properties; (8) decreases basal metabolism; (9) detoxification of poisons in the liver aided by vitamin A; and (10) vitamin A is involved in triose → glucose conversions.

Safety

Vitamin A toxicity can be categorized as either acute or chronic. Acute toxicity results from extremely high doses (≥500,000 IU of vitamin A). In children, approximately half of that amount causes problems. Hypervitaminosis A is characterized by headache, blurred vision, loss of coordination, nausea, and peeling and itchy skin. Chronic vitamin A toxicity occurs in adults with long-term intakes of ≥50,000 IU/d. Symptoms include dry hair, hair loss, weakness, headache, bone thickening, enlarged liver and spleen, anemia, abnormal menstrual periods, stiffness, and joint pain. Most of these symptoms are reversible. In animals, extremely high doses of vitamin are teratogenic. On the other hand, the carotenoids are generally nontoxic and there have been only a few isolated cases of problems associated with a large daily intake. Tanning pills that contain large doses of canthaxanthin were shown to cause canthaxanthin retinopathy in patients with eryrthropoietic porphyria.

Uses

Vitamin A is generally used in feeds, foods, and pharmaceutical applications; however, the principal use of carotenoids is as a colorant. β-Carotene, for example, is used to color fat products such as margarine, shortening, butter, cheese, egg nog, and ice cream. It is also used in baked goods, pasta products, juices, and beverages. It imparts a natural yellow to orange shade. Conversely, if an orange to reddish orange color is desired, the carotenoid of choice is β-apo-8′-carotenal [CAS: 1107-26-2]. This carotenoid is used to color juices, fruit drinks, soups, jams, jellies, and gelatin. Carotenoids are also added to feed to color poultry, fish, and of egg yolks. In order to guard against oxidative damage during feed processing, these compounds are protected in a gelatin matrix as beadlets.

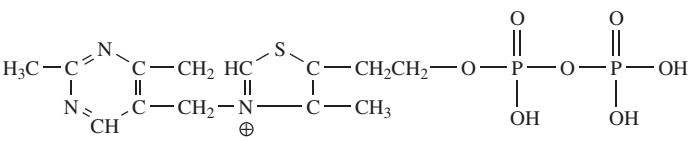
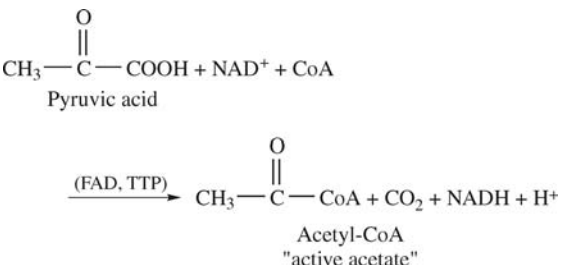
Facts About Vitamin A and Carotenoids: http://www.cc.nih.gov/ccc/supplements/vita.html

VITAMIN B_1 (Thiamine). [CAS: 59-43-8]. Some earlier designations for this substance included aneurin, antineuritic factor, antiberiberi factor, and oryzamin. Thiamine is metabolically active as thiamine pyrophosphate (TPP) [CAS: 154-87-0], the formula of which is:



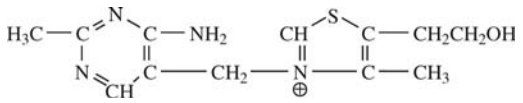
TPP functions as a coenzyme which participates in decarboxylation of α-keto acids. Dehydrogenation and decarboxylation must precede the formation of "active acetate" in the initial reaction of the TCA cycle (citric acid cycle):



This reaction is a good example of the interrelationship of vitamin B coenzymes. Four vitamin coenzymes are necessary for this one reaction: (1) thiamine (in TPP) for decarboxylation; (2) nicotinic acid in nicotinamide adenine dinucleotide (NAD); (3) riboflavin in flavin adenine dinucleotide (FAD); and (4) pantothenic acid in coenzyme A (CoA) for activation of the acetate fragment.

TPP also mediates the oxidative decarboxylation of α-ketoglutaric acid, another intermediate of carboxydrate metabolism in the citric acid cycle. The nutritional requirement for thiamine increases as dietary carbohydrate increases because of a greater demand for TPP.

The structure of thiamine hydrochloride is [CAS: 67-03-8]:



In this form and as other salts, such as thiamine mononitrate, the vitamin is available as a dietary supplement.

Diseases and disorders resulting from a deficiency of thiamine include beriberi, opisthotonos (in birds), polyneuritis, hyperesthesia, bradycardia, and edema. Rather than a specific disease, beriberi may be described as a clinical state resulting from a thiamine deficiency. In body cells, thiamine pyrophosphate is required for removing carbon dioxide from various substances, including pyruvic acid. Actually, this is accomplished by a decarboxylase of which thiamine pyrophosphate is a part. Where thiamine is deficient, the process of oxidation necessary for converting food into energy is impeded, causing a variety of manifestations throughout the body.

In so-called *dry* beriberi, pathologic alterations in neurons and nerve fibers occurs, leading in some instances to degeneration of peripheral nerves. This condition is termed peripheral neuritis, generally affecting the nerves in the arms and legs. There often is altered skin sensitivity to touch in the extremities and pain on pressure over large nerves. There is a gradual loss of muscle strength, which may lead to paralysis of a limb. In *wet* beriberi, there is a lessening of strength of the heart muscles. There is enlargement of the heart, dyspnoea, increased pulse rate, palpitation, and edema. Pathologically, degenerative changes are found in the nervous tissue, heart muscle, and gastrointestinal tract. In later stages, marked enlargement of the heart and liver may be noted.

In one form of thiamine deficiency, Wernicke's syndrome may be noted. Therein is paralysis, or weakness of the muscles that causes motion of the eyeball. Closely associated with thiamine deficiency are dietary problems of alcoholism. The psychotic disturbances of alcoholism, including delirium tremens, frequently respond to thiamine and other B complex vitamins. Injections of thiamine often produce dramatic improvements in persons suffering from beriberi. Beriberi sometimes occurs in infants who are breast-fed by mothers who suffer a thiamine deficiency. Beriberi remains of concern in the Orient where polished rice is a dietary staple.

In cattle, a thiamine deficiency causes podioencephalomalcia (PEM), characterized by blindness, decreased feed intake, incoordination, failure of rumen to contract, spasms, and paralysis. In swine, a deficiency retards growth and sometimes causes cyanosis (insufficient oxygen in blood), enlarged heart, accompanied by fatty degeneration of heart muscles. Chicks suffer from paralysis of peripheral nerves, causing polyneuritis (head drawn back).

Distribution and Sources. Relatively few natural foods are considered high in thiamine content.

High thiamine content (1,000–10,000 micrograms/100 grams). Ham, rice bran, soybean flour, wheat germ, yeast.

Medium thiamine content (100–1000 micrograms/100 grams). Almond, asparagus, barley, brazil nut, bean (kidney, lima, snap, soy, wax), beef, beet greens, broccoli, Brussels sprouts, carp, cashew, cauliflower, chicory, chestnut, chicken, clam, cod, corn (maize), dandelion greens, eggs, endive, gooseberry, groundnut (peanut), hazelnut, kale, kohlrabi, leek, lentil (dry), lobster, mackerel, milk, mushroom, oats, oyster, parsley, pea, pecan, plum, pork, potato, prune (dry), raisin (dry), rice (brown), salmon, turkey, veal, walnut, watercress.

Low thiamine content (10–100 micrograms/100 grams). Apple, apricot, artichoke, avocado, banana, beet, berry (black-, blue-, cran-, rasp-, straw-), cabbage, carrot, celery, cheeses, cherry, coconut, cucumber, currant, date (dry), eggplant, fig, flounder, grape, grapefruit, haddock, halibut, herring, lemon, lettuce, melons, orange, parsnip, peach, pear, pepper (sweet), pike, pineapple, prune, sardine, scallop, shrimp, tangerine, trout, tuna, turnip.

Commercial thiamine dietary supplements are prepared by synthesis: Pyrimidine + thiazole nuclei synthesized separately and then condensed; also build on pyrimidine with acetamidine. Precursors in the biosynthesis of thiamine include thiazole and pyrimidine pyrophosphate, with thiamine phosphate as an intermediate. In plants, production sites are found in grain and cereal germ.

Bioavailability of Thiamine. Factors which contribute to a lessening of thiamine bioavailability include: (1) cooking, inasmuch as the vitamin is heat labile and water soluble; (2) presence of certain enzymes in food, such as thiaminase for vitamin breakdown; (3) destruction by calcium carbonate, dibasic potassium phosphate, and manganous sulfate; (4) destruction by nitrites and sulfites; (5) diuresis and gastrointestinal diseases; and (6) presence of live yeasts and alkalis. An increase in availability can result from: (1) presence of cellulose in diet, which increases intestinal synthesis; (2) storage capacity in heart, liver, and kidney; and (3) stimulation of bacterial synthesis in intestine (normally none).

Antagonists of thiamine include pyrithiamine, oxythiamine, and 2-*n*-butyl homologue. Synergists include vitamins B_2, B_6, B_{12}, and niacin, pantothenic acid, and somatotrophin (growth hormone).

Unusual features of thiamine as observed by some researchers include: (1) it exerts a hormonal function in plants, controlling root growth; (2) it aids phosphorylation in liver, dephosphorylation in kidney; (3) it easily poisoned by heavy metals, acetyl iodide; (4) plant and animal cocarboxylases are identical; (5) it exerts a diuretic effect and it is constipating; (6) it can be allergenic on injection; (7) it is not available from intestinal bacteria; and (8) blood contains most cocarboxylase in leukocytes.

Thiamine is soluble in water and easily destroyed by heat. These two properties account for appreciable losses of thiamine from processed and stored foods. An acid medium favors the retention of thiamine, whereas an alkaline medium is detrimental to retention.

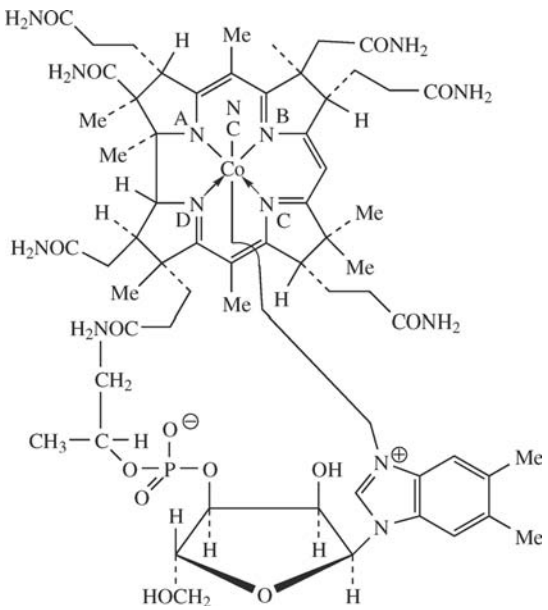
Determination of Thiamine. Bioassay methods include yeast fermentation; polyneuritic rate of cure in rat; bacterial metabolism. Physicochemical methods include thiochrome fluorescence; polarography; chromatography; absorption in neutral and acid solutions.

Most of the thiamine sold worldwide is used for dietary supplements. Primary market areas include the following applications: addition to feed formulations, eg, poultry, pigs, cattle, and fish; fortification of refined foods, eg, flours, rice, and cereal products; and incorporation into multivitamins. Small amounts are used in medicine to treat deficiency diseases and other conditions, in agriculture as an additive to fertilizers, and in foods as flavorings. Generally for dry formulations, the less soluble, nonhygroscopic nitrate is preferred. Only the hydrochloride can be used for intravenous purposes. Coated thiamine is used where flavor is a factor.

VITAMIN B_{12} (Cobalamin). [CAS: 68-19-9]. Sometimes also called cyanocobalamin, this vitamin is one of the more recent of the major B complex vitamins to be fully identified, with its structure not definitized (by Hodkin et al.) until 1955. The vitamin is required by most vertebrates, some protozoa, bacteria, and algae. Principal physiological functions include: (1) Coenzyme in nucleic acid, protein, and lipid synthesis; (2) maintains growth; (3) participates in methylations; (4) maintains epithelial cells and nervous system (myelin sheath); (5) erythropoiesis (with folic acid); (6) leukopoiesis. Deficiency diseases or disorders include retarded growth; pernicious anemia; megaloblastic anemia; macrocytic, hyperchromic anemia; glossitis; spinal cord degeneration; and sprue. The major physiological forms of B_{12} available include hydroxocobalamin (vitamin B_{12a}) and aquocobalamin (vitamin B_{12c}).

In 1926, Minot and Murphy controlled pernicious anemia using liver. In 1944, Castle demonstrated intrinsic factor needed to control pernicious anemia with liver. Rickes et al., in 1948, isolated and crystallized factor in liver controlling pernicious anemia. In that same year, Smith and Parker crystallized and designated liver factor as vitamin B_{12}. West demonstrated, in 1948, clinical activity of vitamin B_{12}, and, in 1955, Hodgkin et al. determined the structure of the vitamin. This is shown in Structure 1. Vitamin B_{12} is the only vitamin with a metal ion — in this case, cobalt. Surrounding the cobalt is a macrocyclic corrin ring that is comprised of four nitrogen-containing, five-membered rings joined through three methylene bridges. There is a similarity between this corrin ring and the dihydroporphyrin (chlorin) ring of chlorophyll.

Absorption of Vitamin B_{12}. This vitamin is not synthesized in animals, but rather it results from the bacterial or fungal fermentation in the rumen, after which it is absorbed and concentrated during metabolism. Among the known vitamins, this exclusive microbial synthesis is of great interest. One of the major results of vitamin B_{12} deficiency is pernicious anemia.



Structure 1. Vitamin B_{12}.

This disease, however, usually does not result from a dietary deficiency of the vitamin, but rather by an absence of a glycoprotein ("gastric intrinsic factor") in the gastric juices that facilitates absorption of the vitamin in the intestine. Control of the diseases hence is either by injection of B_{12} or by oral administration of the intrinsic factor, with or without the vitamin injection. See also **Anemias**.

There are two separate and distinct mechanisms for absorption of vitamin B_{12}. One mechanism is active, the other passive; both operate simultaneously. The active process is physiologically more important, since it is operative primarily in the presence of the small (1–2 micrograms) quantities of vitamin B_{12} made available for absorption from the average meal. This special mechanism, perhaps uniquely necessary for vitamin B_{12} because of its large size and polar properties, operates as follows. The normal gastric mucosa secretes a substance, called the *intrinsic factor of Castle*, which combines with free vitamin B_{12}. The complex travels down the intestine to the ileum, where, in the presence of calcium and pH above 6, it attaches to "receptors" lining the wall of the ileal mucosa. Vitamin B_{12} is then freed from intrinsic factor via a "releasing factor" mechanism of unknown nature, operating either at the surface of or within the ileal mucosal cell, and passes into the bloodstream. Thus, important requirements for normal absorption of vitamin B_{12} from food are: (1) the vitamin must be freed from its peptide bonds in food; (2) the gastric mucosa must secrete an adequate quantity of intrinsic factor; (3) the ileal mucosa must be sufficiently normal both structurally and functionally so that vitamin B_{12} may be absorbed across it.

Intrinsic factor is believed to be a glycoprotein or mucopolysaccharide with a molecular weight in the range of 50,000 and an end-group conformation like that of partly degraded blood group substance. The sole known role of intrinsic factor is to facilitate the transport of the large (molecular weight = 1,355) vitamin B_{12} molecule across the wall of the ileal mucosa and into the bloodstream. Antibodies to intrinsic factor exist in the serum of approximately half of all patients with pernicious anemia.

The second mechanism for vitamin B_{12} absorption is operative primarily in the presence of quantities of vitamin B_{12} greater than those made available for absorption from the average diet (*i.e.*, quantities greater than about 30 micrograms). This mechanism is a passive one, probably diffusion, and most likely occurs along the entire length of the small intestine. It operates when patients with pernicious anemia (vitamin B_{12} deficiency due to inadequate or absent intrinsic factor secretion of unknown cause) are treated with large quantities (500 micrograms or more daily) of oral vitamin B_{12}. Such treatment is probably better than treatment with oral hog intrinsic factor, to which refractoriness often develops, but it is not as certain as treatment with monthly injections of vitamin B_{12}.

Deficiency Effects. Further elucidating on the physiologic functions and deficiency disorders of vitamin B_{12}, this vitamin is required for DNA (deoxyribonucleic acid) synthesis and, therefore, is necessary in every reproducing cell in humans for maintenance of the ability to divide. The vitamin functions coenzymatically in the methylation of homocysteine to methionine. It is important in several isomerization reactions, and as a reducing agent, and is probably of special importance in enzymatic reduction of ribosides to deoxyribosides. It is involved in protein synthesis, partly via its role in the conversion of homocysteine to methionine; in fat and carbohydrate metabolism, partly via its role in the isomerization of succinate to methylmalonate (which then may be decarboxylated to propionate), and in folate metabolism. Where these two vitamins interrelate, vitamin B_{12} appears to serve as a coenzyme and folate as a substrate; such is true in the vitamin B_{12}-mediated transfer of a methyl group from N^5-methyltetrahydrofolic acid to homocysteine, which is thereby converted to methionine.

Vitamin B_{12} is one of the most potent nutrients known; the minimal daily requirement for absorption by the normal adult is probably in the range of 0.1 microgram. This equals, for example, 1/500th of the minimal daily adult folate requirement, which is in the range of 50 micrograms.

As with all nutritional deficiencies, lack of vitamin B_{12} may arise from inadequate ingestion, absorption, or utilization, and from increased requirement or increased excretion. Deficiency of vitamin B_{12} produces megaloblastic (large germ cell) anemia, damage to the alimentary tract (glossitis being the most striking feature), and neurologic damage. The most classic neurologic sign of vitamin B_{12} deficiency is decreased ability to perceive the vibration of a tuning fork pressed against the ankles. This finding is associated with damage to the posterior and lateral columns of the spinal cord, and also with damage to the peripheral nerves. This damage occurs because vitamin B_{12} deficiency results in gradual deterioration of the myelin sheath, which is followed by deterioration of the axon. These processes occur slowly over months to years, and during this stage are reversible by treatment with vitamin B_{12}. However, when the nerve nucleus finally deteriorates, the neurologic damage becomes irreversible.

Distribution and Sources of Vitamin B_{12}. Vegetables, fruits, seeds, and nuts have a very low content of this vitamin.

High vitamin B_{12}content (*50–500 micrograms/100 grams*). Brain (beef), kidney (beef, lamb), liver (beef, calf, lamb, pork).

Medium Vitamin B_{12}content (*5–50 micrograms/100 grams*). Clam, crab, egg yolk, heart (beef, chicken, rabbit), kidney (rabbit), liver (chicken, rabbit), oysters, sardine, salmon.

Low Vitamin B_{12}content (*0.5–5 micrograms/100 grams*). Beef, cod, cheeses, chicken, eggs, flounder, haddock, halibut, lamb, lobster, milk, pork, scallops, shrimp, swordfish, tuna, whale.

Vitamin B_{12} dietary supplements are often prepared commercially by the fermentation of *S. griseus, S. aureofaciens, Propionibacterium*; or as a by-product of antibiotic production.

Certain species of bacteria and actinomycetes biosynthesize vitamin B_{12}. Precursors for this synthesis include glycine-corrin nucleus; δ-aminolevulinic acid-corrin nucleus; and methionine-corrin nucleus. Intermediates during the synthesis include porphobilinogen, α-D-ribosides of benzimidazole; 5,6-dimethylbenzimidazole; and α-ribazole. Antagonists of vitamin B_{12} include methylamide, ethylamide, anilide, lactone derivatives, pteridine, nicotinamide. Synergists include ascorbic acid, biotin, folic acid, pantothenic acid, thiamine, and vitamins A and E.

Bioavailability of Vitamin B_{12}. Factors which tend to decrease the availability of this vitamin include: (1) cooking losses, since the vitamin is heat labile; (2) cobalt deficiency in ruminants; (3) intestinal malabsorption or parasites; (4) lack of intrinsic factor; (5) intestinal disease; (6) aging; (7) vegetarian diet; (8) excretion in feces; (9) gastrectomy. Factors which help to increase availability include: (1) administration of sorbitol; (2) synthesis by intestinal bacteria (not normally); (3) reduced temperature; and (4) presence of food in the stomach.

Although vitamin B_{12} is essentially considered nontoxic, polycythemia has been reported from excessive dosages. From 30 to 60% of the vitamin is stored in the liver; the remainder is found in the kidneys, lungs, and spleen. Target tissues are the central nervous system, kidneys, myocardium, muscle, skin, and bone.

Unusual features of vitamin B_{12} observed by some investigators include: (1) the cyanide group is an artifact of preparation; (2) the only vitamin

synthesized in appreciable amounts only by microorganisms (possible in tumors); (3) only vitamin with a metal ion; (4) works with glutathione; (5) glutathione content decreased on B_{12} deficiency; (6) mitosis retarded in B_{12} deficiency; (7) requires intrinsic factor (enzyme) for oral activity; (8) increases tumor size (Rous sarcoma); (9) diamagnetic properties; (10) no acidic or basic groups revealed on titration (no pKa).

Additional Sources of B_{12}. Fermented soybean and fish products have been found to contain B_{12} (Lee et al., 1958). Nutritionally significant amounts of B_{12} also were found in the Indonesian fermented products, *ontjom* and *tempeh* (Liem et al., 1977). The microbial production of vitamin B_{12} in *kimchi*, Korean fermented vegetables, including cabbage, has been reported (Lee et al., 1958; Kim et al., 1960). The strain producing the vitamin during the fermentation was identified as *Bacillus megaterium*. As reported by Ro, Woodburn, and Sandine (1979), Foods and Nutrition Department and Department of Microbiology, Oregon State University, Corvallis, Oregon, inoculation of fermented foods with strains known to produce vitamin B_{12} has been evaluated as a vitamin enrichment method. Soybean paste inoculated with *Bacillus megaterium* and fermented was found to contain increased vitamin levels (Choe et al., 1963; Ke et al., 1963). Propionibacterium species widely used in the industrial production of vitamin B_{12} (Wuest and Perlman, 1968) have been recommended for vitamin fortification of some dairy products. Karlin (1961) fortified *kefir* with vitamin B_{12} by the addition of *Propionibacterium* to the kefir grains. Kruglova (1963) prepared vitamin-enriched curds from pasteurized cow's milk by fermentation with equal parts of cultures of lactic acid and propionic acid bacteria (2.5% each). The curds had approximately 10 times more vitamin B_{12} than when produced in the usual way with only lactobacilli. In 1979, Ro, Woodburn, and Sandine undertook to increase the vitamin B_{12} content in the production of kimchi. Changes in the ascorbic acid content during the kimchi fermentation were also observed.

Determination of Vitamin B_{12}. Microbial (using *L. leichmanii, O. malhamensis, E. gracilis*, etc.) bioassay methods are used, as are checking the effects of curative doses on experimental animals (chick, rat, etc.). Physicochemical methods used include spectrophotometry, polarography, and isotope dilution.

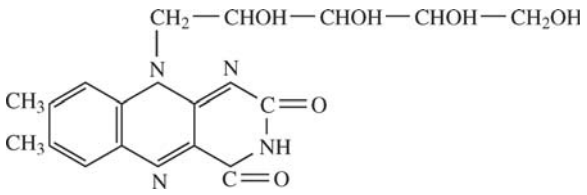
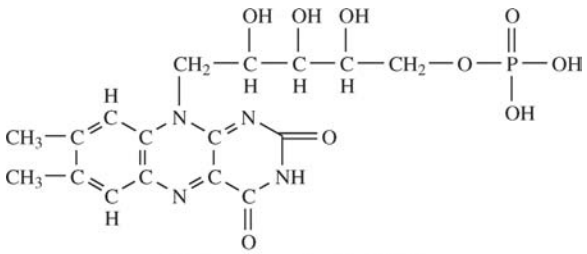
Facts About Vitamin B12:
http://www.cc.nih.gov/ccc/supplements/vitb12.html

VITAMIN B_2 (Riboflavin). [CAS: 83-88-5]. Some earlier designations for this substance included vitamin G, lactoflavin, hepatoflavin, ovoflavin, verdoflavin. The chemical name is 6,7-dimethyl-9-d-l'ribityl isolloxazine. Riboflavin is a complex pigment with a green fluorescence. Riboflavin deficiency frequently accompanies pellagra and the typical lesions of both nicotinic acid and riboflavin deficiency are found in that disease. See also **Niacin**. Riboflavin, like nicotinic acid, forms an oxidation enzyme and, as such, acts as an oxygen carrier to the cell. The structure of riboflavin is:



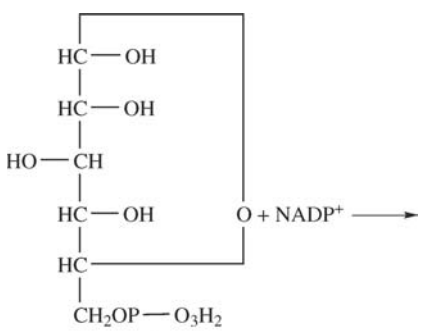
Disorders caused by a deficiency of riboflavin include anemia, cheilosis (a lip disorder); corneal vascularization, seborrheic dermatitis, and glossitis. Research leading to the current knowledge of riboflavin essentially commenced in 1917 when Emmet and McKim showed dietary growth factor for rats in rice polishings. In 1920, Emmet suggested the presence of several dietary growth factors in yeast concentrate, including the heat-stable component and B_1. The British Medical Research Council, in 1927, proposed that the designation B_2 be given to the heat-stable component. Warburg and Christian, in 1932, isolated yellow enzyme (containing riboflavin, FMN) from bottom yeast. In 1933, Kuhn isolated pure B_2 (riboflavin) from milk and recognized its growth-promoting activity. Several researchers (Kuhn et al.; Karrer et al.), in 1935, worked out the structure and synthesis of vitamin B_2, during which period it was named *riboflavin*. By 1954, Christie et al. had determined the structure and synthesized riboflavin dinucleotide (FAD).

Riboflavin has been shown to be a constituent of 2 coenzymes: (1) Flavin mononucleotide (FMN); and (2) flavin adenine dinucleotide (FAD). The structures are:



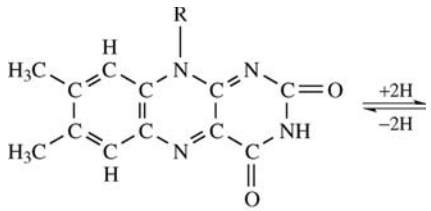
Flavin mononucleotide (FMN)

FMN was first identified as the coenzyme of an enzyme system that catalyzes the oxidation of the reduced nicotinamide coenzyme, NADPH (reduced NADP), to NADP (nicotinamide adenine dinucleotide phosphate). NADP is an essential coenzyme for glucose-6-phosphate dehydrogenase which catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconic acid. This reaction initiates the metabolism of glucose by a pathway other than the TCA cycle (citric acid cycle). The alternative route is known as the phosphogluconate oxidative pathway, or the hexose monophosphate shunt. The first step is:

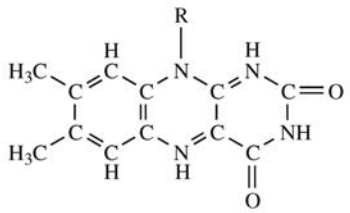


Glucose-6-phosphate

Most of the numerous other riboflavin-containing enzymes contain FAD. FAD is an integral part of the biological oxidation-reduction system where it mediates the transfer of hydrogen ions from NADH to the oxidized cytochrome system. FAD can also accept hydrogen ions directly from a metabolite and transfer them to either NAD, a metal ion, a heme derivative, or molecular oxygen. The various mechanisms of action of FAD are probably due to differences in protein apoenzymes to which it is bound. The oxidized and reduced states of the flavin portion of FAD are:

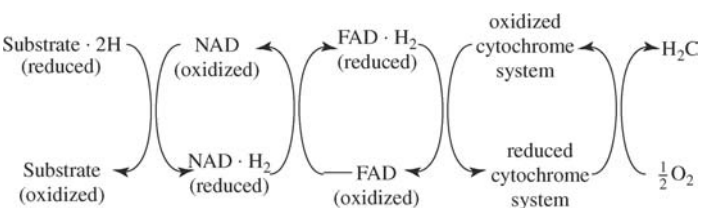


FAD
(oxidized)



$FADH_2$
(reduced)

In the biological oxidation-reduction system, reduced NAD (i.e., ADH) is reoxidized to NAD by the riboflavin-containing coenzyme FAD as shown by:



See also **Coenzymes**.

Distribution and Sources

Research indicates that all organisms require riboflavin. Endogenous sources exist in high plants, algae, some bacteria, and some fungi. All animals, some fungi and bacteria receive at least a partial supply of riboflavin from generation by intestinal bacteria. In the case of humans, there is a large dependence upon exogenous sources.

High riboflavin content (1000–10,000 micrograms/100 grams) Beef (kidneys, liver), calf (kidneys, liver), chicken (liver), pork (heart, kidneys, liver), sheep (kidneys, liver), yeast (killed)

Medium riboflavin content (100–1000 micrograms/100 grams) Almond (dry), asparagus, avocado, bacon, bean (kidney, lima, snap, wax), beef, beet greens, broccoli, Brussels sprouts, cashew, cauliflower, cheeses, chicken, chicory, corn (maize), cream, dandelion greens, eggs, endive, fish, goose, groundnut (peanut), kale, kohlrabi, lamb, lentil (dry), milk, oats, parsley, parsnip, pea, pecan, pork, rice bran, soybean (dry), spinach, turkey, turnip greens, veal, walnut, wheat germ

Low riboflavin content (10–100 micrograms/100 grams) Apple, apricot, artichoke, banana, barley, beet, berry (black-, blue-, cran-, rasp-, straw-), cabbage, carrot, celery, cherry, coconut, cucumber, date (dry), eggplant, fig, grape, grapefruit, lettuce, melons, onion, orange, peach, pear, pepper (sweet), pineapple, plum, potato, radish, raisin (dry), rice, sweet potato, tangerine, tomato, turnip

Commercial riboflavin dietary supplements are prepared (1) by the fermentation process (bacteria or yeast); and (2) by chemical synthesis from alloxan, ribose, and *o*-xylene.

Precursors in the biosynthesis of riboflavin include purines, pyrimidines, and ribose. Intermediate in the synthesis is 6,7-dimethyl-8-ribityllumazine. In plants, riboflavin production sites are found in leaves, germinating seeds, and root nodules. Storage sites in animals are heart and liver, with small amounts in the kidneys. Riboflavin in overdose is essentially nontoxic to humans.

Bioavailability of Riboflavin

Factors which tend to decrease the availability of riboflavin include: (1) cooking, inasmuch as riboflavin is slightly soluble in water; (2) in some plant foods, availability is lower than might be expected because of bound forms; (3) decreased phosphorylation in intestines prevents absorption; (4) exposure of foods to sunlight; (5) enzymes required for breakdown are not present; (6) presence of gastrointestinal disease; and (7) diuresis. Riboflavin availability is increased by storage in heart, liver, and kidneys and by the presence of very actively producing intestinal bacteria.

Antagonists of riboflavin include isoriboflavin, lumiflavin, araboflavin, hydroxyethyl analogue, formyl methyl analogue, galactoflavin, and flavin-monosulfate. Synergists include vitamins A, B_1, B_6, and B_{12}, niacin, pantothenic acid, folic acid, biotin, tetraiodothyronine (thyroxine), insulin, and somatotrophin (growth hormone).

Determination of Riboflavin

Bioassay includes observance of the growth rate of rats; microbiological — *L. caseli*, and *L. mesenteroides*. Physicochemical methods include fluorimetry, paper electrophoresis, and polarography.

Unusual features of riboflavin as recorded by some researchers include: (1) High levels in liver inhibit tumor formation by azo compounds in animals; (2) free radicals are formed by light or dehydrogenation: flavine ⇌ semiquinone ⇌ dihydroflavin+; (3) free vitamin is found only in retina, urine, milk, and semen; (4) substitution of adenine by other purines and pyrimidines destroys activity of flavin adenine dinucleotide (FAD); (5) phosphorylation of vitamin in intestines allows absorption as flavin mononucleotide (FMN); (6) blood levels decrease during life in humans: (7) brain content remains constant; (8) available in plants as FMN and FAD; (8) very concentrated in bull semen.

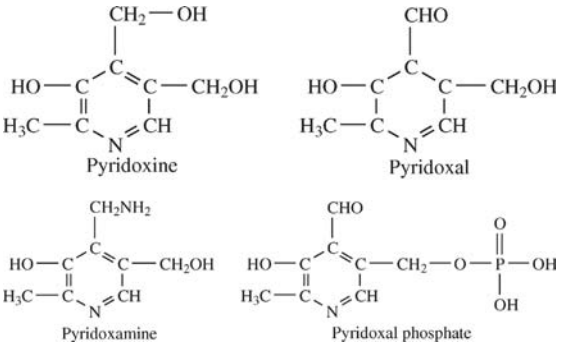
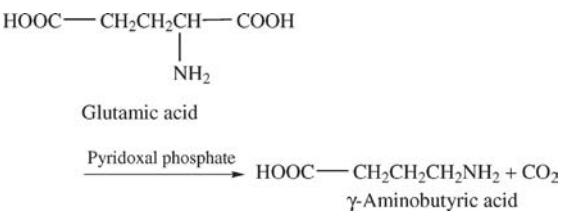
VITAMIN B_6 (Pyridoxine). [CAS: 8059-24-3]. Infrequently called adermine or pyridoxol, this vitamin participates in protein, carbohydrate, and lipid metabolism. The metabolically active form of B_6 is pyridoxal phosphate, the structures of which are:



Pyridoxal phosphate enzymes mediate the nonoxidative decarboxylation of amino acids. This mechanism is of primary importance in bacteria, but it may be essential to proper function of the nervous system in humans by providing a pathway for the synthesis of a nerve impulse inhibitor, γ-amino-butyric acid from glutamic acid:



Pyridoxal phosphate is also a cofactor for transamination reactions. In these reactions, an amino group is transferred from an amino acid to an α-keto acid, thus forming a new amino acid and a new α-keto acid. Transamination reactions are important for the synthesis of amino acids from non-protein metabolites and for the degradation of amino acids for energy production. Since pyridoxal phosphate is intimately involved in amino acid metabolism, the dietary requirement for vitamin B_6 increases as the protein content of the diet increases.

The coenzyme especially participates in gluconeogenesis, production of neural hormones, bile acids, unsaturated fatty acids, and porphyrins.

A deficiency of the vitamin can result in lymphopenia, convulsions, dermatitis, irritability, and nervous disorders in humans. A deficiency in monkeys may cause arteriosclerosis, while in rats, acrodynia. Research indicates that all animals require vitamin B_6. Bacteria in intestines generate some of this vitamin, but relatively little is available to humans in this form. Endogenous sources are available to plants, fungi, and some bacteria.

In 1934, György cured a dermatitis in rats (not due to vitamins B_1 or B_2) with a yeast extract factor. In 1938, Lepkovsky isolated a similar factor from rice bran extract. In that same year, Keresztesy and Stevens isolated and crystallized pure B_6 from rice polishings. Also, in the same year, Kohn, Wendt, and Westphal synthesized pyridoxine and gave pyridoxine its present name. In the following year (1939), Stiller, Keresztesy, and Stevens established the structure of the vitamin. In 1945, Snell observed pyridoxal and pyridoxamine. The recognition of and establishment of B_6 requirements in humans was not achieved until 1953, by Snyderman et al.

In plants, the vitamin is present as pyridoxol-5-phosphate, pyridoxal-5-phosphate, or pyridoxamine-phosphate. In plants, production sites are found in fungi, cereal germ, and seeds.

Commercially, the vitamin is available as a dietary supplement in the compound pyridoxine hydrochloride. The compound can be synthesized by condensing ethoxy acetylacetone with cyanoacetamide (method of Harris and Folkers); or from oxazoles.

Distribution and Sources. Most fruits and vegetables are low in pyridoxine content, although most nuts are quite high. Cereals and a number of other substances have low-to-medium content.

High pyridoxine content (*1,000–10,000 micrograms/100 grams*). Groundnut (peanut), herring, liver (beef, calf, pork), molasses (black strap), rice (brown), salmon, walnut, wheat germ, yeast.

Medium pyridoxine content (*100–1,000 micrograms/100 grams*). Avocado, banana, barley, beef, Brussels sprouts, butter, cabbage, carrot, cauliflower, cod, corn (maize), eggs, flounder, grape, halibut, kale, lamb, mackerel, oats, pea, pear, pork, potato, rye, sardine, soybean, spinach, tomato, tuna, turnip, veal (brain, heart, kidney), whale, wheat, yam.

Low pyridoxine content (*10–100 micrograms/100 grams*). Apple, asparagus, bean, beet greens, cantaloupe, cheese, cherry, currant (red), grapefruit, lemon, lettuce, milk, onion, orange, peach, raisin, strawberry, watermelon.

Bioavailability of Pyridoxine. Factors which tend to decrease bioavailability of pyridoxine include: (1) Administration of isoniazid; (2) loss in cooking (estimated at 30–45%) — vitamin is water-soluble; (3) diuresis and gastrointestinal diseases; (4) irradiation. Availability can be increased by stimulating intestinal bacterial production (very small amount), and storage in liver. The target tissues of B_6 are nervous tissue, liver, lymph nodes, and muscle tissue. Storage is by muscle phosphorylase (skeletal muscle — small amount). It is estimated that 57% of the vitamin ingested per day is excreted. The vitamin exerts only limited toxicity for humans.

Precursors for biosynthesis of the vitamin include glycine, serine, or glycolaldehyde, although further research is required for further confirmation of these substances. Intermediates have not been identified. Antagonists of B_6 include 4-deoxypyridoxine, 4-methoxypyridoxine, toxopyrimidine, penicillamine, semicarbazide, and isoniazid. Synergists include ascorbic acid, biotin, epinephrine, folic acid, glucagon, niacin, norepinephrine, somatotrophin (growth hormone), and vitamins B_1, B_2, and E.

Determination of Vitamin B_6. As pointed out by investigators Gregory and Kirk (Department of Food Science and Human Nutrition, Michigan State University, East Lansing, Michigan), development of an adequate chemical procedure for the determination of biologically active forms of vitamin B_6 in foods has been a complex problem. Basic studies by Bonavita (1960), Toepfer et al. (1961), and Polansky et al. (1964) have demonstrated the feasibility of fluorometric measurement of pyridoxal (PAL), pyridoxamine (PAM), and pyrodixine (PIN) by conversion to PAL and reaction with potassium cyanide, forming the fluorphore 4-pyridoxic acid lactone. Various fluorometric methods have been applied to vitamin B_6 compounds in biological materials (Fujiita et al., 1955; Contractor and Shane, 1968; Loo and Badger, 1969; Takanashi et al., 1970; Fieldlerova and Davidek, 1974; Chin, 1975). The results of Chin suggested that interfering compounds may be present in the PAL fraction after column chromatographic separation of the B_6 analogs by the procedure of Toepfer and Lehmann (1961). In the Gregory-Kirk (1977) study, methods for improving chromatographic separation and fluorometric determination of vitamin B_6 compounds in foods were investigated. Their findings are presented in the reference indicated.

Traditionally, B_6 compounds also have been determined by bioassay, including rat and chicken growth assays.

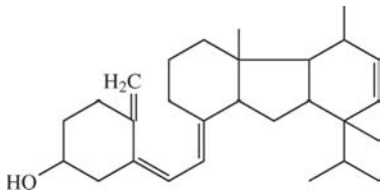
Facts About Vitamin B6: http://www.cc.nih.gov/ccc/supplements/vitb6.html

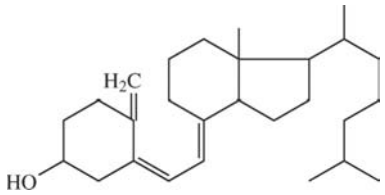
VITAMIN D. [CAS: 50-14-6]. Although the term "Vitamin D" is convenient to use in discussions of nutrition, this singular term is unsatisfactory when used in a strict biochemical context — because there are different substances, each of which is capable of performing vitamin D nutritional functions, namely, that of promoting growth, including bone growth, and preventing rickets in young animals. With reference to generalized terms used over the years in the development and refining of knowledge of related substances, such terms as *antirachitic vitamin, rachitamin, rachiasterol, cholecalciferol, activated 7-dehydrocholesterol*, etc., have been used. As pointed out later, some of these terms remain quite appropriate.

As a brief introductory summary, vitamin D substances perform the following fundamental physiological functions: (1) promote normal growth (via bone growth); (2) enhance calcium and phosphorus absorption from the intestine; (3) serve to prevent rickets; (4) increase tubular phosphorus reabsorption; (5) increase citrate blood levels; (6) maintain and activate alkaline phosphatase in bone; (7) maintain serum calcium and phosphorus levels. A deficiency of D substances may be manifested in the form of rickets, osteomalacia, and hypoparathyroidism. Vitamin D substances are required by vertebrates, who synthesize these substances in the skin when under ultraviolet radiation. Animals requiring exogenous sources include infant vertebrates and deficient adult vertebrates. Included there are vitamin D_2 (calciferol; ergocalciferol) and vitamin D_3 (activated 7-dehydrocholesterol; cholecalciferol).

The most important or at least the best-known members of the family of D vitamins are vitamin D_2 (calciferol), which is indicated in abbreviated form in Structure 1 and can be produced by ultraviolet irradiation of ergosterol, and vitamin D_3 [Structure 2], which may be produced by the irradiation of 7-dehydrocholesterol.



Structure 1. Vitamin D_2.



Structure 2. Vitamin D_3.

Nomenclature. Subscript numerals have a different connotation in connection with vitamin D substances than is true, for example, with B vitamins. Vitamins B_1, B_2, B_6, B_{12}, etc., represent individual substances which have little or no chemical resemblance to each other and perform different metabolic functions. The various vitamin D's, however, have very similar structures, differing only in the side chains, and perform the same functions.

Biochemical Requirements. There are several unique features exhibited by the D vitamins. First, they are not required nutritionally at all if the organism has access to ultraviolet light (which is present in sunlight). Some animals, kept away from ultraviolet light, require so little D vitamins that the need cannot be demonstrated using ordinary diets. Rats, for example, exhibit a need for D vitamins when the calcium/phosphorus ratio in the diet is about 5:1 but not when it is the more usual 1:1. Chickens, on the other hand, exhibit a need even when the calcium/phosphorus ratio is "normal" (1.5:1)

Different species of animals respond distinctively to the different members of the vitamin D family. The most striking example of this is the fact that vitamin D_2 (calciferol) has practically no vitamin D activity for chickens. Rats respond about equally to D_2 and D_3. Human beings respond both to D_2 and D_3. Information as to how various animals react to the other less known forms of vitamin D is largely lacking and for practical reasons is not sought after.

Members of the vitamin D family are extremely difficult to isolate and identify in pure form from any source. Fish liver oils are rich sources, and vitamins D_2 and D_3 have been isolated from them. Most ordinary foods are such poor sources in terms of amounts present, that the presence of D vitamins in them has not been demonstrated. Sterols that can be converted into some form of vitamin D by ultraviolet light are, however, widespread, and it may be inferred that D vitamins are often present even when their presence has never been demonstrated.

The requirements of animals for D vitamins in terms of actual weight are extremely small. It is estimated that human beings need about 400 international units of vitamin D per day. Since an international unit of vitamin D corresponds to 0.025 microgram of crystalline vitamin D, this means that the daily human requirement is about 0.01 milligram. Foods can contain as little as 0.02 parts per million of vitamin D and yet furnish an ample supply on the basis of the foregoing estimate.

Excessive dosages of D vitamins have caused excessive calcification and damage (hypervitaminosis). The full story of vitamin D dosage remains obscure. It has been observed, for example, that some "susceptible" children do not respond to the usual doses, but require 5,000–10,000 units per day to keep them free from rickets. There are other children that are afflicted with "vitamin D-resistant rickets" who do not respond even to these high doses, but may do so when doses of the order of 500,000–1,000,000 units are administered. Although unclear, it would seem that in some individuals the vitamin D has difficulty in getting through to where it is needed.

For many years it has been recognized that all cells need calcium to function because their growth and development is related to changes in their intracellular calcium content. Reasoning further, it has been postulated that calcium may serve as a cellular regulatory agent. Growing interest has been shown by investigators, in a steroid that is derived from vitamin D and that regulates the amount of calcium in the animal's blood. This substance has been referred to as a hormone. It is 1,25-dihydroxyvitamin D_3 and is metabolized from vitamin D. In response to a skeletal need for calcium, the hormone is secreted by the kidney and transported to the intestine and bones. Many authorities believe that parathyroid hormone is involved in signaling the kidney to release $1,25\text{-}(OH)_2D_3$. Hypoparathyroid patients lack parathyroid hormone and fail to make $1,25\text{-}(OH)_2D_3$. The result is an abnormally low concentration of calcium in the blood, producing severe bone disease. DeLuca and associates have used $1,25(OH)_2D_3$ along with calcium to correct deficits in serum calcium concentrations of a limited number of patients. Corticosteroid therapy of long duration is known to produce bone disease. Corticosteroids are frequently administered to persons with rheumatoid arthritis, systemic lupus erythematosis, and asthma, in addition to persons who have received transplants. Some investigators have found that large doses of vitamin D tend to overcome the adverse effects of the corticosteroids. Findings to date essentially are the results of clinical applications rather than based upon a more detailed knowledge of the molecular mechanisms that operate in the metabolism of D vitamins.

Chronology of Vitamin D Substances. In 1918, Mellanby produced experimental rickets in dogs. In 1919, Huldschinsky ameliorated rachitic symptoms in children with ultraviolet radiation. Hess, in 1922, showed that liver oils contain the same antirachitic factor as sunlight. In that same year, McCollum increased calcium deposition in rachitic rats with cod liver oil factor. In 1924, Steenbook and Hess demonstrated irradiated foods have antirachitic properties. It was in 1925 that McCollum named antirachitic factor as vitamin D. In 1931, Angus isolated crystalline vitamin D (calciferol). In 1936, Windaus isolated vitamin D3 (activated 7-dehydrocholesterol).

Rickets. Vitamin D deficiency (also calcium deficiency) produces a condition known in children as *rickets* and in adults as *osteomalacia*. The bones and teeth of children with rickets are poorly formed and soft. A child with rickets frequently has malformed limbs, especially bowlegs. Blood

clotting may be impaired, and, in extreme cases, there may be disturbances of the nervous system. An improvement in the level of calcium in the diet, along with vitamin D or parathyroid extract when required, brings about a hardening of the bones, but leaves them misshapen if deformity has already occurred. Adults, particularly pregnant or nursing women, also require vitamin D because calcium and phosphorus are continually dissolving from bones; and vitamin D is necessary for their utilization. Rickets is not to be confused with the entirely unrelated Rickeetsial group of diseases (Rocky Mountain fever, etc.) that are of virus origin.

Distribution and Sources. Fruits, nuts, and grains are not sources of vitamin D. Animal sources predominate.

High Vitamin D content (*1,000 − 25 × 10⁶ I.U./100 grams*).[1] Liver oils from: Bonito, cod, halibut, herring, lingcod, sablefish, sea bass, soupfin shark, swordfish, tuna.

Medium Vitamin D content (*100–1,000 I.U./100 grams*) Egg yolk, herring, kippers, lard, mackerel, margarine, pilchards, salmon, sardine, shrimp, tuna.

Low Vitamin D content (*10–100 I.U./100 grams*). Beef, butter, cheeses, cod roe, cream, eggs, grain oils, halibut, horse meat, liver (beef, calf, lamb, pork), milk (vitamin D fortified),[2] veal, vegetable oils.

Bioavailability. Factors which tend to cause a decrease in available vitamin D substances include: (1) liver damage; (2) presence of antagonists; (3) presence of phytin in gut; (4) low bile salts in gut; (5) high pH in gut; (6) destruction of intestinal flora; and (7) excretion in feces. Factors that enhance availability include: (1) storage in liver and skin; (2) absorption aids, such as bile salts; (3) decrease in pH of lower intestine; and (4) irradiation by ultraviolet. Antagonists of vitamin D include toxisterol, phytin, phlorizin, cortisone, cortisol, thyrocalcitonin, and parathormone. Synergists include niacin, parathormone (concentration dependent), and somatotrophin (growth hormone).

Dosages exceeding 4000 I.U./day may cause varying degrees of toxicity in humans. Symptoms include anorexia, nausea, thirst, and diarrhea. There also may be polyuria, muscular weakness, and joint pains. Serum calcium increases and calcification of soft tissues (arteries, muscle) may commence. Arterial lesions and kidney injury have been noted in rats.

In the biosynthesis of vitamin D substances, precursors include cholesterol (skin+ultraviolet radiation) in animals; ergosterol (algae, yeast+ultraviolet radiation). Intermediates in the biosynthesis include preergocalciferol, tachysterol, and 7-dehydrocholesterol. Provitamins in very small quantities are generated in the leaves, seeds, and shoots of plants. In animals, the production site is the skin. Target tissues in animals are bone, intestine, kidney, and liver. Storage sites in animals are liver and skin.

Commercial vitamin D dietary supplements are prepared by the irradiation of ergosterol, 7-dehydrocholesterol; or by extraction of fish liver oils.

Unusual features of vitamin D substances noted by some investigators include: (1) vitamin has hormonal qualities due to internal synthesis; (2) vitamin D2 has little activity for chickens — various species differ in response to the vitamin; (3) vitamin D substances may play a role in aging calcification phenomena, especially in skin; (4) the vitamin can mimic rickets with a high-calcium–low-phosphorus diet; (5) the vitamin can mimic osteomalacia under same conditions; (6) the vitamin is absorbed through skin; (7) the vitamin activates transport of heavy metals by intestinal cells; (8) the vitamin has an exceptionally long half-life (days to weeks); (9) furred and feathered animals obtain some vitamin D as the result of grooming and licking; (10) fishes are believed to obtain vitamin D from marine invertebrates; (11) the vitamin has been found useful in the treatment of lead poisoning.

Determination of Vitamin D. Bioassay techniques involve testing rats on antirachitic qualities. An important physicochemical method involves reaction with antimony trichloride.

See also entries on **Calcium**; **Hormone**; **Lipids**; and **Phosphorus**.

[1] One I.U. = 0.025 microgram vitamin D_3.

[2] Milk is normally a poor source of vitamin D. Since mild forms a major part of the diet in many countries, particularly for children, the product is commonly fortified with vitamin D substances.

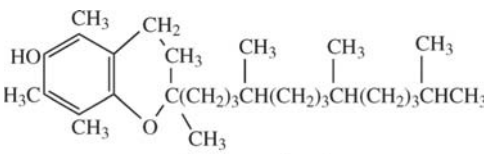
Web Reference

Facts About Vitamin D: http://www.cc.nih.gov/ccc/supplements/vitd.html

VITAMIN E. [CAS: 59-02-9]. Sometimes referred to as the *antisterility vitamin*, factor X (an earlier designation), chemically vitamin E is alpha-tocopherol, the structure of which is:



Alpha-tocopherol

Active analogues and related compounds include: dl-α-Tocopherol; 1-α-tocopherol; esters (succinate, acetate, phosphate), and β, ζ_1, ζ_2-tocopherols. The principal physiological forms are D-a-tocopherol, tocopheronolactone, and their phosphate esters.

The physiological functions of vitamin E substances include: (1) bio logical antioxidant; (2) normal growth maintenance; (3) protects unsaturated fatty acids and membrane structures; (4) aids intestinal absorption of unsaturated fatty acids; (5) maintains normal muscle metabolism; (6) maintains integrity of vascular system and central nervous system; (7) detoxifying agent; and (8) maintains kidney tubules, lungs, genital structures, liver, and red blood cell membranes.

In livestock and laboratory animals, a deficiency of vitamin E substances may cause degeneration of reproductive tissues, muscular dystrophy, encephalomalacia, and liver necrosis. Considerable research is required to fully determine supplementation of livestock diets unless typical symptoms of a deficiency appear. Symptoms have appeared where there are selenium deficiencies in the soil and where there are excessive levels of nitrates in the soil. "White muscle" is the term used to describe a condition of muscular dystrophy in cattle.

In 1922, Evans and Bishop reported dietary factor "X" needed for normal rat reproduction. In that same year, Matill found dietary factor "X" in yeast and lettuce. Evans et al., in 1923, found factor "X" in alfalfa, butterfat, meat, oats, and wheat. The designation *factor "X"* was changed to *vitamin E* by Sure in 1924. In 1936, Evans et al. demonstrated that vitamin E belongs to the tocopherol family of compounds. During that year, these researchers isolated several active tocopherols and found a-tocopherol to be the most active of the number. Fernholz, in 1938, determined the structure of vitamin E. It was first synthesized by Karrer during that same year. During the interim between 1938 and 1956, several tocopherols were identified and studied. It was in 1956 that Green observed the eighth in the family of tocopherols.

The tocopherols were identified as naturally occurring oily substances and the first three were characterized as alpha, beta, and gamma forms, the biological activity of which decreased in that order.

Vitamin E substances are necessary for the normal growth of animals. Without vitamin E, the animals develop infertility, abnormalities of the central nervous system, and myopathies involving both skeletal and cardiac muscle. The antioxidant activity of the tocopherols is in reverse order to that of their vitamin activity. Muscular tissue taken from a deficient animal has an increased rate of oxygen utilization. The tocopherols are so widely distributed in natural foods that a spontaneous deficiency is infrequent unless diseases of the gastrointestinal or biliary system hinder absorption. Symptoms indicating a vitamin E deficiency include: (1) Red blood cell hemolysis, creatinuria, xanthomatosis and cirrhosis of gall bladder, steatorrhea (in young), cystic fibrosis of pancreases (in young), poorly developed muscles. Rats, dogs, monkeys, and chickens display muscular dystrophy; myocardial degeneration is observed in dogs and rabbits; resorption of fetus, degeneration of germ epithelium, disturbance of estrus cycle are observed in rats; hepatic necrosis is shown in rats; encephalomalacia and vascular degeneration is manifested in chickens.

Role of Vitamin E in Humans. The fundamental needs for vitamin E in humans have long been established. There are factors associated with this vitamin, however, that have created controversy and disagreement among highly qualified professional people. Although nearly every vitamin, at one time or other, has been used unwisely (in retrospect) in the treatment of human diseases, perhaps no other vitamin substance has aroused more discussion among clinicians than vitamin E. Because deficient animals develop a form of myopathy, it was natural to test the therapeutic efficacy of vitamin E in various forms of progressive muscular dystrophy and in diseases of the reproductive system. Enthusiastic claims have been made, and refuted, by investigators. From the standpoint of solid evidence, as of the early 1980s, the principal advantage of administering vitamin E lies exclusively in those instances where a vitamin E malabsorption syndrome exists. Associated with this fundamental situation are hemolytic anemia of premature infants; diseases caused by poor fat and oil absorption, and intermittent claudication (limping). A 1979 Institute of Food Technologists "Food Safety and Nutrition Panel" reported no incidence of vitamin E deficiency. Three underlying reasons were cited for this: (1) ample storage in adipose tissue; (2) slow elimination from the body; and (3) prevalence in foods. Significant amounts are present in vegetable oils and margarine (70% of the average daily intake), cereal products, fish, meat, eggs, dairy products, and leafy green vegetables.

Cure-all claims for the vitamin appear to stem from the vitamin's antioxidant properties and subsequent ability to neutralize harmful free radical products of oxidation. This had led to vitamin E administration for diseases of the circulatory, reproductive, and nervous systems, increased athletic and sexual endurance, and protection against aging and air pollution effects. Although some claims have been verified by animal studies, evidence is not conclusive for humans. Elderly individuals have resorted to vitamin E in hopes of slowing the aging process. The idea is not unfounded, for in the laboratory, the nutrient neutralizes radicals normally contributing to aging pigment formation. Neutralization within humans, however, remains unproven.

Distribution and Sources. Oily substances are, by far, the best natural sources of vitamin E.

High vitamin E content (*50–300 milligrams/100 grams*). Corn (maize) oil, cottonseed oil, margarine, safflower oil, soybean oil, wheat germ oil.

Medium vitamin E content (*5–50 milligrams/100 grams*). Alfalfa, apple seeds, asparagus, barley, cabbage, chocolate, coconut oil, groundnut (peanut), groundnut (peanut) oil, olive oil, rose hips, soybean (dry), spinach, wheat germ, yeast.

Low vitamin E content (*0.5–5 milligrams/100 grams*). Apple, bacon, bean (dry navy), beef, beef liver, blackberry, Brussels sprouts, butter, carrot, cauliflower, cheeses, coconut, corn (maize), corn (maize) meal, eggs, flour (whole wheat), kale, kohlrabi, lamb, lettuce, mustard, oats, oatmeal, olive, parsnip, pea, pear, pepper (sweet), pork, rice (brown), rye, sweet potato, turnip greens, veal, wheat.

Production sites for vitamin E biosynthesis occur in nuts, seeds, cereal germ, green leaves, legumes. Biosynthesis also occurs in some microorganisms. Precursors for biosynthesis include mevalonic acid and phenylalanine (probably these compounds with side chains). Considerably more research is required to pinpoint the exact precursors. Tocotrienol occurs as an intermediate in the biosynthesis.

Commercial production of vitamin E tocopherols is by way of molecular distillation from vegetable oils.

Antagonists of the tocopherols include α-tocopherol quinone, oxidants, cod liver oil, and thyroxine. Synergists include ascorbic acid, estradiol, somatotrophin (growth hormone), testosterone, and vitamins A, B_6, B_{12}, and K.

Bioavailability of Vitamin E. Factors which tend to reduce availability of the vitamin include: (1) presence of antagonists; (2) mineral oil ingestion; (3) presence of vitamin E oxidation products; (4) occurrence with other less active analogues; (5) excessive excretion in feces; (6) impaired fat absorption; (7) chemical binding in foods; (8) cooking losses (vitamin is heat and oxygen labile); (9) losses in frozen storage, steatorrhea, and variability of natural sources. Factors which may increase absorption include: (1) Storage of vitamin in adipose and muscle tissues; (2) esterification, which increases stability; (3) use of unprocessed fresh food sources; and (4) absorption aids, such as bile salts.

Storage sites for the tocopherols in the body include muscle and adipose tissues and the liver. Target tissues include the adrenals, pituitary, kidney, genital organs, muscles, liver, lungs, and bone marrow.

Unusual features of vitamin E substances as observed by various investigators include: (1) the vitamin may be involved in aging mechanisms by protecting unsaturated fatty acids and membranes against free radicals; (2) only D-isomers occur naturally; (3) vitamin E is replaceable by selenium salts in therapy of rat and pig liver necrosis, and chick exudative diathesis; (4) vitamin E is replaceable by coenzyme Q (see also **Coenzymes**) and antioxidants for certain symptoms of vitamin E deficiency, but not for all, e.g., red blood cell hemolysis, resorption gestation not affected; (5) species differences in response to vitamin E treatment of similar symptoms, e.g., muscular dystrophy — positive in rabbits, negative in humans; (6) other tocopherols are only slightly active as compared with vitamin E; (7) vitamin content is decreased in tumors.

Alpha-Tocopherol and Nitrosamine Formation. Because of the growing concern, commencing in the late 1970s, as regards the formation of *N*-nitrosamines, such as dimethylnitrosamine and *N*-nitrosopyrrolidine, upon cooking of certain meat products cured with sodium nitrite, a number of investigators began studies to find materials that may inhibit nitrosamine formation. Reporting in late 1978, W.J. Mergens and a team of investigators (Hoffmann–LaRoche Inc., Nutley, New Jersey) observed that *N*-nitrosopyrrolidine has been found in fried bacon, but not in raw bacon (Fazio et al., 1973 Fiddler et al., 1974), apparently because of the influence of heat in accelerating the reaction of nitrite with the amine group of proline or its decarboxylated product, pyrrolidine, formed in frying (Archer et al., 1976 Hwang and Rosen, 1976). The effect of ascorbic acid in inhibiting nitrosamine formation has been demonstrated by various workers both in vitro and in vivo (Mirvish et al., 1972, 1973; Kamm et al., 1973, 1975; Greenblatt, 1973 Ivankovic et al., 1973).

The promising contribution of adding tocopherol to bacon, along with sodium ascorbate, to inhibit nitrosamine formation undertaken by Mergens and associates is reported in detail in the Mergens et al. reference (1978).

Determination of Vitamin E. Bioassay methods include measurements of quantity required to prevent fetal resorption; and for red blood cell hemolysis (in rat). Measurements also are made of liver storage in the chick. Physicochemical methods used include colorimetric two-dimensional paper chromatography.

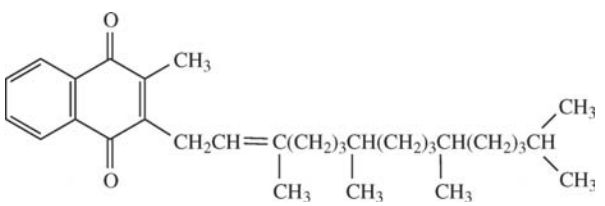
Facts About Vitamin E: http://www.cc.nih.gov/ccc/supplements/vite.html

VITAMIN K. [CAS: 12001-79-5]. Sometimes referred to as the *anti-hemmorhagic vitamin*, and, earlier in its development, the prothrombin factor or Koagulations-vitamin, vitamin K is a substituted derivative of naphthoquinone and occurs in several forms. The designation *phylloquinone*, or K_1, refers to 2-methyl-3-phytyl-1,4 naphthoquinone; the designations *farnoquinone* and *prenylmenaquinone*, or K_2, refer to 2-difarnesyl-3-methyl-1,4-naphthoquinone. *Menadione*, sometimes called oil-soluble vitamin K3, is 2-methyl-1,4-naphthoquinone. The structure of phylloquinone is:



Generally, when vitamin K substances are absent or deficient in the diet of animals, including humans, a hemorrhagic disorder will appear. Young fowls that are allowed to continue on a deficient diet for extended periods will ultimately die of internal hemorrhage, or from extensive bleeding from small external wounds. Fowls experience difficulty in absorbing vitamin K from the intestine, whereas humans, rats, and dogs absorb it readily and normally obtain their requirement form intestinal bacteria without need of dietary supplementation. If, however, bacterial synthesis is inhibited by the use of sulfa drugs or certain antibiotics, the disease will develop, unless the diet is supplemented with some form of vitamin K. When there is a decrease in the amount of bile salts in the intestine, as in obstructive jaundice, vitamin K is absorbed in such small amounts that the disease will also ensue. The use of vitamin K also is suggested to control and prevent the disease in premature babies. Vitamin K_1 is also able to reverse the hemorrhagic condition resulting from the administration of dicumarol to animals.

It has been reported that vitamin K_1 and several of the vitamin K_2 homologues are capable of restoring electron transport in solvent-extracted or irradiated bacterial and mitochondrial preparations. Other reports suggest that vitamin K is concerned with the phosphorylation reactions accompanying oxidative phosphorylation. The capacity of these compounds to exist in several forms, e.g., quinone, quinol, chromanol, etc., appears to strengthen the proposal that links them to oxidative phosphorylation. Information has suggested that vitamin K acts to induce prothrombin synthesis. Since prothrombin has been shown to be synthesized only by liver parenchymal cells in the dog, it would appear that the proposed role for vitamin K is not specific for only prothrombin synthesis, but applicable to other proteins.

In 1929, Dam reported chicks on a synthetic diet develop hemorrhagic conditions. In 1935, Dam named vitamin K as the missing factor in synthetic diets. In that same year, Almquist and Stokstad demonstrated the presence of vitamin K in fish meal and alfalfa. In 1939, Dam and Karrer isolated vitamin K from alfalfa; and, in that same year, Doisy isolated K_1 from alfalfa, K_2 from fish meal, and demonstrated differences of the two substances. Also, in 1939, MacCorquodale, Cheney, and Fieser determined the structure of vitamin K_1. In that same year, Almquist and Klose synthesized vitamin K_1 for the first time. In 1941, Link et al. discovered dicoumarol, an anticoagulant and antagonist of vitamin K.

In addition to compounds previously mentioned, active analogues and related compounds include menadiol diphosphate, menadione bisulfite, phthicol, synkayvite, menadiol (vitamin K_4), and compounds designated as vitamins K_5, K_6, and K_7.

Many species require vitamin K. The vitamin is frequently administered to poultry via feedstuffs. Intestinal bacteria, normally functioning, supply the vitamin to the human body.

In the therapy of deep venous thrombosis, heparin is commonly administered. This drug takes effect immediately to prevent further thrombus formation. However, heparin is regarded as a hazardous drug and possibly may be the leading cause of drug-related deaths in hospitalized patients who are relatively well. Usually administered intravenously, preferably by pump-driven infusion at a constant rate rather than by intermittent injections, it sometimes may cause major bleeding, which is particularly hazardous if it is intracranial. The action of heparin can be terminated almost immediately by intravenous injection of protamine sulfate, but where there may be less urgency, vitamin K_1 may be used. The vitamin preparation may be administered intravenously, intramuscularly, or subcutaneously.

Vitamin K is also an antagonist of warfarin, which is sometimes used in rodenticides. Pets that have been exposed to warfarin-containing poisons may be saved from death by internal hemorrhaging through the immediate administration of vitamin K.

Vitamin K is sometimes used in the treatment of viral hepatitis.

It has been found that vitamin K analogues possess an ability to insert themselves into the oxygen-binding cleft of hemoglobin. This may result in hemolysis (dissolution of red blood corpuscles with liberation of their hemoglobin).

See also **Anticoagulants**.

Distribution and Sources. Some fruits, vegetables, and nuts, as well as meat products, contain good sources of K vitamins. Intestinal bacteria, M. phlei, synthesize it.

High vitamin K content (*100–300 micrograms/100 grams*). Beef kidney, beef liver, cabbage, cauliflower, pork, soybean, spinach.

Medium vitamin K content (*10–100 micrograms/100 grams*). Alfalfa, egg yolk, pine needles, potato, strawberry, tomato, wheat (bran, germ, whole).

Low vitamin K content (*0–10 micrograms/100 grams*). Carrot, corn (maize), milk, mushroom, parsley, pea.

Commercial production of vitamin K is by column chromatography of fish meal extracts. In biosynthesis, precursors include polyacetic acid (ring); acetate (side chain). Intermediates include dehydroquinic acid (ring); farnesol (side chain).

Bioavailability of Vitamin K. Factors which decrease availability of the vitamin include: (1) biliary obstruction; (2) liver damage—cirrhosis, toxins; (3) poor food preparation (vitamin is strong-acid, alkali, light, and reduction labile); (4) impaired lipid absorption in gut; (5) presence of antagonists; (6) ingestion of mineral oil; (7) sterilization of gut with antibiotics and sulfa drugs; and (8) excessive excretion in feces. Availability may be increased by way of storage in the liver and absorption aids, such as bile salts.

Antagonists of vitamin K substances include dicoumarol, sulfonamides, antibiotics, α-tocopherol quinone, dihydroxystearic acid glycide, salicylates, iodinin, warfarin. Synergists include ascorbic acid, somatotrophin (growth hormone), and vitamins A and E.

General symptoms of a vitamin K deficiency include hypoprothrombinemia, increased bleeding and hemorrhage, increased clotting time, and neonatal hemorrhage. Internal hemorrhage is a symptom in chicks. Usually the vitamin is nontoxic, but, in humans, very excessive dosages can cause thrombosis, vomiting, and porphyrinuria. Target tissues are liver and vascular system. Small quantities are stored in liver.

Determination of Vitamin K. A vitamin K deficient chick assay may be made; or physicochemical techniques, including polarographic methods, spectrophotometry of pure solutions, and prothrombin time determinations, may be used.

VITREOUS DETACHMENT. Vitreous detachment, often called posterior vitreous detachment, occurs when the vitreous humor, the gel that fills the inside of the eye behind the lens, shifts and separates from the retina. This shift is often harmless, although it does produce visible symptoms.

One is the appearance of floaters, particles floating in the vitreous humor that appear to be circular spots or small spots strung together with a weblike thread. Floaters are most noticeable in bright light or when looking at distant objects. These floaters occur because of the formation of opaque spots in the vitreous. They sometimes disappear in weeks, but can persist for much longer periods, months or years.

Vitreous detachment can also result in flashes; quick bursts of light caused when the vitreous rubs against the retina. These generally are short-lived.

If the floaters increase in number or the flashing becomes continuous, an immediate visit to an ophthalmologist is recommended because these can be symptoms of a retinal detachment or other problem resulting from the shift of the vitreous. Left untreated, a retinal detachment can lead to permanent loss of vision.

A major warning sign of a possible retinal detachment is that the flashers and floaters occur in just one eye. (Flashers in both eyes are unusual, and generally are caused by migraine headaches.) Floaters in one eye can also be symptoms of a hemorrhage in the eye or an infection, which also require quick treatment. Other warning signs include blurred or distorted vision, the appearance of cobwebs or veils, and the feeling that a curtain is descending over the visual field.

Persons who are at higher risk of retinal detachment caused by a vitreous detachment include those who are nearsighted because myopia is associated with a thinner-than-normal retina, those who have undergone eye surgery such as a cataract operation, and those with eye inflammation (uveitis) or a previous eye injury. The occurrence of vitreous detachment in one eye indicates an increased risk for the same detachment to occur in the other eye.

Fortunately, most people who experience vitreous detachment will not require medical care. If the floaters are persistent or very bothersome, the only treatment available is vitrectomy surgery during which the vitreous gel is surgically removed and replaced with a saline solution. Although the risks associated with vitrectomy surgery are relatively small, they usually outweigh the benefits as a treatment for floaters. See also **Floaters**; **Retinal Detachment**; and **Uveitis**.

VITREOUS STATE. When certain liquids are cooled fairly rapidly, crystals do not form at a definite temperature, but the viscosity of the liquid increases steadily until a glassy substance is obtained. A glass may be thought of as a disordered amorphous solid, or as a supercooled liquid, which only devitrifies into the crystalline state after extremely long standing. Glasses are optically isotropic, which explains their value in optical instruments. The property of forming a glass is possessed particularly by the oxides of silicon, boron, germanium, arsenic, phosphorus, etc., and by many organic compounds, especially those containing several hydroxyl groups per molecule. See Fig. 1.

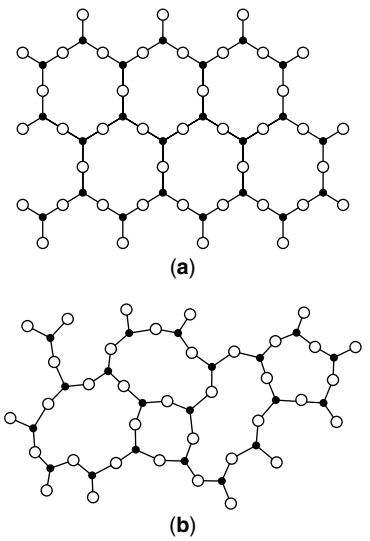

Fig. 1. Two-dimensional diagram showing (**a**) an oxide of composition X_2O_3 in the crystalline form; and (**b**) the same oxide in the vitreous state.

VITROPHYRE. A volcanic glass carrying sporadic distinct crystals of feldspar and other minerals; in short, a porphyritic glass.

VIVERRINES *(Mammalia, Carnivora).* A family of carnivores, sometimes referred to as the civet family. The general organization of the viverrines is indicated in the Table 1. Civets are closely related to the hyenas and the cats. They have relatively coarse hair and, in some species, an erectile mane. The teeth are hyena-like, but the claws and tail are cat-like. Civets range from 2 to 3 feet (0.6 to 0.9 meter) in length and possess black and white stripes and spots. They are found in the more tropical parts of the Old World, particularly in Africa and Malaya. They are not found in the Australian region. Dietary items include birds' eggs, smaller mammals, snakes, and lizards. They are known to devour large quantities of crocodile eggs along the Nile and hence are considered of economic value. They possess an odorous and fatty substance in a pouch connected with the sexual organs. The material can be used for compounding perfumes when properly treated. This material is known as *civet* when purified. The so-called civet-cat in the Americas is not a true civet, but is related to the raccoons. The *rasse* is a civet of the Oriental region. *Genets* have more slender bodies and shorter legs than the civets, but are closely related. Several species are found in Africa, Asia, and Europe. *Linsangs*, also closely

TABLE 1. GENERAL ORGANIZATION OF THE VIVERRINES

Civets (*Viverrinae*)	Galidines (*Galidiinae*)
True Civets (*Viverra* and *Civettictis*)	FOSSAS (*Cryptoproctinae*)
Rasse (*Viverricula*)	
Genets (*Genetta*)	MONGOOSES (*Herpestinae*)
African Linsang (*Poiana*)	
Linsangs (*Prionodon*. . . .)	True Mongooses (*Herpestes*)
Water-Civet (*Osbornictis*)	Banded Mongoose (*Mungos*)
Palm-Civets (*Paradoxurinae*)	Dwarf Mongooses (*Helogale*)

HEMIGALES (*Hemigalinae*)	
Hemigales (*Hemigale*, . . .)	
Otter-Civet (*Cynogale*)	
Fanaloka (*Fossa*)	
Anteater-Civet (*Eupleres*)	

related to civets, are slender predacious animals with short legs and very long tails. They occur in the Oriental region and to a lesser extent in Africa.

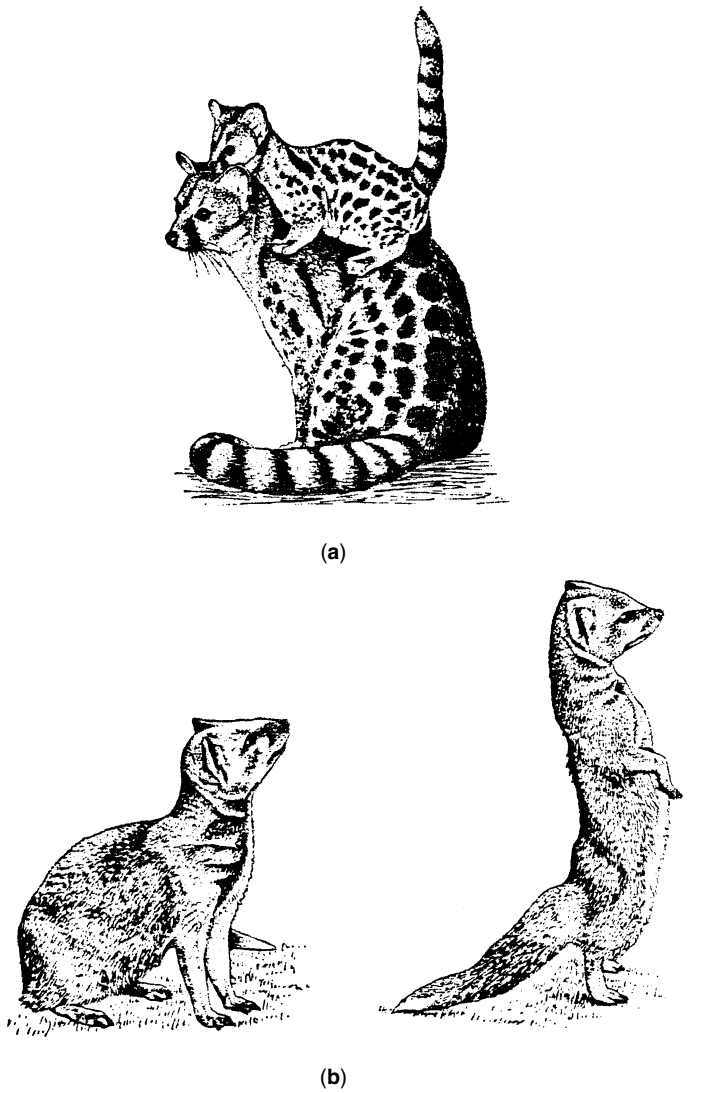
The *mongoose* is a slender animal with short legs and long tail, related to the civets, but it possesses no scent glands. These animals live in Africa and the Oriental region and have been introduced successfully into the West Indies and other regions. Mongooses kill many small animals and are valuable for destroying rats and other vermin, but they will also attack useful animals when the supply of vermin is low. Mongooses are particularly noted for their ability to kill snakes. The Indian mongoose (*Herpestes mungo*) is readily tamed and is frequently kept to free a household of undesirable pests. The Egyptian mongoose (*H. ichneumon*) is also called the *ichneumon*.

The *meerkat* is a South African animal of the civet family, related to the mongooses. The name is sometimes applied to the penciled mongoose. The *suricate* is an animal of southern Africa (*Suricata tetradactyla*) related to the mongooses and a part of the civet family. The suricate is of moderate size, gray with transverse dark bands on the back and a whitish crown, and has rather short legs. The animal can make an interesting pet. This species shares the name *meerkat* with one of the mongooses.

See Fig. 1.

VIVIANITE. The mineral vivianite is a hydrous iron phosphate, $Fe_3(PO_4)_2 \cdot 8H_2O$, its monoclinic crystals are usually prismatic or blade-like but may be in massive forms. Vivianite has one perfect cleavage; hardness 1.5–2; specific gravity 2.58–2.68; luster, pearly on cleavage; faces, otherwise vitreous; colorless, when freshly exposed, but becoming blue or brownish with the alteration of the ferrous to ferric iron; transparent to translucent. Vivianite is an associate of pyrrhotite, pyrite and copper and tin ores. It is found also in clay beds forming the so-called blue iron earth which is common and of wide distribution in peat bogs. Vivianite is found in Rumania; Bavaria; Cornwall in England; and elsewhere in Europe; Australia; Bolivia; and Greenland. In the United States it occurs in New Jersey, Delaware, and Colorado. This mineral was named by Werner in 1817 after the English mineralogist J.G. Vivian, who first discovered crystals of the mineral in Cornwall, UK.

VIVIPAROUS REPRODUCTION. The production of live offspring following a period of internal nourishment from the mother by means of a placenta. Only the mammals have this type of reproduction, although a few simple mammals, such as the marsupials and the prototheria still produce eggs with coverings, so that the embryo forms no connection with the mother before birth.



(**a**)

(**b**)

Fig. 1. Examples of viverrines: (**a**) Young genet about to invite its mother to play suddenly reacts to a suspicious noise; (**b**) yellow mongoose (left) in sitting position; (right) in standing guard position.

VIVIPAROUS TOPMINNOWS *(Osteichthyes)*. Of the order *Microcyprini*, family *Poeciliidae*, probably the most famous of this family of beautiful, streamlined little fishes is the "guppy," named for its discoverer, R.J.L. Guppy, who first noted the fish in 1866 in streams on the island of Trinidad. The *Lebistes reticulatus* remains a favorite of tropical-fish hobbyists, and literally millions have found their way to home fish tanks. The guppy, of course, is well known for the live bearing of its young. Fully grown females reach 2–21/2 inches (5–6.4 centimeters) in length; the males are considerably shorter. The natural habitat of the guppy is the southern Caribbean extending as far south as southern Brazil.

There are some 45 genera in the topminnow family, and their natural range is quite wide, but all in the western hemisphere. In addition to the guppy, of course, numerous other species are found in small aquariums. For example, the *Gambusia affins* (mosquito fish) was well known by aquarists prior to the discovery of the guppy. It is somewhat larger, ranging up to 3 inches (7.5 centimeters) in length. This fish is welcome in the tropics because of its ability to destroy mosquito larvae and pupae. The dwarf mosquito fish (*Heterandria formosa*) reaches only about 1 inch (2.5 centimeters) in length and inhabits the waters from North Carolina to Florida. Another very popular fish with hobbyists is *Mollienesia latipinna* (mollies). This species attains a length of about 4 inches and ranges from South Carolina to Mexico. Through selective breeding, all black mollies have been produced. Other popular varieties include the "platys" and "swordtails." These varieties are of the genus *Xiphophorus*.

Topminnows have been used extensively in medical research, notably in genetic investigations.

VODKA. A colorless, essentially tasteless and odorless, highly rectified alcoholic beverage that until after World War II was essentially limited in its production and distribution to the Slavic nations (Russia, Poland, etc.) of eastern Europe and to a few mideastern countries (Iran, Turkey). Vodka has been made and consumed in these countries for hundreds of years. In the western countries, the drink probably most reminiscent of vodka is a high-quality gin. In the late 1940s and early 1950s, vodka was introduced (on a commercially sponsored scale) to several of the western countries, including western Europe, the United Kingdom, and the United States, and received wide and early acclaim. It was no longer regarded as a curiosity in these countries. As of the early 1980s, vodka is rapidly crowding into second place in American alcoholic beverage consumption, with Bourbon whiskeys and blends still maintaining an impressive lead. Generally, traditionalists in the field of alcoholic beverage production and distribution were taken by surprise at the rapid spread of vodka's acceptance and, during the interim, have offered a number of explanations. Surprise was registered particularly because vodka is such a neutral and "bland" beverage, with no real character other than its "lack of character" so to speak. However, some authorities believe that it was this very lack of character that made it a superior substitute for gin in numerous cocktail recipes, particularly in the United States where cocktails are very popular. Some authorities also believe that vodka, because of its lack of a characteristic whiskey, gin, or wine taste, may have increased overall liquor consumption because of the objections of some consumers to characteristic tastes and aromas. For a while, it appeared that vodka was probably a fad, but this has long since been disproved. For example, vodka has been accepted in Scotland, where native whiskies had been essentially regarded as the only strong alcoholic beverage to consider.

Traditionally, vodka has been prepared from a variety of starch-or sugar-containing raw materials (grains, molasses, grapes, potatoes, etc.). In the eastern European countries, a source that was in surplus was usually selected at any given time for making vodka. Up to and including the fermenting process, vodka is essentially prepared like whiskies and gins. It is the rectification that is different. The vodka distiller uses a series of columnar fractionators to produce an effluent of approximately 190° proof that is essentially neutral — a very strong ethanol-water solution. To remove any substances that would add to flavor or aroma, the distillate is then usually filtered through activated charcoal. In contrast with gin, no artificial or natural flavorings or colorings are added to vodka. In the United States, vodka is sold as 80° and 100° proof.

Although most usually mixed with water (or in cocktails), the eastern Europeans frequently prefer drinking vodka *straight* (without water). Vodka also is available, mainly in Europe, with some flavoring and sweetening.

VOICE AND SOUND PRODUCTION. The incidental production of sound waves in air or similar vibrations in the water by the movements of living things is so common that a sense of hearing serves animals as a valuable means of detecting the presence of enemies, prey, or members of their own species. Together with this sense, the ability to produce sound voluntarily serves many uses, as we know from our own experience. In some cases the act involves only the special use of common organs, as when the beaver slaps the water with his broad tail in a warning signal. Sound production immediately brings to mind, however, organs such as the human larynx with its great range of activity and other organs specially developed for sound production.

Among the vertebrates, the production of sound is very commonly associated with the respiratory system, since the air-breathing forms have an opportunity to vibrate special structures by controlled currents of air expelled from the lungs. In the birds the apparatus is the syrinx, located at the inner end of the trachea, and, in mammals, it is the larynx, near the outer end of the same passage. The frog also has a larynx with vocal cords in its very short trachea. Vocal cords are lacking in the reptiles, although some of these animals produce sound by the expulsion of air from the respiratory system, as in the hissing of snakes and the so-called bellow of the alligator. Whispering of human beings is in the same category. Some fishes produce sound by means of the swim bladder. A noteworthy example is the croaker (*Micropogon undulatus* Linn.) of the eastern and southern coastal waters of the United States.

Of all vertebrates, the mammals and birds are most generally equipped with elaborate vocal organs; hence, the syrinx and larynx of these classes claim special attention. The two organs are quite different in origin and structure.

The syrinx is a chamber located at the junction of the trachea and the two major bronchi. It is supported by modified cartilages and contains a projecting flexible membrane, which is thrown into vibration by the expulsion of air from the lungs. Muscular control of the tension of this membrane permits the bird to control the pitch of the sounds produced, which vary from comparatively simple calls to elaborate songs. Some birds are able to mimic sounds very faithfully, hence modulation of the sounds produced by the syrinx is involved, as in the case of human speech. The mocking bird (*Mimus polyglottos*) affords an excellent example of mimicry of the songs of other species, while parrots and mynas extend their virtuosity to mimicry of human speech. The mynas, especially, enunciate words with amazing delicacy of inflection.

The larynx is essentially a chamber at the pharyngeal end of the trachea, supported by modified cartilages and in most species of mammals containing vocal folds, or cords, whose tension is regulated by muscles acting on the laryngeal wall. The human larynx is among the most highly developed organs of the kind. See Fig. 1. A slit-like opening, the glottis, leads into it from the pharynx. This opening is flanked by lobes of the cricoid cartilage and by ligamentous folds, the vocal cords, imbedded in the mucous lining. The larynx is further supported by large right and left quadrangular plates of the thyroid cartilage whose ventral junction forms the "Adam's apple." A flap-like epiglottis closes down over the glottis during the act of swallowing. During ordinary breathing the glottis is V-shaped, becoming more rounded in deep inspiration. When high tones are produced, the tension of the vocal cords closely approximates them and narrows the opening to a mere slit. Although the production of sound by this organ is due simply to the vibration of the cords by the properly controlled ejection of air, sound may be produced, in whispering, without the vibration of the cords. In either case, an important modulating effect is produced by the mouth and tongue. The oral, nasal and pharyngeal cavities also act as resonators. Individual differences in the pitch of the human voice depend on the length, thickness and elasticity of the cords. In any one individual, pitch is varied by changing the tension of the cords.

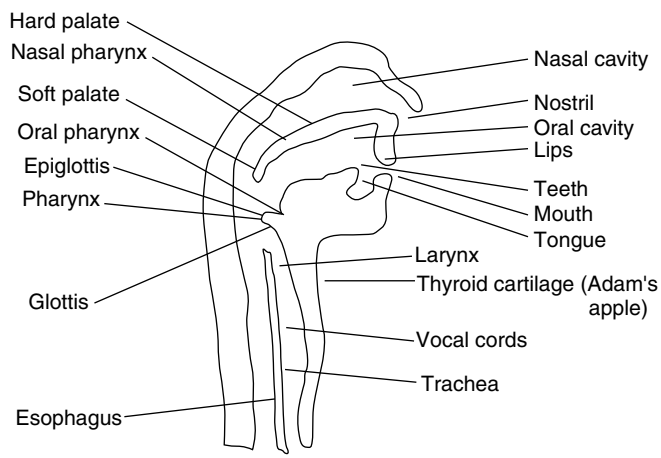


Fig. 1. The human vocal tract is basically an acoustic tube with the lips at one end and the vocal cords at the other. During speech production, the shape of the tract changes continuously, due to movements of the tongue, jaw, and lips. Vocal tract models suitable for speech coding have been under study for several years. (*AT&T Bell Laboratories*.)

Much research in recent years has been directed toward thoroughly understanding how the human vocal system functions, not simply in terms of generalities which are relatively well understood, but in terms of specific parameters, so that computer models can be constructed and manipulated. See Fig. 2. Such research will one day become important in terms of human communication between computers and machines, but an even

more practical and immediate priority is finding efficient and realistically acceptable ways of digitizing human speech for distant transmission and, in turn, converting the received signals into voice sounds. Very important is the rate at which such signals can be transmitted, a factor in determining cost and offering numerous other advantages.

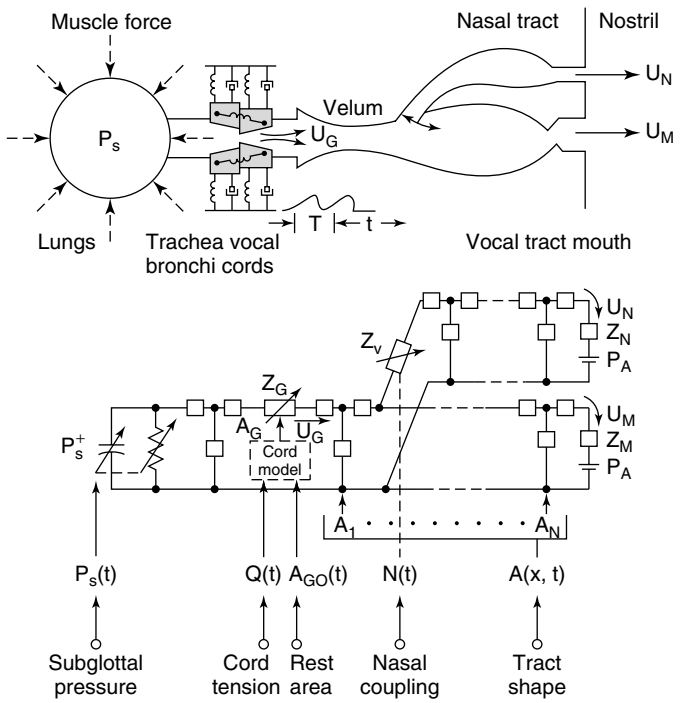

Fig. 2. Speech synthesizer based upon computer models for vocal cord vibration, sound propagation in a yielding-wall tube, and turbulent flow generation at places of constriction. The control inputs are analogous to the human physiology and represent subglottal air pressure in the lungs (P_s); vocal-cord tension (Q) and area of opening at rest (A_{g0}); the cross-sectional shape of the vocal tract, [$A(x)$]; and the area of coupling to the nasal tract (N). (*AT&T Bell Laboratories*.)

Supplementary resonating structures occur in some mammals, such as the enormously dilated hyoid bone and cavernous diverticula of the larynx in the howler monkeys (*Alouata* sp.). In the bats the voice and the highly developed ears serve to detect obstacles in flight by the reflection of sounds.

Among the insects sound production is highly specialized. Here it is of the type called stridulation. The apparatus varies from a comparatively simple roughening of apposed surfaces, which produce vibrations when rubbed together, to the elaborate organs of the male cicada. A common example of the simple form is found in the milkweek beetles (*Tetraopes*). By moving the prohorax up and down, its ventral sclerite is rubbed against the mesosternum, producing a squeaking sound audible to the human ear at very short distances. A more elaborate stridulation occurs in the order *Orthoptera*, exemplified by the crickets, katydids and grasshoppers. The crickets have parts called scrapers and files developed on the basal portion of the wings. When rubbed together they throw the entire wing membrane into vibration, producing the shrill singing so familiar to everyone. The short-horned grasshoppers set the wings into vibration by means of a row of fine projections on the inner surface of the hind legs.

The sound-producing organs of the male cicada consist of a pair of deep depressions at the base of the abdomen, covered with thin plates. Within the cavities are membranes that are thrown into vibration by direct muscular action, thus producing sound, and others which serve as resonators. Although the sound produced by cicadas of different species varies greatly in volume and quality, probably no insects exceed in volume or incisiveness the shrill vibrant singing of some of the common cicadas of the United States.

Auditory organs occur in many insects with special stridulating organs, but in others, such as some members of the order *Diptera*, their presence suggests that the rapid movement of the wings in flight produces the sound that the insect hears, thus providing for recognition within the species. Certainly the wing beat may have such an effect, since it is quite evident to us in the humming of mosquitoes and midges.

Voice and Speech Coding

Researchers have and are continuing to explore efficient digital speech coding algorithms to create natural-sounding voice signals at low bit rates. The traditional high quality of voice transmission will continue to be maintained in a majority of telephone networks, but the methods of encoding used most likely will change within the relatively near future. Instead of transmitting the acoustic voice signal in the conventional manner at 64,000 bits per second, the target is to deliver a more efficiently digitized telephone voice signal using as low a bit rate as possible, while the speech the listener hears is comparable in quality to speech produced by high-bit-rate coding. Speech coding at low bit rates most likely will play an important part in providing future capabilities for telephone communication systems, including voice encryption, transmitting voice mail over telephone networks, and flexible management of voice and data over packet networks.

Various Speech Coding Methods[1]. The conventional method of digital encoding, known as pulse code modulation (PCM) and first standardized in the 1960s, uses *waveform coding*. Limited to a bandwidth of 4 kHz, the analog voice signal is sampled 8000 times a second, and each sample is converted into an 8-bit digital code. The resulting bit rate is 64 kilobits per second.

Introduced at a later date was a waveform coding technique, known as Adaptive Differential Pulse Code Modulation (ADPCM), used for encoding toll-quality speech at 32 kilobits per second. A new concept, now under intense investigation, is based on *source coding* concepts. This approach generates the digitized voice signal by analyzing how human speech is produced and how the ears perceive the synthesized version. Coding and decoding are done at 9.6 kilobits per second, which is only one-sixth the rate of the most widely used standard rate of 64 kilobits per second.

Low-Bit-Rate Speech Coding. Low-bit-rate coding can offer several advantages. First, carriers may be able to increase the number of channels handled by a given system. For example, a T1 carrier rated for 1.544 megabits per second can carry up to 24 voice-grade channels at 64 kilobits per second each, or up to 47 channels at 32 kilobits per second each, but the same digital carrier could be upgraded to as many as 160 voice channels at 9.6 kilobits per second each. Some of these channels could be assigned for use as specific signaling channels used by the telecommunications carrier.

Second, speech coding at low bit rates eventually may help to implement the use of digitized voice signals in public switched loop circuits that presently are unable to carry high-quality, digitally encoded speech. Digitized speech must be transmitted over unconditioned, ordinary loop circuits before end-to-end digital voice and data transmission through the public switched network can become a reality.

The highest bit rate considered acceptable for an unconditioned circuit in the public loop plant today is about 4.8 kilobits per second, which is used by voiceband data modems. Digital transmission rates higher than 4.8 kilobits per second on a dial-up public line could experience significant pulse distortions, which would increase error rates. Signal errors on a digitized voice line could introduce unacceptable speech distortions, depending upon the type of speech decoder used.

A digital voice coder capable of transmitting intelligible digitized speech over dial-up lines, known as a vocoder (voice coder), was introduced a few years ago. It typically operates at 2.4 kilobits per second, but the speech signal sounds mechanical and artificial. Continuing research has shown that *synthesized speech* encoded at 9.6 kilobits per second produces voice quality far more natural than that created by the vocoders, but toll quality continues to be sought.

Past efforts toward source coding were impeded by the lack of high-speed microchips. Research on the complex behavior of human vocal and aural organs as they produce and listen to speech signals has revealed how complex the speech communication process is. It is very difficult to synthesize the human voice with artificial devices, especially in real time.

[1] Information furnished by B.S. Atal and R.Q. Hofacker, Jr., AT&T Bell Laboratories.

When algorithms were designed around relatively unsophisticated hardware, the low-bit-rate synthesized voice could not equal a normal telephone voice transmitted by analog or PCM digital systems. However, with the improvement of available hardware, particularly in speed, high-speed digital signal processing could markedly improve the source coding system and thus achieve high-quality voice synthesis in real time. Alternatively, the coded bit rate could be reduced even further — perhaps as low as 2.4 kilobits per second, while generating a high-quality voice signal. Further advances can be made from learning more about the physics of speaking and hearing. For example, speech scientists know that average speech is burdened with a tremendous load of redundant information.

Two speech signals need not be *physically* identical to conclude that they are *perceptually identical*. This means that there is some latitude when the signal is reproduced. The key to success in speech coding lies in the proper appreciation of *what we hear* and *what we do not*. Nature requires redundant components in speech signals to reinforce speech sounds so they will survive passage through the air in noisy environments. These redundant components are not required when speech is being transmitted across a telecommunications network. They take up valuable transmission capacity. Source coding research seeks ways to eliminate such redundant speech components before the voice is transmitted over the digital channel, restoring only the necessary components at the receiving end. See Fig. 3.

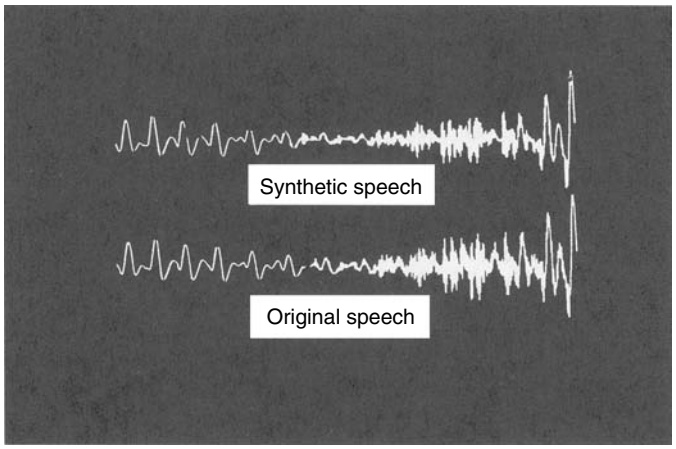

Fig. 3. Most of the average speech signal is full of redundant components. By identifying and removing those redundancies during coding for telephone transmission, the efficiency of low-bit-rate digitized voice systems can be greatly improved with minimum loss of quality.

Minimizing the Information Rate. Human speech *perception* is complex. It consists of a sequence of transformations occurring at several levels in the ear and the brain. An extremely important transformation occurs in the ear's cochlea, where the acoustic signal is converted into neural signals. These are transmitted by the auditory nerve to the higher auditory centers of the brain. See Fig. 4. For efficient coding, we need to know just how much of the speech signal's information is processed in the acoustic-to-neural transformation. If certain irrelevant details are going to be lost during the conversion anyway, why transmit them through the digital communication channel?

Coding speech efficiently therefore requires that we determine just how closely the synthesized signal matches the natural speech signal in a perceptual sense. This continuous comparison of the two signals is done by including both a speech synthesis model and a model of auditory perception in the encoding process.

Teaching Machines to Talk. Speech coders are guided by a speech synthesis model. A properly developed speech synthesis model plays a key role in generating high-quality voice signals at low bit rates. The most commonly used speech synthesis model in source coding is the time-varying linear filter, an electronic version of the human vocal tract. This is excited by either a periodic pulse train (to produce voiced sounds), or a white-noise source (to generate unvoiced sounds). Voiced sounds, such as vowels, semivowels, voiced stops, and nasals, come from vocalcord vibrations. Unvoiced sounds, including fricatives (like "f", "s", "sh", etc.),

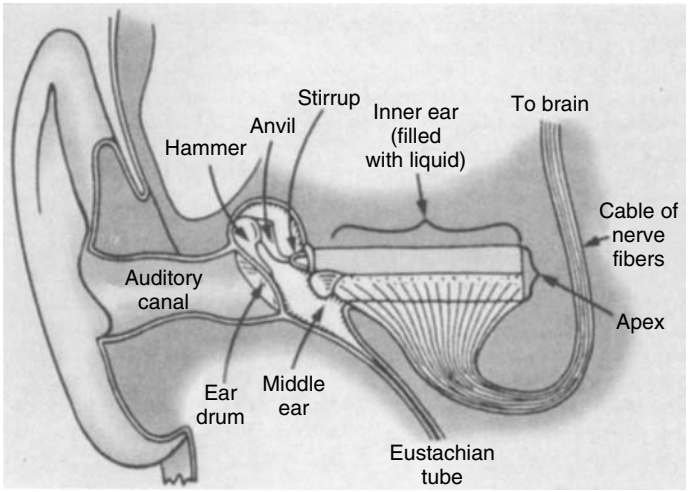

Fig. 4. Schematic of human ear shows snailshell-shaped cochlea as a flattened "inner ear" structure that houses the basilar membrane, which connects to thousands of nerve endings. The membrane acts as a peripheral frequency analyzer, selecting frequency bands and transforming acoustical energy into nerve impulses when stimulated by signal waves traveling through the inner ear's fluid. Not all of the signal detail that enters the cochlea is changed into nerve impulses that the brain understands as sound. If the signal components are ignored by the acoustic-to-neural transformation, then these signals need not be transmitted through a digital telecommunications system. This would potentially increase digital transmission capacity, offer more flexibility in system utilization, and lower costs for the analog/digital conversion hardware.

During the transformation of sound waves to neural impulses, the delicate components of the ear perform much like a bank of bandpass filters. Sounds are grouped together in frequency bands, some of which are broader than others. An important factor is *masking*, the inability of the human hearing mechanism to detect weak sounds in the presence of strong ones. Traditionally, a communications problem involves a signal being masked by noise. In speech coding, the opposite can be true. Every coder introduces errors during the encoding and decoding processes. These errors (or noise) can be masked by clever manipulation of the speech signal. By taking these factors into account, the digitized speech signal sent over telephone transmission circuits could be trimmed substantially. (*AT&T Bell Laboratories*.)

are made without using the vocal cords, but by generating turbulence in the vocal tract. The voice synthesis model requires information about the characteristics of the speech signal we want to code — whether it is voiced or unvoiced, its pitch period, and its linear filter parameters. Present low-bit-rate speech coders, such as the *linear predictive code* (LPC) vocoders, use this synthesis model. Their machine-like sound is a major drawback. See Fig. 5.

A more natural-sounding speech signal is produced when the newer *multi-pulse* linear predictive coder (MPLPC) concept[2] is used. Instead of pacing the excitation pulses at only one per pitch period as speech proceeds, MPLPC uses many pulses per period and positions them dynamically according to variations in the speech signal. This approach does not require the knowledge of speech characteristics, such as pitch period, or whether the speech signal is voiced or unvoiced (often used in the older vocoders and which are often difficult to determine). Multi-pulse LPC is sufficiently flexible to achieve any desired performance level within hardware limitations. See Fig. 6.

Average Versus Peak Bit Rates. Information in any speech signal is not spread evenly in time. Some speech segments are more important than others. Although this is well known, waveform speech coding systems in the past often allocated the same number of bits for each and every sample of the speech signal, with the result that the average bit rate equalled the peak bit rate.

An early approach to utilization of the variations in speech patterns was Time Assignment Speech Interpolation (TASI). Noting that voice conversations were formed of "talk spurts" with pauses between them, researchers

[2] An invention of AT&T Bell Laboratories.

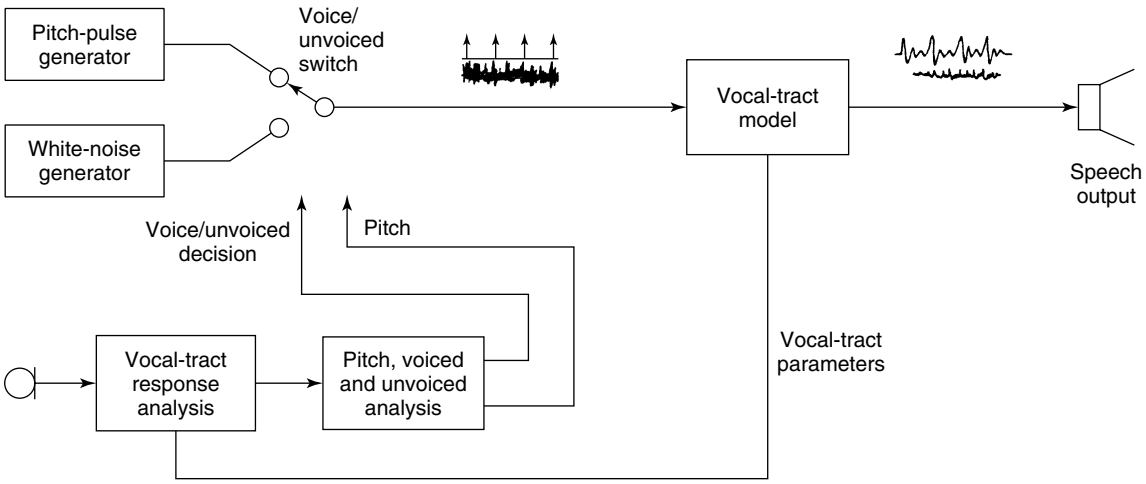

Fig. 5. Vocoder model for speech synthesis, useful for synthesizing digitally encoded speech at a bit rate sufficiently low for use on loop transmission facilities. The device operates with primtive source coding to digitally generate speech at 2.4 kilobits per second. Because its excitation pulses are paced at only one per pitch period, the synthesized speech sounds mechanical. (*AT&T Bell Laboratories*.)

developed a high-speed switch that interleaved various conversations on the same channel.

From a listener's viewpoint, what is most important in voice synthesis is constant voice quality during a conversation. By functioning as a variable rate coder, the new multipulse coder provides much more flexibility in assigning the bits needed as the different portions of the speech signal change.

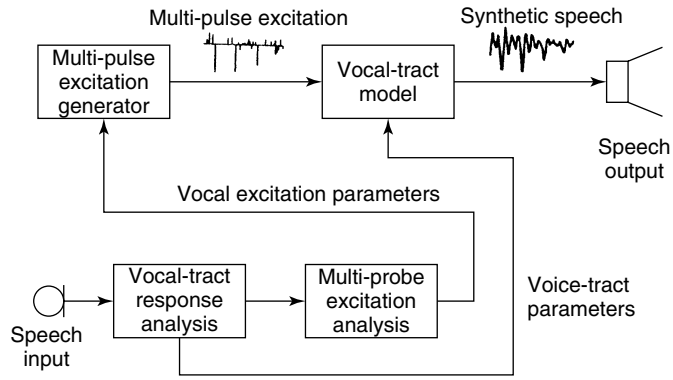

Fig. 6. Multi-pulse linear predictive coding (MPLPC) model for speech synthesis. By using a number of excitation pulses in every pitch period (usually about 10 milliseconds in an adult male voice), the MPLPC produces natural-sounding speech at bit rates as low as 9.6 kilobits per second. Normally, only a few pulses — typically, 8 to 16 pulses every 10 milliseconds — are needed to generate speech dramatically superior to that of the vocoder. (*AT&T Bell Laboratories*.)

Many of the newer applications of speech coding, such as voice mail and packetized voice transmission, can achieve superior efficiency by taking advantage of the difference between average and peak bit rates. In voice mail applications, for example, the total message-storage capacity is determined by the *average* bit rate, not the *peak* bit rate. By exploiting the variable nature of the speech signal, a hypothetical coder operating at a peak bit rate of only 9.6 kilobits per second might achieve acceptable performance with an average bit rate of only 9.6 kilobits per second. That means four times more digital storage capacity than with a fixed bit rate of 32 kilobits per second. Moreover, for packetized voice transmission, a programmed speech coder could help to reduce the transmission delays inherent in variable rate coding and control loss of important packets during transmission. Low-bit-rate voice coders, such as multi-pulse LPC, have the built-in capabilities to provide this control.

Another application may be interactive business transaction that use synthesized voice prompts. A customer could key in data on the telephone keypad, while following instructions, confirmations, and summaries provided by the synthesized voice prompts.

VOIDS. Empty spaces of molecular dimensions occurring between closely packed solid particles, as in powder metallurgy. Their presence permits barriers made by powder metallurgy techniques to act as diffusion membranes for separation of uranium isotopes in the gaseous diffusion process.

See also **Diffusion**.

VOLATILE. Having a low boiling or subliming temperature at ordinary pressure; in other words, having a high vapor pressure, as ether, camphor, naphthalene, iodine, chloroform, benzene; or methyl chloride.

VOLATILE OILS. The volatile oils are distinguished from the fixed oils by the fact that a drop of one of the former does not leave a spot on paper. Members of certain plant families, such as the *Labiatae*, contain a larger percentage of such oils than do other families. But volatile oils are in no sense restricted to any small group, nor are they found only in certain tissues. Sometimes, certain parts may be principally used for the oils, as the seeds of the *Umbelliferae*.

Various methods are used in extracting the oils from the plant tissue. Many are distilled with water or steam, the oil being carried over with the

distillate. In others, as for example oil of bitter almonds, the oil develops in the tissues only after fermentation. It is then obtained by distillation. Another method, and one especially used for more delicate and valuable oils, is called "enfleurage." In this method the flowers containing the oil are spread as a thin layer over a layer of lard or olive oil. The latter absorbs the delicate oil in the flowers, after which distillation may separate the volatile oil from the other. See also **Essential Oil**.

VOLATILE ORGANIC COMPOUND (VOC). Any hydrocarbon, except methane and ethane, with vapor pressure to or greater than 0.1 mm Hg.

VOLATILITY PRODUCT. The product of the concentrations of two or more ions or molecules that react to produce a volatile substance. The volatility product is analogous to the solubility product, except that, when it is exceeded, the substance escapes from the system by volatilization rather than precipitation. As with the solubility product, if any of the reacting ions or molecules have a numerical coefficient greater than one, then the concentration term of that ion or molecule is raised to the corresponding power.

VOLCANIC MAGMA. See **Lava**.

VOLCANO. A generalized definition of a volcano would be, "A vent in the surface of the earth through which magma and associated gases and ash erupt." The word is also used to designate the form or structure, usually conical, that is produced by the ejected material (ejecta). There are active and dormant volcanoes on Earth, and volcanoes also have been recognized in imagery received from exploring some of the other planets in the solar system, notably Venus, and Jupiter's moon Io, on which at least eight active volcanoes have been identified. As is explained later, volcanoes on earth are the result of tectonic activity, which provides openings in the earth's crust, allowing the release of energy and material from below the planet's lithosphere. The concept of plate tectonics is fundamental to understanding the formation of volcanoes, as it also is in connection with earthquakes. Both phenomena reflect the subterranean forces that do not attain permanent equilibria, but that are constantly shifting, if ever so slowly. A rather comprehensive table listing major volcanoes on the Earth known since several centuries B.C. is given in article on **Earth**.

Most geothermal regions where underground hot water and steam are extracted for commercial heating and electric power generation are found near active or dormant volcanoes. Examples include the Larderello field in Italy, where electric power has been generated since 1913; the terrain under Reykjavik, Iceland; the Wairakei geothermal fields on the North Island of New Zealand; the Geysers area of California, discovered in 1847, but not exploited commercially until 1970. See also **Geothermal Energy**.

Ill-Famed Volcanoes

A thorough inventory of volcanoes, ranging from active to dormat and "extinct" would number in the thousands. Volcanoes range widely in their physical dimensions and in their behavior. Only a few can be described here.

Mt. Etna (Sicily). The activity of this volcano dates back to the beginning of recorded history, with more than 11 eruptions known to have occurred prior to 1 A.D. About 70 eruptions have been recorded since then, several entailing high losses of life and property. A relatively major eruption occurred in November 1979, followed by activity in 1989 and a major eruption on December 14, 1991. This followed nearly 2 years of inactivity. Extensive measures were taken to combat the volcano in 1991 in an effort to protect the village of Zafferana Etnea, with a population of 7000 people, at the base of the volcano. As reported by Gasparini (University of Naples), "A 234-meter (768-foot) long and 21-meter (69-foot) high dam was constructed of earth, scoriae, and stones. The dam contained the lava and was breached after about one month. Three additional smaller earthen barriers were built to slow the flow toward Zafferana. Another effort consisted of several attempts to stop the advance of the lava front by the diversion of the flow out of its natural and extensively tunneled channel. The main intervention was made at an elevation of 2,000 meters (6,532 feet) in an almost inaccessible zone with the extensive use of helicopters." In the end, these and additional efforts saved the village. The eruption ended on March 30, 1993, culminating 473 days of continuous lava flows. It has been estimated that this probably was the largest eruption of Etna in the last 300 years, covering about 7 square kilometers (2.6 square miles) with in excess of 250 million cubic meters (8.8 billion cubic feet) of lava.

Cone-shaped Mt. Etna rises some 3300 meters (10,380 feet), with a circumference at the base of about 145 kilometers (90 miles).

In 1991, a group of French scientists found that Mt. Etna is one of the Earth's most potent sources of carbon dioxide (CO_2), estimating that even during quiescent periods, the volcano releases some 25 million tons of CO_2 into the atmosphere each year. This is many more times the amount released by the more spectacular Hawaiian volcanoes. Because of difficulties in measuring CO_2 directly, the researchers measured sulfur dioxide (SO_2) and used a ratio function for estimating the relative abundance of the two gases. The investigators found that not only do large amounts of CO_2 emanate from the crater, but that the atmosphere surrounding the base of the volcano also is inordinately heavy with the gas. The basic cause of the CO_2 has not been determined precisely, but one investigator suspects that the CO_2 is released from carbon-rich rocks around the volcano. Another researcher attributes the relatively alkaline lava as the principal source. See description of the Lake Nyos disaster (1976) described later in this article.

Mt. Vesuvius (Italy). Ash and lava from this dreaded volcano literally buried thousands of people and their homes in the cities of Pompeii and Herculanum on August 24, 79 A.D. Although Mt. Vesuvius has not erupted since 1944 and currently does not indicate renewed activity, the Phlegraaean Fields caldera in nearby geothermal areas has shown signs of unrest since 1970. This area has produced sporadic earthquake swarms, often regarded as precursors of volcanic eruptions.

Charles Dickens in his "Pictures from Italy" described a visit to Pompeii and Herculanum and his ascent and descent of Mt. Vesuvius in 1844.

Mt. Vesuvius and the Phlegraean Fields are of major concern to the Italian government because of the proximity of Naples, a city of 2 million people. In fact, in recent years European scientists have shown an increasing interest in the possible future threats of volcanoes in western and Eastern Europe. During the early 1990s, the European Science Foundation created the European Volcanological Project (EVOP), which is chartered to gather the knowledge of volcanologists all across Europe. Although not within the "Ring of Fire" mentioned later, there are volcanoes designated as active in Greece, Turkey, the Canary Islands (under Spanish control), the Azores (under Portuguese control), and Iceland. It is interesting to note that the volcanoes of Italy and Greece have erupted about 140 times since the great eruption of Santorini in the Aegean Sea in 1500 B.C. The disappearance of the Minoan civilization on the island of Crete is attributed to that eruption.

Krakatau (Indonesia). This volcano is remembered most in the literature as the "volcanic island that literally disappeared into the sea." This eruption occurred in late August 1883, following unrest that commenced in May of that year. Actually, one-third of the island remained above sea level, with the remainder of the island sinking well below sea level. The remaining island was about 15.5 square kilometers (6 square miles). The power released by the volcano has been estimated as being equal to or greater than one of the early military nuclear bombs. Essentially all life of any form was consumed by the blast. A submarine earthquake accompanying the blast created ocean waves as high as 15 meters (50 feet) that traveled several thousand miles. The waves killed more than 36,000 people along the coasts of Java and Sumatra and destroyed incalculable amounts of property. Historians recorded reports of the blast being heard by persons some 4800 kilometers (about 3000 miles) distant. The dust cloud produced by Krakatau was noted in the upper atmosphere for about 3 years.

As reported by D. and M. Plage, who visited the wildlife reserve of Ujung Kulon Peninsula on the large island of Java, "Thirty-five miles across the sea from Ujung Kulon, the island of Krakatau ripped itself apart in 1883. Tsunamis reaching the Javanese shore washed away the few villages that dotted this isolated outpost. The people never returned; the wildlife did, and it is protected today by the Ujung Kulon National Park. We spent a year there, examining the regeneration of life on both the peninsula and Krakatau a century after eruption."

El Chichón Volcano, Chiapas, Mexico. Between March 28 and April 4, 1982, this volcano in southern Mexico, even though regarded as a relatively small volcanic event, injected a fine mist of sulfuric acid droplets into the stratosphere considered denser than any volcanic cloud since the great eruption of Krakatau in 1883. The blast tore away the upper 200-meter (656-ft) portion of the old volcanic cone, after approximately 600 years of dormancy. The crater left by the 1982 eruption lies within the old crater, which is masked by new volcanic deposit. Satellite observations made shortly after the volcano erupted for the first time indicated that an aerosol cloud moved rapidly westward and, within a few weeks, a veil of fine material reached around the globe. As reported by Rampino (NASA) and Self (University of Texas), in less than a year the stratospheric cloud (some 25 km; 15.6 mi aloft) had blanketed the entire Northern Hemisphere and much of the Southern Hemisphere. El Chichón ejected a volume of ash comparable to that of Mount Saint Helens in 1980, but the cloud from El Chichón was estimated to be at least 100 times denser. It has been suggested that the sulfur, from which the sulfuric acid aerosol was formed through photochemical reaction, originated either from sedimentary deposits underlying the volcano, or from sulfide deposits on one tectonic plate of the Earth's crust that is plunging under another and melting. Tectonically, El Chichón is related to the Guatemalan volcanic belts. Three major plates meet near this region — the Caribbean plate is sliding past the North American plate along a series of faults in Guatemala; the Cocos plate is being subducted under the North American and Caribbean plates at the Middle American trench off the coast of Mexico. See the map of plates in the article on **Earth Tectonics and Earthquakes**. Acidity of ice in the Greenland ice sheet were found to correlate with the eruption of El Chichón, as did those of an earlier similar eruption of the Agung volcano in Indonesia in 1963. Effects on the climate as caused by the El Chichón eruption are still being studied. The first description of El Chichón in the literature did not appear until 1928. Carbon-14 dating indicates that the last prior eruption of the volcano occurred between A.D. 1350 and 1400, and that the magnitude of that eruption was probably ten times greater in magnitude than that of 1982. El Chichón is located in a very remote and relatively inaccessible area of Mexico. For comparison purposes, scientists had only a few photographs that were made of the volcano prior to 1982.

Mt. Pinatubo (The Philippines). There are approximately 100 eruptive centers in the Philippine Islands. There was a major eruption of Mt. Taal on Luzon in 1965, costing 190 lives as well as property damage. This volcano also erupted in 1968, but on a smaller scale. Mt. Pinatubo on Luzon erupted on June 10, 1991, after not having erupted for over 500 years (1380). As with numerous volcanoes, an eruption may be "expected" at most any time, but the enormity of the 1991 eruption was surprising even to most experts in the field. As observed by one scientist at the National Aeronautics and Space Administration, "It's no Krakatau, but this is possibly the largest eruption of this century." Of major significance is the possible effects the eruption may have on global weather. In this regard, Mt. Pinatubo is sometimes compared with the 1982 eruption of El Chichón (Mexico).

Detailed studies of the 1992 and 1993 weather data remain to be completely analyzed, and it may require a few more years to study and build models of the data accumulated before definite conclusions on the volcano's effects can be announced with confidence. The NASA spaceborne Earth Radiation Budget Experiment has been used in connection with these studies. The change in the Earth's radiation budget that is initiated by the eruptions is termed *volcanic aerosol forcing*, or, simply, *volcanic forcing*. Needless to say, fundamental studies of the "greenhouse effect," or global warming, become more complex each time there is a major volcanic eruption of the enormit Pinatubo buto or El Chichón.

Mt. Unzen (Japan). After a quiescent period of about 200 years, Mt. Unzen, located near Nagasaki, Japan, collapsed, sending a half-million cubic meters of lava and hot ash traveling at high speed down the Mizunashi River and into the nearby town of Kamikoba. A total of 43 peopled were killed, including a large number of volcanologists from several countries. The group of scientists was engaged in research. There also were civilian deaths and property damage near Kamikoba. Since the disaster, which occurred on the afternoon of June 3, 1991, the Japanese government has been investigating ways and means to counter the volcano's destructive capabilities. The volcano remains reasonably active. For example, an eruption on June 23, 1993, produced damage in a previously untouched river valley on the volcano's northeast slope. This caused one death and destroyed 80 structures.

Despite a willingness on the part of the Japanese government to invest heavily in protecting lives and property at the base of the volcano (reminiscent of the previously described success at Mt. Etna), some specialists believe that the volcano is entirely too fickle to justify strategic protective plans. One volcanologist at the Kyusu University's Simabara Earthquake and Volcano Observatory has indicated that the best solution most probably would be that of moving the people who live in dangerous areas to safer places.

Mt. Pelée (Lesser Antilles). Located on the island of Martinique in the Caribbean northeast of Venezuela, Mt. Pelée erupted in 1902, destroying Saint-Pierre, formerly the largest city on the island. An estimated 36,000 persons were killed as the result of the blast.

Nevado del Ruiz Volcano, Colombia. After an inactive period of some 140 years, Nevado del Ruiz, a volcano located in northwestern Colombia, became seismically active in November 1984 and erupted explosively on November 13, 1985. Earlier eruptions between 1828 and 1833 and again in 1845 were relatively minor, but the latter did create a volcanic mudflow (lahar) that traveled down the 5300-meter (17,390 ft) high mountain on its eastern flank, reaching the site of Amero (a distance of over 50 km; 31 mi) and causing over a thousand casualties. A major eruption occurred in 1595, producing an ash and lapilli (pyroclastic particles) and lahars.

In terms of lives lost, the 1985 eruption of Ruiz was a major disaster. Pyroclastic flows and surges, generated during the initial stage of the eruption, triggered surface melting of approximately 10% of the volcano's ice cap, thus resulting in meltwater flooding. The erosive floods swept soils and loose sediments from the volcano's flanks and developed mud flows, which claimed at least 25,000 lives. Volcanologists regard the 1985 eruption of Ruiz as the largest volcanic disaster since the 1902 eruption of Mount Pelée in Martinique that killed some 28,000 people. Investigators reported that Ruiz released a small volume of pyroclastic material and a disproportionately large volume of volcanic gases.

Before the eruption, summit fumarole gases became less water-rich and the sulfur/chlorine ratio increased. Remote measurements of sulfur dioxide (SO_2) flux after the eruption indicated active degassing at levels associated with eruptive or inter-eruptive stages of other volcanoes. Thermal water analyses revealed increases in magnesium, calcium, and potassium and an increase in the magnesium/chlorine ratio, suggesting that these elements may have been leached from new magma. Water from the lahar contained high concentrations of sulfate and had a sulfur/chlorine ratio of 4.67, suggesting to experts that water ejected from the crater lake and turbulent mixing of pyroclasts and glacial ice triggered the lahar. The uniform composition of the pumices and the unusually high ratio of gas to magma suggest that, although a new batch of magma triggered the eruption, the pumice that erupted may have been old.

In June 1993, D.L. López (University of British Columbia) and S.N. Williams (Arizona State University) observed, "Catastrophic volcanic collapse, without precursory magmatic activity, is characteristic of many volcanic disasters. The extent and locations of hydrothermal discharges at Nevado del Ruiz suggest that many volcanoes' collapse may result from the interactions between hydrothermal fluids and the volcanic edifice. Rock dissolution and hydrothermal mineral alteration, combined with physical triggers such as earthquakes, can produce volcanic collapse. Hot spring water compositions, residence times, and flow paths through faults were used to model potential collapse at Ruiz. Caldera dimensions, deposits, and alteration mineral volumes are consistent with parameters observed at other volcanoes." Details are given in this scholarly paper. See reference listed.

Kilauea Volcano, Hawaii. Volcanic activity in this region of the world might be described as semi-continuous, much of which does not reach the newspaper headlines. In 1983, an eruption of Kilauea occurred along the volcano's east rift zone. The eruption commenced on January 2, 1983 and continued for about two weeks, during which a number of eruptive episodes produced several lava flows. Additional lava flows occurred during eruptions in February of that year. Scientists found the active laval flows useful for running field verification measurements of induced convective heat flow in basaltic lava. Convective heat flow in lava and magma has been studied because of its importance to energy extraction from molten magma and because of its relation to tectonic processes.

As reported by Hardee (Geophysics Research Division, Sandia National Laboratories), eight field measurements of induced natural convection were made, giving heat flux values that ranged from 1.78 to 8.09 kW/cm^2 at lava temperatures of 1088 and 1128 °C (1993 and 2064 °F), respectively. The field measurements agreed with prior laboratory measurements in furnace-melted samples of molten lava.

The Hawaiian Islands, of volcanic origin, were not created simultaneously. The island of Kauai, for example, is estimated to be 5.1 million years old; Maui, 1.3 million years old; and Hawaii, 800,000 years old. Considerably further distant, the Midway islands are estimated to be 28 million years old. As the seamounts rose above sea level, numerous life forms commenced to occupy the islands. The process of occupation by living forms remains poorly understood. The Scottish biologist, Sir John Arthur Thomson, commented in 1920, "Living creatures press up against all barriers; they fill every possible niche all the world over. . . . We see life persistent and intrusive — spreading everywhere, insinuating itself, adapting itself, resisting everything, defying everything, surviving everything!"

The Hawaiian Islands resulted from plate tectonic activity, but, according to many scientists, were not directly influenced by continental landmasses.

G. Sen (Florida International University) and R.E. Jones (University of California, Los Angeles) in their studies of the origination of Hawaiian volcanism have reported, "The maximum depth at which large (greater than 1000 km^3) terrestrial mafic magma chambers can form has generally been thought to be the Moho, which occurs at a mean depth of about 35 km beneath the continents and 8 km beneath the ocean basins. However, the presence of layers of cumulus magnesium-rich spinel and olivine and intercumulus garnet in an unusual mantle xenolith from Oahu, Hawaii, suggests that this rock is a fragment of a large magma chamber that formed at a depth of about 90 km; Hawaiian shield-building magmas may pond and fractionate in such magma chambers before continuing their ascent. This depth is at or near the base of the 90-million-year-old lithosphere beneath Oahu; thus, rejuvenated stage alkalic magmas containing mantle xenoliths evidently also originate below the lithosphere."

The researchers report in exquisite detail their findings pertaining to the evolution of a typical Hawaiian volcano, indicating that this is a four-stage process.

System studies of Kilauea began as early as 1912, with the establishment of the Hawaiian Volcano Observatory, and continue to the present. These studies have revealed much about the physical and chemical processes that trigger and sustain volcanic eruption and have served as models for investigations of other, often more violent volcanoes in many parts of the world. The Observatory is managed by the U.S. Geological Survey. A detailed description of the Observatory's findings is given in the Delaney reference listed.

It is interesting to note that some of the world's largest optical telescopes are located atop Mauna Kea, long considered to be an "extinct" volcano.

Further reference to article on **Earth Tectonics and Earthquakes** is suggested.

Oldoinyo Lengai (Tanzania). This volcano is famous for its unusual alkali-rich magma, termed *natrocarbonatite*, and is believed to be the only active *carbonatite* volcano on Earth. The volcano has a steep cone about 2900 meters (9515 feet) high. It is located just a few km south of Lake Narron in the Tanzanian part of the Gregory Rift Valley. Early explorers reached the area in 1880. Since then, about ten eruptions have been noted, most of them of an explosive nature. However, until the 1960 lava eruption, the carbonatitic composition of the lava had not been recognized. Another explosive eruption occurred in 1966. No additional activity was reported until an explosive eruption in January 1983. Activity during 1988 was purely effusive.

The lava chemistry of this volcano has attracted the interests of volcanologists, even though the volcano is very difficult to reach. Reporting on recent findings, M. Krafft (Centre Vulcain, Cernay, France) and J. Keller (Mineralogisch-Petrographisches Institut der Universität, Freiburg, Germany) observe, "The petrogenesis of cerbonatites has important implications for mantle processes and for the magmatic evolution of mantle melts rich in carbon dioxide. Oldoinyo Lengai has highly alkalic, sodium-rich lava. Although different in composition from the more common calcium-rich carbonatites, this provides the opportunity for observation of the physical characteristics of carbonatite melts. Temperature measurements on active carbonatitic lava flows and from carbonatitic lava lakes were carried out during a period of effusive activity in June 1988. Temperatures ranged from 491° to 519 °C. The highest temperature, measured from a carbonatitic lava lake, was 544 °C. These temperatures are several hundred degrees lower than measurements from any silicate lava. At the observed temperatures, the carbonatite melt had lower viscosities than most fluid basaltic lavas. The unusually low magmatic temperatures were confirmed with 1-atmosphere melting experiments on natural samples."

Soufrière Volcano, St. Vincent, Lesser Antilles. A swarm of local earthquakes on the island of St. Vincent occurred just a few hours before the eruption of this volcano got underway in the spring of 1979. The eruption consisted of two phases. As reported by Fiske (Smithsonian Institution) and Sigurdsson (University of Rhode Island), during the initial vulcanian explosive phase (April 13 to 26), a series of vertical explosions blasted a new vent through the lava island (created in 1971–1972) in the middle of the crater lake (1 km; 0.6 mi wide), causing steam and tephra to rise 8 to 20 km (5 to 12$\frac{1}{2}$ mi) into the atmosphere. This phase also added layers of air-fall debris on the island and surrounding sea. Also, during this period, small pyroclastic and mud flows traveled down the slopes. In a few days, the crater lake flooded the vent of the volcano. During the next few days, the lake completely disappeared. The second phase consisted of the quiet extrusion of viscous basaltic andesite lava, resulting in the growth of a dome over the vent. It was estimated that the total mass of rock produced during the eruption was 2.4×10^{11} kg as compared with 3.8×10^{11} kg produced by the same volcano in a destructive eruption that occurred in 1902.

Scientific coverage of the event was exceptional, including observations from the ground, aircraft, and satellites. Because of intense interest and the large amounts of data collected, the Smithsonian Institution hosted a "Soufrière Conference" in September 1979. Meteorologists concluded that the atmospheric plume created was not an important climate modifier. Fascinating "skirt" cloud formations were noted during the eruption. These clouds had a nearly vertical orientation. They are described in the Barr reference listed.

Alaska's Katmai Region. What was described as a colossal volcanic eruption occurred at Mt. Katmai on June 6, 1912. At the time, the region was very sparsely populated and observations were few. No casualties or property damage were reported. Mt. Katmai is located in the Alaskan region denoted as the "Valley of Ten Thousand Smokes." Mt. Katmai is about 2042 meters (6700 feet) high. There are numerous volcanoes in Alaska and the nearby Aleutian Islands. Among these are Mt. Wrangell, 4317 meters (14,163 feet) high, in Alaska and over 30 active vents and numerous inactive cones in the Aleutians. A volcano on Akutan Island, 1220 meters (4000 feet) high, exploded in 1974, with ash and debris rising several hundred meters. The volcano Great Sitkin, 1750 meters (5741 feet) high displayed explosive activity in the spring of 1974. A volcano on Augustine Island, 1220 meters (4000 feet) high, erupted in 1976 and again on March 17, 1986.

The area around Mt. Katmai was designated a national monument in 1918 and presently is part of Katmai National Park. Commencing in 1989, scientists have been making a geophysical study of the region's immense volcanic system. As of 1991, plans called for drilling approximately 1220 meters (4000 feet) beneath the surface to determine the underground mechanics of the volcanic system. Site of the drilling is the dome-plugged volcanic throat of Novarupta in Katmai. Also, it is hoped that details of the Katmai eruption of 1912 can be understood better by analyzing core samples. It has been estimated that when Katmai erupted it produced 30 times the ash of Mt. St. Helens. Careful regard for the environment will be a predominant consideration.

Cascade Range (Northwestern United States). From the standpoint of plate tectonics, this region is ideally located in terms of volcanic activity. Prior to the eruption of Mt. St. Helens in southwest Washington on May 18, 1983, the last prior eruption in the region was a period of activity at Lassen Peak (California) during the 1914–1917 time span. The Mt. St. Helens eruption is described later in this article. Some 7000 years ago, Mazama, a 3000-meter (9843-feet) high volcano in southern Oregon erupted violently, ejecting about 40 cubic kilometers (9.6 cubic miles) of ash and lava. The ash spread over the entire northwestern United States and as far as Saskatchewan (Canada). During the eruption, the top of the mountain

collapsed, leaving a caldera about 10 kilometers (6.2 miles) across and about one kilometer (0.62 mile) deep, which filled with rainwater to form what is now called Crater Lake.

Principal Types of Volcanoes[1]

The word "volcano" is derived from the name of a small island, *Vulcano*, situated in the Mediterranean Sea off Sicily. Centuries ago, the people living in the area believed that Vulcano was the chimney of the forge of Vulcan — that is, the blacksmith of the Roman gods. They thought that the hot lava fragments and clouds of dust erupting from Vulcano came from Vulcan's forge. Modern geologists generally put volcanoes into four generalized groups, but obviously there could be other classifications and numerous subclassifications.

Cinder Cones. These are the simplest type of volcano. They are built from particles and "blobs" of congealed lava ejected from a *single* vent. As the gas-charged lava is blown violently into the air, it breaks into small fragments that solidify and fall as cinders around the vent, forming a circular or oval dome. Most cinder cones have a bowl-shaped crater at the summit and rarely rise more than about 300 meters (~1000 feet) above their surroundings. Cinder cones are numerous in western North America as well as throughout other volcanic terrains of the world.

Composite Volcanoes. Some of the Earth's grandest mountains are *composite* volcanoes (sometimes called *stratovolcanoes*). Typically, they are steep-sided symmetrical cones of large dimension built of alternating layers of lava flows, volcanic ash, cinders, and blocks of material and may rise as much as 2400 meters (~8000 feet) above their bases. Some of the most conspicuous and beautiful mountains in the world are composite volcanoes, including Mt. Fuji (Japan), Mt. Cotopaxi (Ecuador), Mt. Shasta (California), Mt. Hood (Oregon), Mt. St. Helens (Washington), and Mt. Rainier (Washington).

Most composite volcanoes have a crater at the summit that contains a central vent or a clustered group of vents. Lava either lows through breaks in the crater wall or issues from fissures on the flanks of the cone. Lava, solidified within the fissures, forms dikes that act as ribs that greatly strengthen the cone.

The essential features of a composite volcano is a conduit system through which magma from a reservoir deep in the Earth's crust rises to the surface. The volcano is built up by the accumulation of material erupted through the conduit and increases in size as lava, cinders, ash, and so forth are added to the slopes.

Shield Volcanoes. These volcanoes are built almost entirely of fluid lava flows. Flow after flow pours out in all directions from a central summit vent or group of vents, building a broad, gently sloping cone of flat, domical shape, with a profile much like that of a warrior's shield. They are built up slowly by the accretion of thousands of flows of highly fluid basaltic[2] lava that spread widely over great distances and then may cool as thin, gently dipping sheets. Lavas also commonly erupt from vents along fractures (rift zones) that develop on the flanks of the cone. Some of the larger volcanoes in the world are shield volcanoes. In northern California and Oregon, many shield volcanoes have diameters of 4.8 to 6.4 kilometers (~3 to 4 miles) and heights of 460 to 610 meters (1500 to 2000 feet). The Hawaiian Islands are composed of linear chains of these volcanoes, including Mt. Kilauea and Mt. Loa on the island of Hawaii.

In some shield-volcanic eruptions, basaltic lava pours out quietly from long fissures instead of central vents, flooding the surrounding countryside with lava flow upon lava flow and forming broad plateaus. Lava plateaus of this type can be seen in Iceland, southeastern Washington, eastern Oregon, and southern Idaho.

Lava Dome Volcanoes. Volcanic or lava domes are formed by relatively small, bulbous masses of lava too viscous to flow any great distance. Consequently, upon extrusion, the lava piles over and around its vent. A dome grows largely by expansion from within. As it grows its outer surface cools and hardens and then shatters, spilling loose fragments down its sides. Some domes form craggy knobs or spines over the volcanic vent, whereas others form short, steep-sided lava flows known as "coulees." Volcanic domes commonly occur within the craters or on the flanks of large composite volcanoes. The nearly circular Novarupta Dome that formed during the 1912 eruption of Mt. Katmai (Alaska) measures 274 meters (~900 feet) across and is 61 meters (~200 feet) high. The internal structure of this dome, defined by layering of lava fanning upward and outward from the center, indicates that it grew largely by expansion from within. Mount Pelée in Martinique and Lassen Peak and Mono dome in California are examples of lava domes.

Submarine Volcanoes. These volcanoes and volcanic vents are common features on certain zones of the ocean floor. Some are active at the present time and, in shallow water, disclose their presence by blasting steam and rock debris high above the surface of the sea. Many others lie at such great depths that the tremendous weight of the water above them results in high, confining pressure and prevents the formation and release of steam and gases. Even very large, deepwater eruptions may not disturb the ocean floor.

The famous black sand beaches of Hawaii were created virtually instantaneously by the violent interaction between hot lava and seawater. Underwater mountains sometimes are referred to as *seamounts*.

Macdonald Seamount. When surveyed in 1975, the peak of this seamount was found to be only 49 meters (161 ft) below the surface of the Pacific. Since then, this undersea volcano (about 1600 km; 1000 mi southeast of Tahiti) has been erupting and growing fast. Since 1977, seismic stations on several Polynesian islands have detected a total of 12 seismic swarms, directly attributed to eruptions at Macdonald. French divers, in 1983, explored the plateau around the summit and found evidence of recent volcanism — lava spatter cones, free of algae, flanking a fissure with fresh walls. Soundings then indicated that the summit of the volcano had risen to just 27 meters (88 ft) below sea level. Macdonald may be an island "in the making."

The Mechanisms of Volcano Origination

As viewed from the perspective of *plate tectonics*, volcanoes appear to originate in three ways:

(1) *Plate Collisions*. Volcanoes which are associated with the coming together of two tectonic plates and, in particular, where one plate commences advancement under an adjacent plate. This process is called *subduction* which may be defined as the process of one crustal block descending beneath another, by folding or faulting or both. The concept was originally used by Alpine geologists. Movement along the subduction zone (the "line" of contact between adjacent crustal blocks) will range from a very few to several centimeters per year and there is some correlation between these rates of movement and the activity of volcanoes on one of these blocks. According to current plate tectonics theory, there are several large plates that "float" on viscous underlayers in the Earth's mantle, such as the Pacific Plate, North American Plate, Eurasian Plate, Antarctic Plate, etc. There are usually several smaller plates or "plate regions" associated with these large main plates. As shown by Fig. 1, the Juan de Fuca Plate which lies between the Pacific Plate and the North American Plate has been responsible for the actions of Mount St. Helens in Washington (U.S.A.). It has been estimated that movement along the subduction zone between these two plates is in the range of 2–3 centimeters (0.8–1.2 inches) per year. The underthrusting of one plate relative to another generates high pressures and temperatures and disturbs the magma chamber, a reservoir of magma in the shallow part of the lithosphere (to a few thousand meters), as well as exposing pathways for the flow of magma upward to the surface of the Earth. Hays (1979) suggested that increased volcanism will occur when the underthrust oceanic plate reaches a depth of between 100 and 200 meters (328 and 656 feet), where conditions are suitable for the production of andesitic magma. The vent of a volcano is first formed because it provides a path of least resistance to flow to the surface. This vent, once formed, serves during periods of dormancy as a solidified rock plug. However, the pathways can change, as witness the number of supplementary vents found on some volcanoes. The vent of a volcano is, in essence, one end of a natural pipeline. See Fig. 2.

As observed by Hékinian (Centre Océanologique de Bretagne, Brest) in an excellent paper on undersea volcanoes (see reference), the volcanic activity that continually remakes the surface of the Earth takes place almost entirely at the bottom of the ocean, far beyond the reach of

[1] Source of Information: *U.S. Geological Survey.*

[2] From *basalt*, a hard, dense, dark volcanic rock.

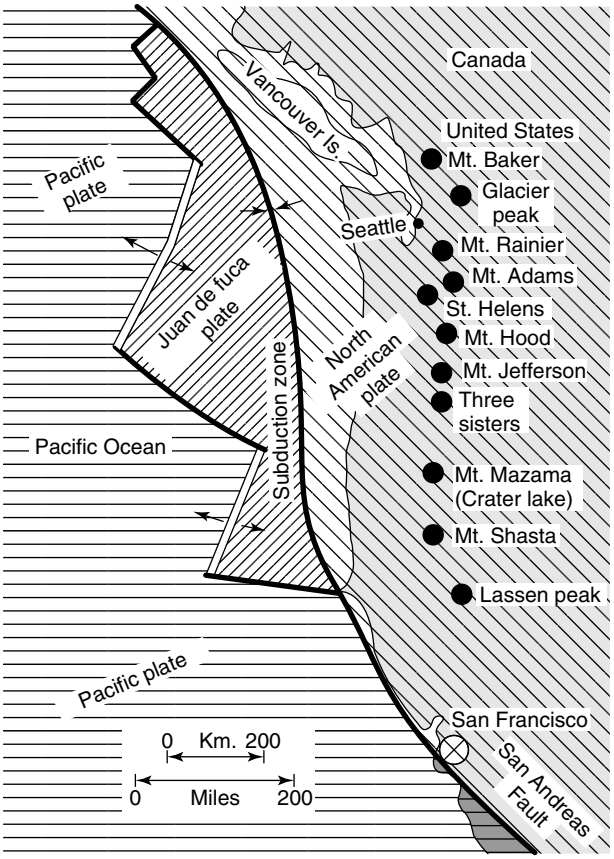

Fig. 1. Chain of volcanoes in the western United States, extending from Mt. Baker in northern Washington to Lassen Peak in northern California. Diagram shows position of the Juan de Fuca Plate with reference to the North American and Pacific Plates.

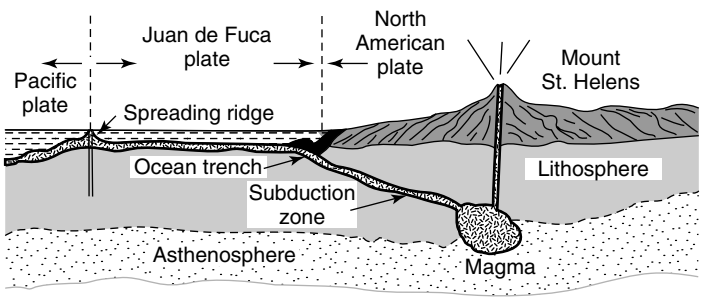

Fig. 2. Generalized arrangement of principal elements of a subduction-process-associated volcano as visualized by some scientists.

the traditional investigative tools of the volcanologist. Magma wells up from the mantle in two characteristic locations: along the active midocean ridges, where the spreading tectonic plates grow by the steady accretion of solidifying mantle material; and at the isolated volcanic structures called seamounts, which typically are strung out in chains across the interior of the plates. Sonar, special lighting for photography, seismology, and submersible vessels, manned and unmanned, have contributed much to the knowledge of undersea volcanic activity during the past few years. Some of the volcanoes observed appear in sonar images much the same as an aerial view of volcanoes located above sea level. An early sonar image, using side-looking sonar (system name, GLORIA) was made by the Institute of Oceanographic Sciences (Wormley, England) in 1980. It showed a volcano some 1.5 km (0.9 mi) high and about 9.5 km (6 mi) in diameter at the base. Volcanic activity is associated with hydrothermal vents ("black smokers") that vent noxious gases and the spiral-like tower structure of which contain metal-rich sulfide deposits. These are other volcanic features of the ocean floor, such as ocean floor fissures, pillow lava, and sheet lava, are described and illustrated in the article on **Ocean**.

The eruptive behavior of a volcano is directly related to the character of the magma that feeds it and, in particular, to the viscosity and innate strength of the magma.

Volcanoes associated with the subduction process occur all around the so-called Ring of Fire, which is associated with the Pacific Plate and its subplates. See Fig. 3. The numerous volcanoes found in the Aleutians, Alaska, and along the Pacific coast of the United States are a part of this ring. With exception of some volcanoes in the Aleutians and Alaska and, more recently, of Mt. Saint Helens in Washington, volcanoes in the North American portion of the ring have been dormant for several decades. The volcanoes of Indonesia, Java, the Philippines and other parts of Southeast Asia and the South Pacific, which are much more active, as well as those volcanoes located along the western edges of South and Central America, are also a part of this ring. Because of this, the subduction-associated volcanoes are sometimes called Ring of Fire volcanoes. The magma of these volcanoes is siliceous, with a relatively high viscosity and a high content of dissolved gases. As the magma rises toward the Earth's surface, a combination of high temperature and lessening pressure cause some of the gases to come out of solution and form bubbles. However, because of a combination of factors, including the mechanical strength of the bubble envelope materials, the bubbles do not reach an equilibrium size. Rather, they remain somewhat analogous to little grenades that confine pressures up to several hundred atmospheres. Thus, instead of a smooth lava flow rising and flowing from the vent, the gas bubbles, which also contain solid particles, retain their pent-up energy until a final massive eruption takes place, freeing them to a low pressure of one atmosphere. As they emerge and as they rise to heights in the atmosphere, they explode, thus releasing not only gaseous vapors, but much entrained solid material as well. Because the siliceous magma is very viscous, it forms pyroclastic avalanche flows rather than smooth-flowing rivers of lava. The 1980 eruption of Mt. Saint Helens, described a bit later, was characteristic of the behavior of this kind of volcano.

(2) *Divergence of Plates*. A second category of volcanoes, as viewed from plate tectonics, is the *rift volcano*, which occurs where plates are diverging rather than converging. Their eruptions are more effusive,[3] yielding a basaltic magma which has relatively low viscosity and low content of dissolved gases. See also **Basalt**. However, when these volcanoes erupt in shallow water or through continental crust, they can be explosive.

(3) *Island Volcanoes*. A third category, the *hot-spot volcano*, penetrates the Earth's crust, but how directly it is associated with plate mechanics is subject to some debate, particularly if the view is taken that *all* plates are coupled globally. The oceanic island volcanoes are usually of this type and are exemplified by the volcanoes of the Hawaiian Islands. Particularly when these volcanoes penetrate oceanic crust, they are effusive, but under certain conditions also can produce violent explosions. These volcanoes also yield basaltic magmas and may exhibit a most unusual and beautiful behavior when they are active. They may be characterized by numerous vents and large calderas. Molten lava in the caldera may light up the night sky for long periods and steam and heat combine to generate cumulonimbus clouds overhead. Although the gas content of basaltic magma is less than that of siliceous magma, nevertheless carbon dioxide, water, and other gases come out of solution as the magma rises upward. The bubbles expand easily against low viscous forces and frequently, during just the last few meters of their escape, form beautiful and dramatic incandescent fountains of lava. These volcanoes, however, do not always behave in an effusive manner. For example, Kilauea Volcano on the island of Hawaii suddenly erupted in 1790 with a severe explosion. A similar, but lesser explosion occurred in 1924. Otherwise, the 44 eruptions of the volcano recorded since 1900 have been of the gentle kind, producing prodigious quantities of lava that change some part of the island's surface every few years. This volcano has been the object of continuing research for many years.

Energy and Ejecta of Volcanoes

Estimates of prehistoric volcanic eruptions, which produced quantities of ejecta (gas, ash, debris) in excess of 1000 cubic kilometers (240 cubic

[3] As contrasted with being violently explosive, the flow of magma from an effusive volcano is much smoother and gentle and sometimes has been likened to t "toothpaste flowing out of a tube."

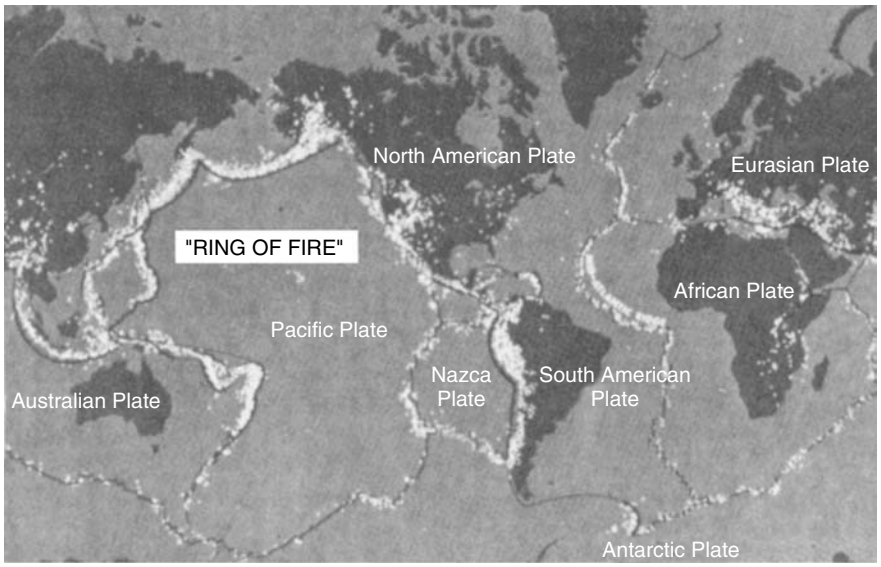

Fig. 3. Location of "Ring of Fire" as related to major tectonic plates of the world.

miles), tend to dwarf the eruptions which have occurred during the period of recorded history. As the result of paleogeological findings of recent years, it is believed that very early volcanic activity was concentrated largely in Japan, New Zealand, Central America, and the western United States. Geologists have estimated that volcanic activity experienced during the lifetime of the Earth to date is but a fraction of what could occur under the most favorable conditions for such eruptions, i.e., there is no indication of any diminution of thermal energy below the Earth's crust.

In describing volcanic eruptions, the news media are prone to compare the power of a volcano with that of a bomb. For example, the 1980 explosion of Mt. Saint Helens was likened to a 400-megaton nuclear bomb (over 8 times more powerful than any nuclear device detonated to date). This kind of comparison is misleading because it does not give proper recognition to the *rate of energy release*. A bomb made of TNT or of nuclear components releases energy essentially in an instant, whereas the energy of a volcanic eruption is spread over a much longer time span. It is estimated that Mt. Saint Helens released 1.7×10^{18} joules over a 9-hour period, whereas a 400-megaton bomb would release only 4.2×10^{15} joules. Thus, the sustained power output exhibited by Mt. Saint Helens was approximately equivalent to detonating 27,000 Hiroshima-size nuclear bombs at a rate of one detonation per second over a 7.5-hour period. Decker (1981) estimated the power generation by Mt. Saint Helens on May 18, 1980 was on the order of 100 times the electric generating capacity of all U.S. power stations. Or, to express it differently, if all of the energy of the Mt. Saint Helens event could have been converted into usable electrical energy and fed into the power network, all generating plants in the United States could have been shut down for about 900 hours, or 37.5 days (10.3% of the total annual U.S. electric power supply).

Detailed studies of the energy profile of Mt. Saint Helens have been made since the main eruption in 1980. See Table 1. In this type of analysis, the volcanic event is looked at as a total energy-releasing and consuming system. For example, as the result of disturbances created by the explosion, materials flowed downward in an avalanche, thus utilizing previously stored potential energy as the result of the higher position occupied by these materials. Similarly, stores of water were released to form mud flows as well as steam. This water prior to the explosion was in the form of groundwater, ice, and adjacent lakes and streams. Although some of the energy components, as a percent of the total energy system, appear insignificant, they were nevertheless very large, as evidenced by the destruction which they wrought. The thermal energy of steam explosions, not shown on table, was estimated at 10^{14} joules; the mechanical energy of blasts, 3×10^6 joules; and the pre-eruption seismic energy, 1.8×10^{13} joules.

The energy profile and the amount and characteristics of the ejecta are affected by the kind of magma, dissolved gas, groundwater, and originating pressure. Volcanic eruptions are commonly evaluated in terms of the tonnage of ejecta produced. However, there is no direct relationship between ejecta and damage. As shown by Fig. 4, the eruption of Mt. Saint Helens in 1980 was very low in terms of ejecta produced by a number of other volcanoes and including a prior eruption of Mt. Saint Helens about 1900 B.C., which produced about 4 times the quantity of ejecta produced in the 1980 event. Total damage is related to numerous factors in addition to production of ash, which destroys by rapidly covering over (literally burying) structures and people or by chemical poisoning from gases evolved. As in the case of Mt. Saint Helens, the ejecta principally posed a severe inconvenience over a relatively limited region, with the majority of damage stemming from the thermal and blast energy that destroyed large areas of forest and recreational grounds; and from the disturbance of water flow and the clogging of streams and reservoirs with ash-created mud; and the destruction of adjacent land by the mud and avalanche flow. This type of event is contrasted with the notable event of Vesuvius, which in A.D. 79 literally covered Herculaneum and Pompeii with ash.

As with earthquakes, the relative importance of volcanic events is usually equated much more with loss of life and property statistics rather than with measurements of a strictly scientific nature.

The rather different nature of the eruption of Krakatoa (1883), previously mentioned, has intrigued geologists and volcanologists for many years. In recent years, it has been suggested that possibly underwater volcanic eruptions, such as Krakatoa, may be accompanied by enormous vapor explosions. As pointed out in the entry on **Natural Gas**, vapor phase

TABLE 1. ENERGY COMPONENTS OF MT. SAINT HELENS EVENT (MAY 18, 1980)

Energy Component	Percent of Total Energy of System
Seismic energy	*
Deformational energy	1.0
Thermal energy of steam explosions	*
Gravitational energy of avalanche	2.6
Thermal energy of avalanche	10.5
Thermal energy of blast deposits	10.5
Hydrothermal energy	5.3
Mechanical energy of blasts	*
Thermal energy of high ash cloud	43.7
Thermal energy of pyroclastic flows	17.4
Thermal energy of eruptions after main event	8.9
All other	0.1
Total	100.0

*Insignificant on this scale. However, as explained in text these were nevertheless large amounts of energy.

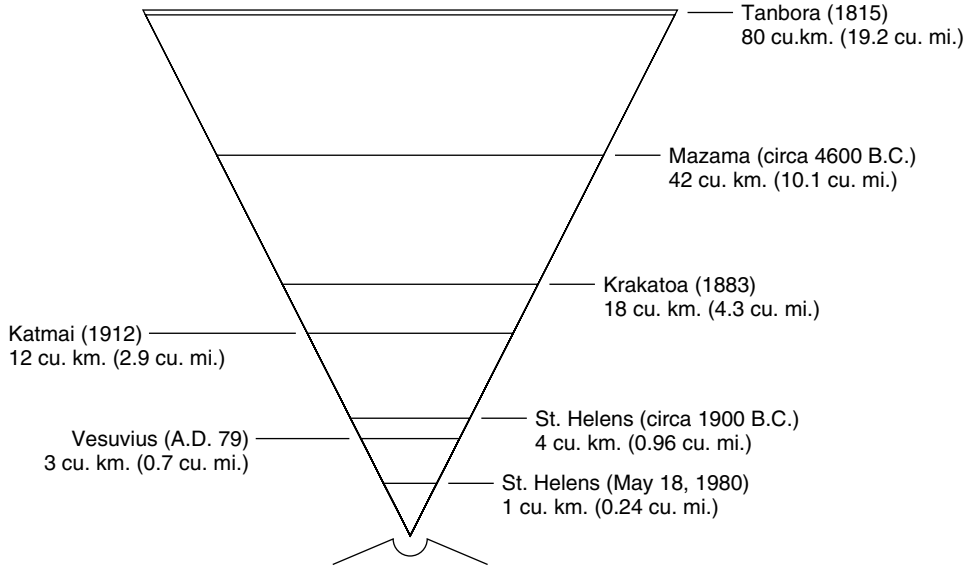

Fig. 4. Relative quantities of ejecta from major and well-known volcanic eruptions.

explosions are known to occur, but to date there is no established explanation for their initiation and propagation (Fowles, 1979).

The effect of gases and aerosols (particles) in the stratosphere and troposphere upon the amount of solar radiation reaching the surface of the earth is not thoroughly understood. In the case of the Mt. Saint Helens 1980 eruption, due to gravitational sedimentation, larger particles were found in the tropospheric samples than in the stratospheric ones. Most of the particles in the stratosphere were several tenths of a micrometer in size, whereas a strong enhancement of micrometer-sized particles was observed in the tropospheric samples. Sulfuric acid was present chiefly as a coating on the ash particles in the troposphere and as both separate small particles and large composite particles in the stratosphere (Chuan et al., 1981; Farlow et al., 1981). The concentrations of particles less than 10 micrometers in diameter in the ash emissions from Mt. Saint Helens were more than 1000 times greater than those in the ambient air. Mass loadings of particles less than 2 micrometers in diameter were generally several hundred micrograms per cubic meter. Mineralogy of the particles varied considerably with time after eruption. The volume percent of glass ranged from 37 to 100%; of plagioclase, 0 to 32%; hornblende, 0 to 21%; and pyroxene, 0 to 22%.

Increased burdens of atmospheric aerosols can lead to either a cooling or warming of the Earth, depending upon the optical properties of the particles. Samples of particles from Mt. Saint Helens were collected in both the stratosphere and troposphere for measurement of the light absorption coefficient. Results indicate that the stratospheric dust had a small but finite absorption coefficient, ranging up to 2×10^{-7} per meter at a wavelength of 0.55 micrometer, which is estimated to yield an albedo for single scatter of 0.98 or greater. Tropospheric results showed similar high values of an albedo for single scatter.

Gaseous emissions vary greatly from one volcano to the next and, in fact, from one eruption to the next. During the steady-state period of activity of Soufrière Volcano (St. Vincent) in 1979, the mass emissions of sulfur dioxide into the troposphere amounted to a mean value of 339 ± 126 metric tons per day. This value is similar to the sulfur dioxide emissions of other Central American volcanoes, but less than those measured at Mount Etna, which is an exceptionally strong volcanic source of sulfur dioxide.

Volcanic Introduction of Chlorine into the Stratosphere. Some researchers (Johnston, 1980) now suspect that considerably more hydrogen chloride (HCl) is injected into the stratosphere by certain volcanic eruptions than previously estimated. In fact, this could amount to as much as 17–36% of the worldwide production of industrial production of chlorine in fluorocarbons — as of 1975 prior to severe reductions in such production brought about by concern with degradation of the protective ozone layer in the stratosphere. Under normal conditions, hydrogen chloride emanating from anthropogenic sources is not a threat to the ozone layer simply because the HCl is soluble in water and thus is removed in rain prior to reaching the stratosphere. Large volcanic eruptions inject HCl directly into the stratosphere forcefully and in significant quantities and thus bypass the absorptive effects of the lower atmosphere. It has been estimated that eruptions of this nature occur at least once per year. As pointed out by Johnston, the moderately to highly silicic magmas of volcanoes along the continental and island arcs, because of their high chlorine content, extreme explosivity, and frequent eruptions are likely to have the greatest atmospheric impact. These observations suggest that the impact of anthropogenic production of chlorine in fluorcarbons should once again be reviewed against the backdrop of disturbance of the ozone layer that may arise from natural, volcanic causes. Researchers have observed, for example, that the Augustine Volcano (Alaska), which erupted in 1976, may have injected 289×10^9 kilograms of HCl into the stratosphere. This quantity is about 570 times the 1975 world industrial production of chlorine and fluorocarbons.

Volcano-Climate and Climate-Volcano Relationships. Although it is readily apparent that volcanic eruptions can affect weather, at least over the short term, the effect of climatic change as a precursor of volcanic eruption is less apparent and still rather poorly understood. Research along these lines has been active in recent years (Ninkovich and Donn, 1976, among others). The general theme is that variations in climate lead to stress changes in the Earth's crust as, for example, by loading and unloading of ice and water masses and by axial and global spin-axis rate changes (due to change in symmetry of mass), factors that may augment volcanic and seismic potential. Relatively recent research has indicated that active volcanic periods (sometimes called "volcanic pulses") which, in past theory, were supposed to have triggered glacial advances, actually occurred hundreds of years after glacial activity. Further, major ice-sheet expansions that have occurred during the past two million years appear to have lagged volcanic triggering events by as much as 70,000 years. However, other research points to some correlation of past major volcanic eruptions and cooling periods. A major part of the problem in sorting out the sequence of events arises from inaccuracies in the dating of ancient volcanic and glacial events.

Rampino, et al. (1979) observe that, although some of the geological dates may be questioned, the instrumental temperature records for the past 200 years show that the major historical eruptions associated with coolings actually occurred after decade-long temperature decreases had been initiated. The examples cited include Tambora (1815), Krakatoa (1883), the 1902 series of eruptions (Santa Maria, Mount Pelée, etc.), and Katmai (1912). Rampino et al. also observe that probably one of the greatest single explosive events of the last 2 million years was the eruption of Toba in Sumatra; its vast ash shower extended from Malaysia to India. Dated at 75,000 years ago, it apparently followed the initiation of the cooling that began with the end of the Brørup (Saint Pierre) interstadial by several thousand years.

Ninkovich and Donn (1976) point out that during historic times, the atmospheric temperature quickly recovered after relatively large eruptions. Only an unusually high frequency of eruptions could have a long-term climatic effect. During historic times, this has not occurred.

As pointed out in the entry on **Climate**, the weather (over a period of a year or so) and the climate (over several centuries or more) are two different considerations. The effects of volcanic ash in the atmosphere on weather have been well documented in a number of instances. One of the most thoroughly researched is the so-called Year without a Summer, which adversely affected New England in 1816, following the eruption of Tambora in 1815. In New England in 1816, it snowed in June, with killing frosts continuing through August. The economic and social effects of this weather change are well portrayed by Stommel and Stommel (1979).

Because of its recent interest, it should be pointed out that, in the observations of one scientist, Mt. Saint Helens just did not have what it takes to thicken the light haze in the stratosphere sufficiently to block off much sunlight and thus cool the air near the ground. Little or no detectable effects were observed after the May 18, 1980 eruption.

Tsunamis Generated by Volcanic Eruptions. As reported by Kienle and Kowalik (University of Alaska-Fairbanks) and Murty (Institute of Ocean Sciences, British Columbia), during an eruption of the Alaskan volcano Mount St. Augustine in the spring of 1986, concern developed over the possibility that a tsunami (large water wave induced by sudden upheaval or subsidence of the sea floor) might be generated by the collapse of a portion of the volcano into the shallow water of Cook Inlet. A similar edifice collapse of the volcano and ensuing sea wave occurred during an eruption in 1883. Other sea waves resulting in large loss of life and property have been generated by the eruption of coastal volcanoes in various parts of the world. Fortunately, this did not occur in 1986.

Tsunamis can travel across the sea over long distances and can be profoundly hazardous, sometimes arriving unexpectedly, long distances from the source. The researchers estimate that tsunamis of volcanic origin (not including earthquakes and submarine landslides) have killed about 25% of the people who have experienced the direct effects of catastrophic volcanic eruptions since A.D. 1000. See also **Tsunami**.

Because progress toward fully understanding how volcanic processes can trigger tsunamis has been slow, and because few modern field observations are available to study the problem of wave generation, propagation, and run-up, the investigators targeted on the case of Mount St. Augustine in creating numerical simulations and models. Details are beyond editorial limitations here. See reference listed.

Mount Saint Helens. The eruption of Mount St Helens in 1980 has been one of the most analyzed and discussed of volcanic events in recent decades. The eruption was the first such eruption in the lower 48 United States since the milder eruptions of Lassen Peak in California in 1914–1917. In the 1980 event, 62 persons were killed or reported missing. Property damage exceeded $1 billion.

About 2.6 cubic kilometers (0.65 cubic mile) of volcanic rock were displaced. About 0.5 cubic kilometer (0.12 cubic mile) of liquid rock magma were produced. An area of over 500 square kilometers (193 square miles), essentially mountainous and forested terrain, was devastated. One of the largest avalanches in recorded history resulted.

Although comparatively small on the long-term scale of volcanic power, the eruption was the fourth largest to occur in the past 100 years, surpassed (in terms of ejecta) only be Krakatoa (1883), Santa Maria (Guatemala) (1902), and Katmai (Alaska) (1912).

Mount Saint Helens was last active in 1831–1857. For years, it has been considered by geologists to have a "bad record," dating back some 4500 years, with at least 20 separate events.

The volcano gave its first warning of recent activity by seismographic measurements on April 20, just short of one month prior to the big eruption. Heightened seismographic activity was followed on March 17 by small steam and ash eruptions. The column of gases and aerosols from the main eruption reached a height of some 4.9 kilometers (3 miles). The vapor released contained small amounts of carbon dioxide, sulfur dioxide, hydrogen sulfide, and hydrogen chloride, along with much steam. A prior small crater progressively changed to an oval basin (500 × 300 meters; 1640 × 984 feet) and a depth of 200 meters (656 feet). See Fig. 5.

Geologists estimate that, during the preliminary period of activity, energy dissipated by the volcano amounted to only 1/17,000th of the energy release during the great eruption. Prior to the large eruption, seismic activity increased to a rate of about 50 earthquakes of magnitude 3+ (known as an "earthquake swarm") per day. A bulge in the mountain appeared. In early May, the bulge expanded at about a rate of 1.5 meters (about 5 feet) per day. The diameter of the bulge reached about 2 kilometers (1.2 miles) and had moved outward from the original profile of the mountain by about 100 meters (382 feet). See Fig. 6.

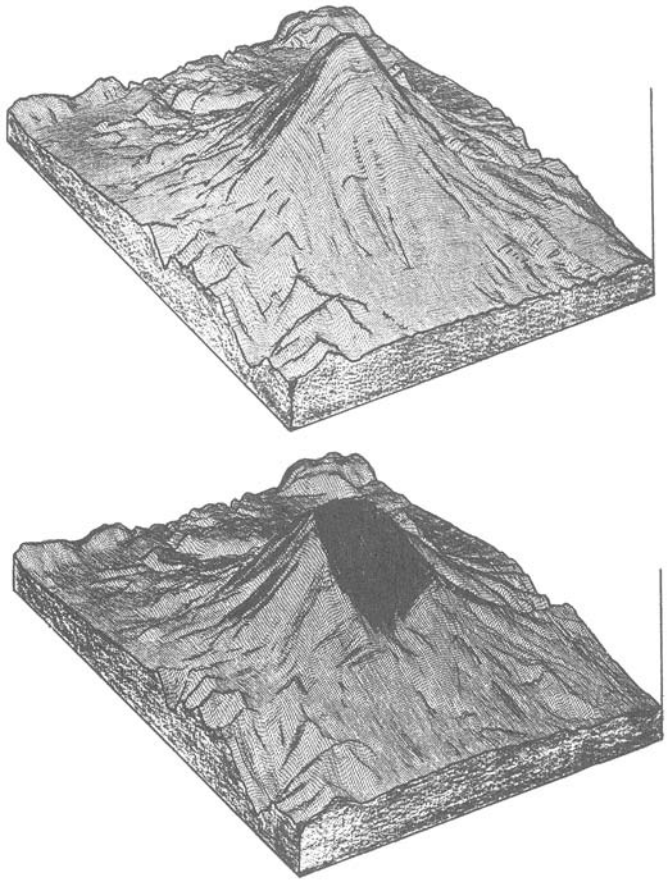

Fig. 5. Alteration of the peak of Mount Saint Helens by explosive eruption of May 18, 1980. Upper view, before explosion; lower view, after. Some 400 meters (1312 feet) of the top were removed, forming a crater of about 750 meters (2461 feet) deep. (*Drawings based on digitally prepared map created at the Western Mapping Center of the U.S. Geological Survey.*)

The major eruption occurred at 8:32 AM (May 18, 1980). In addition to the explosion the avalanche produced was catastrophic. Some 2 cubic kilometers (0.5 cubic mile) of crushed rock and glacier ice plunged into nearby Spirit Lake. Mud and avalanche flows proceeded in all directions from the center of the eruption. Estimates suggest that the avalanche at one point accelerated to a velocity of about 250 kilometers (155 miles) per hour. Another path of the avalanche took it over a nearby mountainous ridge that was some 360 meters (1181 feet) high. Ultimate measurements showed that in just one direction the avalanche (pyroclastic flow) deposited debris over a length of 21 kilometers (13 miles) and from 1 to 2 kilometers (0.6 to 1.2 miles) wide and about 150 meters (492 feet) deep.

The lateral blast of the explosion is estimated to have reached a temperature of 300 °C (572 °F) with steam-and-debris-filled clouds traveling at a rate of 100–400 kilometers (62–248 miles) per hour (well below the speed of sound). This blast destroyed some 550 square kilometers (212 square miles) of mountain topography in the northeast-northwest arc out of the volcano. Large trees were burned and uprooted in an area some 10–15 kilometers (6.2–9.3 miles) across and beyond this, in a blowdown zone.

The vertical plume from Saint Helens reached a high altitude and due to high-altitude winds commenced to fall on central Washington within a few hours. At one location (Ritzville, Washington), located about 330 kilometers (205 miles) from the volcano, the ash fall accumulation measured 70 millimeters (2.75 inches) in thickness. The ash fall was comprised of sand-sized fragments of dark volcanic rock with feldspar

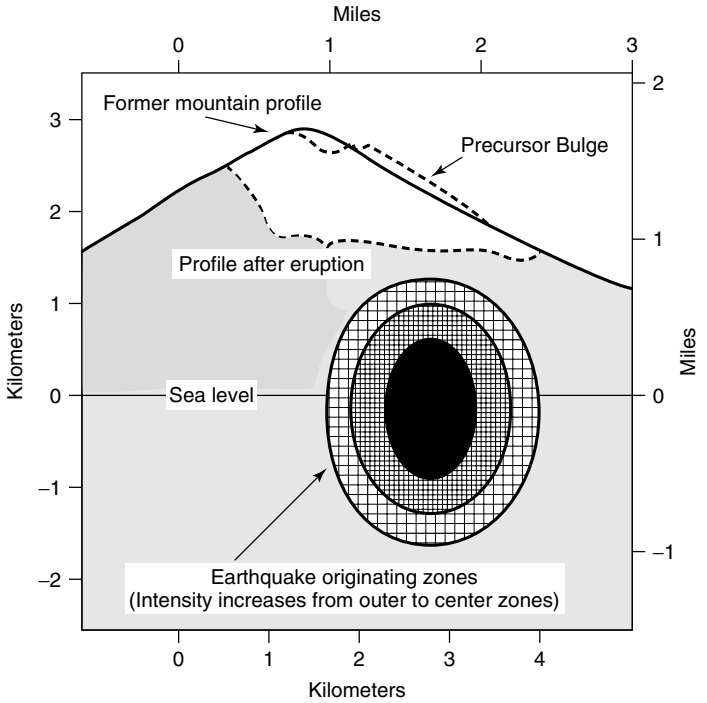

Fig. 6. Sectional profile of Mount Saint Helens showing outline of mountaintop before May 18, 1980 eruption. Note the precursor bulge which commenced to form in April and the profile after eruption. The large oval depicts assumed originating zones of "earthquake swarms." (*Drawing based on data gathered by the U.S. Geological Survey and the Department of Geophysics, University of Washington. Portrayal suggested by Decker and Decker, 1981.*)

crystals of a lighter color. A bit later, a deposit of saltlike volcanic glass followed.

Mud flows were a serious consequence of the eruption. The Toutle and Cowlitz rivers were clogged. Historic highwater marks were exceeded by some 9 meters (29.5 feet).

The explosion of Mt. Saint Helens has been compared technically with that of the eruption of Bezymianny in Kamchatka (1955–1956). The latter event also went through five similar phases. The earthquake swarm persisted 23 days instead of only a few days in the case of Mt. Saint Helens. Seismic monitoring gave geologists some warning of the probable nature of the eruption, although its extent exceeded expectations.

Ash from the eruption fell over a diverse agricultural area with some deposits up to 30 kilograms per square meter (6.1 pounds per square foot). Crop losses were estimated in eastern Washington at about $100 million, or about 7% of the annual crop. Ash on plant leaves reduced photosynthesis by up to 90%, but most plants shed the ash through actions of wind and rain. With the possible exception of sulfur, there was no nutrient value of the ash. Insect loss (destructive and beneficial) was significant, but no populations were fully destroyed.

Since 1980, magma has worked its way upward to form a new dome, measuring approximately 320 meters high and 1 km wide (1050 ft; 0.6 mi), which rests on the crater floor. Mount Saint Helens has become a real-time laboratory for the U.S. Geological Survey and other scientists interested in volcanology. The USGS operates the Cascades Volcano Observatory (CVO) near Mount Saint Helens. The scientists at CVO are reasonably confident that they will be able to warn days or even weeks in advance of the next dome-building eruption. Numerous seismometers and tiltmeters are placed on the dome. Other instrumentation includes laser distance-measuring equipment for monitoring "imperceptible" dome movements. Studies to date indicate that slow but accelerating outward movement of the dome will occur before an actual eruption. CVO scientists have reported that the precursory dome movement is a sluggish version of one way that the dome grows during a full-blown explosion. A model of dome growth has been called the "ruptured onion": as new magma enters a molten core within the dome, it adds to the dome and causes it to expand laterally to form a layered, onionlike structure. Some highly viscous magma may also escape as lava as it nears the top of the dome. The driving force appears to be magma that exists in temporary storage that is about 2 km (1.2 mi) below the crater floor. This underground magma pushes the less buoyant and more viscous magma ahead by way of a conduit that is only 5 to 10 meters (15 to 30 ft) wide. As increasing amounts of the volcano's "throat" is cleared, the flow increases, thus causing the characteristic accelerating dome growth.

It is interesting to note the correlation between eruption precursors and the moon, a relationship that may prove useful for forecasting the volcano's behavior. It is assumed that additional stress resulting from the lunar gravitational distortion of the Earth's crust affect the volcano's behavior and could, when coupled with other forces, trigger a dome-building eruption (to be distinguished from a major explosive eruption). The correlation still is regarded speculatively by some scientists.

In considering what factors may cause the next explosive eruption of Mount Saint Helens, three are regarded most likely: (1) a catastrophic landslide that may fall off the dome; (2) a new injection of magma into the system; or (3) blockage of the volcano's throat by congealing magma that would result in a great build-up of pressure in the system. Because CVO scientists are confident in predicting short-term behavior of the volcano, the general area of Mount Saint Helens has been reopened to the public.

Most everyone agrees with Herbert E. McLean, who in writing for American Forests magazine in 1991, stated, "In the 10 years since it blew its top, the world's most monitored mountain has become a monumental showplace and schoolroom."

Lake Nyos Disaster — Not of Volcanic Origin, But Related. On August 21, 1986, a sudden catastrophic release of gas from Lake Nyos (Cameroon, West Africa) caused the deaths of at least 1700 people. Inasmuch as this is a crater lake, there was strong initial speculation that the disaster was related to volcanic activity. This impression among the lay public has persisted, although official reports of investigations of the incident have since disproved a direct volcanic connection. Testimonies of survivors and autopsies of the victims conclusively support the cause of death (including over 3000 cattle) was a gas cloud composed mainly (estimated 98 to 99%) of carbon dioxide (CO_2), which resulted in CO_2 asphyxiation. Because CO_2 is denser than ambient air and because its density would have increased as it cooled upon expansion, the cloud tended to maintain its integrity as it spilled over the crater rim into low-lying areas. Typical volcanic gases — hydrogen, hydrogen sulfide, carbon monoxide, hydrogen fluoride, and sulfur dioxide — were below detection limits of a few parts per million 12 days after the disaster. Carbon dioxide in the lake water was estimated at least 100 times more abundant relative to sulfur than in volcanic gases. A further clue to the existence of an overwhelming CO_2 cloud, as contrasted with that which might have resulted from a volcanic eruption, is the observation that foliage was not harmed during the incident.

It is interesting to note that a similar catastrophe occurred in Cameroon in 1984, when 37 persons died along the shore of Lake Monoun, another typical deep, tropical lake, perennially warmed at the top to form a lid shutting in deeper, denser waters. Decomposition of organic matter in such lakes consumes all available oxygen in its deep waters, resulting in production of CO_2 and some methane. Investigators of the 1984 disaster also concluded that the cause of fatalities was an overwhelming presence of carbon dioxide.

An official report summarizes the scenario of the disaster as follows. Chemical, isotopic, geologic, and medical evidence supports the hypotheses that (1) the bulk of gas released was CO_2 that had been stored in the lake's hypolimnion (the lowermost layer of water in a lake, characterized by an essentially uniform temperature that is generally colder than elsewhere in the lake and often by relatively stagnant or oxygen-poor water); (2) the victims exposed to the gas cloud died of CO_2 asphyxiation; (3) the CO_2 was derived from magmatic sources; and (4) there was no significant, direct volcanic activity involved. The limnological nature of the gas release suggests that hazardous lakes may be identical and thus should

be monitored to warn of future incidents of this type. See Kling, et al. reference listed.

An abridged glossary of terms used to describe Volcano activity and features would include:

Aa: Aa (pronounced "ah-ah" -a Hawaiian term), is lava that has a rough, jagged, spiny, and generally clinkery surface.

Active volcano: A volcano that is currently erupting, or has erupted during recorded history.

Aerosol: Fine liquid or solid particles suspended in the atmosphere. Aerosols resulting from volcanic eruptions are tiny droplets of sulfuric acid — sulfur dioxide that has picked up oxygen and water.

Airfall: Volcanic ash that has fallen through the air from an eruption cloud. A deposit so formed is usually well sorted and layered. Also called *ashfall*.

Andesite: A medium-colored dark gray volcanic rock containing 53–63 percent silica with a moderate viscosity when in a molten state. Intermediate in color, composition, and eruptive character between basalt and dacite.

Ash (volcanic): Fragments less than 2 millimeters (about 1/8 inch) in diameter of lava or rock blasted into the air by volcanic explosions.

Ash cloud: The fine material that is generated by a pyroclastic flow and rises above it.

Ash flow: A pyroclastic flow consisting predominantly of ash-sized (less than 4 millimeters in diameter) particles. Also called a *glowing avalanche* if it is of very high temperature.

Atmospheric shock wave: Strong compressive atmospheric wave driven by volcanic ejecta.

Ballistic fragment: An explosively ejected rock fragment that follows a ballistic trajectory.

Basalt: Dark-colored, low-silica (less than 53 percent SiO_2), low viscosity volcanic rock that is relatively fluid when molten; eruptions of basalt are generally nonexplosive and tend to produce relatively long thin lava flows like those common in Hawaii.

Base surge: Turbulent, low-density cloud of rock debris and water and (or) steam that moves over the ground surface at high speed.

Black Sand Beach: The famous "black sand" beaches of Hawaii were created virtually instantaneously by the violent interaction between hot lava and sea water.

Blowdown: Trees felled by a volcanic blast.

Caldera: A large volcanic collapse depression, commonly circular or elliptical when seen from above.

Cinders: Cinders are lava fragments about 1 centimeter (about 1/2 inch) in diameter.

Cinder cone: A steep-sided volcano formed by the explosive eruption of cinders that form around a vent.

Conduit (volcanic): A subterranean passage through which magma reaches the surface during volcanic activity.

"Continental" Volcanoes: In the typical "continental" environment, volcanoes are located in unstable, mountainous belts that have thick roots of granite or granitelike rock. Magmas, generated near the base of the mountain root, rise slowly or intermittently along fractures in the crust. During passage through the granite layer, magmas are commonly modified or changed in composition and erupt on the surface to form volcanoes constructed of nonbasaltic rocks.

Crater: A steep-sided, usually circular depression formed by either explosion or collapse at a volcanic vent.

Dacite: Typically light-colored, fairly silica-rich (63 to 68 percent SiO_2) volcanic rock with a high viscosity when in a molten state; eruptions are commonly explosive (e.g., Mount St. Helens' eruption of May 18, 1980) and may produce voluminous tephra, pyroclastic flows, and lava domes.

Diatreme: A general term for a volcanic vent or pipe drilled through enclosing rocks (usually flat-lying sedimentary rocks) by the explosive energy of gas-charged magmas.

Directed blast: A hot, low-density mixture of rock debris, ash, and gases that moves at high speed along the ground surface, and generated by explosions.

Dome: A steep-sided mount that forms when very viscous lava is extruded from a volcanic vent. Also called *Lava dome*.

Fumarole: A vent or opening in the ground from which hot water vapor (steam) and (or) volcanic gases are emitted.

Harmonic Tremor: Continuous rhythmic earthquakes in the Earth's upper lithosphere that can be detected by seismographs. Harmonic tremors often precede or accompany volcanic eruptions.

Hot Spot: An area in the middle of a lithospheric plate where magma rises from the mantle and erupts at the Earth's surface. Volcanoes sometimes occur above a hot spot.

Igneous rocks:

K-Ar dating: Determination of the age of a mineral or rock in years based on the known radioactive decay rate of potassium-40 to argon-40.

Lahar: A flowing mixture of water-saturated rock debris that forms on the slopes of a volcano, and moves downslope under the force of gravity, sometimes referred to as debris flow or mudflow. The term comes from Indonesia.

Lava: The term used for magma once it has erupted onto the Earth's surface.

Lava tube: During long-lived eruptions, lava flows tend to become "channeled" into a few main streams. Overflows of lava from these streams solidify quickly and plaster on to the channel walls, building natural levees or ramparts that allow the level of the lava to be raised. Lava streams that flow steadily in a confined channel for many hours to days may develop a solid crust or roof and thus change gradually into streams within lava tubes. Tube-fed lava can be transported for great distances from the eruption sites.

Lithic (volcanic): Pertains to pyroclastic deposits that contain abundant fragments of previously-formed rocks and/or dense fragments.

Loess: A well-sorted deposit of windblown silt-sized particles that forms a blanket over the landscape.

Maars: Also called "tuff cones", maars are shallow, flat-floored craters formed above diatremes as a result of a violent expansion of magmatic gas or steam. Maars range in size from 200 to 6,500 feet across and from 30 to 650 feet deep, and most are commonly filled with water to form natural lakes.

Magma: Molten rock containing liquids, crystals, and dissolved gases that forms within the upper part of the Earth's mantle and crust. When erupted onto the Earth's surface, it is called lava.

Mantle: A zone in the Earth's interior between the crust and the core that is 2,900 kilometers (1,740 miles) thick. (The lithosphere is composed of the topmost 65–70 kilometers (39–42 miles) of mantle and the crust).

Mudflow: The flowing mixture of water and debris (intermediate between a volcanic avalanche and a water flood) that forms on the slopes of a volcano. Sometimes called a *debris flow* or *lahar*, a term from Indonesia where volcanic mudflows are a major hazard.

Pahoehoe: Pahoehoe (pronounced "pah-hoy-hoy" -a Hawaiian term), is lava that in solidified form is characterized by a smooth, billowy, or ropy surface.

Pillow Lava: Fluid lava erupted or flowing under water may form a special structure called *pillow lava*. Such structures form when molten lava breaks through the thin walls of underwater tubes, squeezes out like toothpaste, and quickly solidifies as irregular, tongue-like protrusions. This process is repeated countless times, and the resulting protrusions stack one upon another as the lava flow advances underwater. The term pillow comes from the observation that these stacked protrusions are sack-or pillow-shaped in cross section. The bulk of the submarine part of a Hawaiian volcano is composed of pillow lavas.

Pluton: Pertaining to igneous rock bodies that form at great depth.

Pumice: A light-colored, frothy volcanic rock, usually of dacite or rhyolite composition, formed by the expansion of gas in erupting lava. Commonly perceived as lumps or fragments of pea size and larger but can also occur abundantly as ash-size particles. Because of its numerous gas bubbles, pumice commonly floats on water.

Pyroclastic: Pertaining to fragmented (clastic) rock material formed by a volcanic explosion or ejection from a volcanic vent.

Reticulite: During the exceptionally high fountaining episodes of some eruptions, an extremely vesicular, feathery light pumice, called *reticulite*

or thread-lace scoria, can form and be carried many miles downwind from the high lava fountains.

Rhyolite: Typically a light-colored crystalline or black glassy volcanic rock or magma, containing more than 68 percent silica with a very high viscosity when in a molten state.

Satellite vent: A secondary vent of flank vent at a volcanic center.

Shield volcano: A volcano that resembles an inverted warrior's shield. It has long gentle slopes produced by multiple eruptions of fluid lava flows.

Spreading Ridges: Places on the ocean floor where lithospheric plates separate and magma erupts. About 80 percent of the Earth's volcanic activity occurs on the ocean floor.

Subduction Zone: The place where two lithosphere plates come together, one riding over the other. Most volcanoes on land occur parallel to and inland from the boundary between the two plates. (Teacher's Packet)

Tephra: Solid material of all sizes explosively ejected from a volcano into the atmosphere.

Tuff: Used loosely as a collective term for all consolidated pyroclastic rocks.

Vent: The opening at the Earth's surface through which volcanic materials (lava, tephra, and gases) erupt. Vents can be at a volcano's summit or on its slopes; they can be circular (craters) or linear (fissures).

VOLTAGE DIVIDER. The ordinary three-terminal resistance may be used as a voltage divider. If no current is taken from the intermediate tap the voltages will be in proportion to the resistance included between the taps. In many applications a potentiometer is used as a voltage divider so the voltage may be adjusted by varying the position of the tap. If current is drawn from the tap the exact distribution of the voltage is altered but the total voltage applied across the divider is still divided between the various sections. Figure 1 shows some typical arrangements.

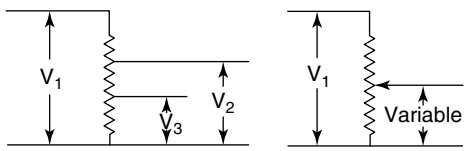

Fig. 1. Voltage divider.

VOLTAGE DOUBLER. This is a connection of capacitance and rectifiers across an ac source which gives a dc output voltage approximately twice that of the normal connection. The exact value of the output voltage depends upon the load and for very high loads may not even approach the theoretical double value. A circuit is shown in the accompanying figure. On one half-cycle C_1 charges through rectifier 1 and on the other half-cycle C_2 charges through rectifier 2, the polarities being as shown in Fig. 1. It is seen then that the output voltage is the sum of the two capacitor voltages.

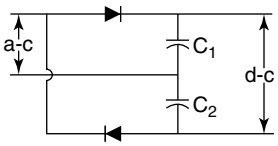

Fig. 1. Voltage doubler.

VOLTAGE-TO-FREQUENCY A/D CONVERTER. This type of analog-to-digital converter converts the magnitude of the analog-input signal (usually a current or a voltage) into a frequency which can be measured digitally. As an example, the analog-input signal could control the bias of a varacter diode. If the diode is used as the frequency-determining component of a resonant circuit in an oscillator, then the frequency of oscillation would depend on the value of the input signal.

In the Fig. 1, the voltage-to-frequency A/D converter uses an integrator. At commencement of conversion, the counter is returned to zero and the integrator is reset. An input signal V_S is integrated until an output value V_r is reached by the integrator. A change in state of the comparator output detects this point. Upon this change of state of the comparator, the integrator is reset and the process repeated.

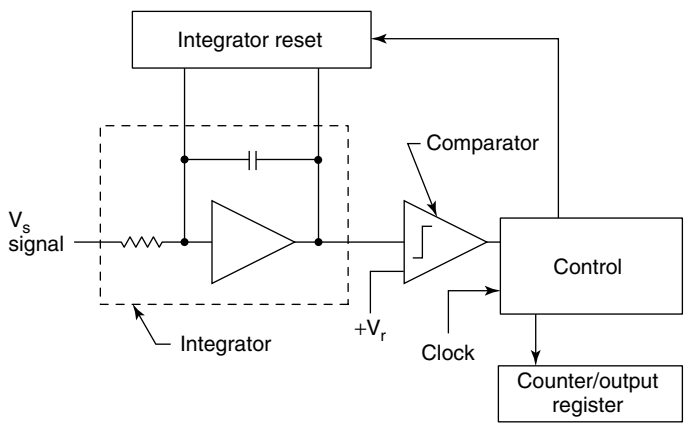

Fig. 1. Voltage-to-frequency analog-to-digital converter.

The rate of integration depends upon the value of the input signal. Thus, the frequency of the sawtooth waveform that is generated by the integrator is a function of the input signal. If the number of integration cycles that take place in a fixed time period are counted, a digital representation of the input signal is yielded. Clock pulses in a separate counter determine the counting interval.

An advantage of the voltage-to-frequency A/D converter is that it provides a digital representation of the average value of the input signal during the conversion interval. Thus, input-noise transients have minimal effect on performance. As the result of serial counting, this A/D converter is comparatively slow. Speed usually is less than 1,000 samples/second at a resolution of 10 bits or less.

THOMAS J. HARRISON, International Business Machines Corporation, Boca Raton, FL

VOLTAIC CELL. Two conductive metals of different potentials, in contact with an electrolyte, which generate an electric current. The original

voltaic cell was composed of silver and zinc, with brine-moistened paper as electrolyte. Semisolid pastes are now used; electrodes may be lead, nickel, zinc, of cadmium.

See also **Photovoltaic Cells**.

VOLTERRA, VITO (1860–1940). Volterra was an Italian mathematician and physicist. It is believed that at about age thirteen he was so inspired by the Jules Verne's novel, *From the Earth to the Moon*, that he tried to determine the trajectory of a projectile in the combined gravitational fields of the Earth and moon. Volterra made important contributions to areas of higher analysis and mathematical physics. His name is associated with the creation of the theory of functionals and with the theory of integral and integro-differential equations. He also made important contributions in many areas of applied science. He did significant work on the mathematics of population growth, arguing that cooperation among people would encourage increases in the food supply and thus the Earth could accommodate a greater increase in population.

In 1917, Volterra established the Office for War Inventions in Italy and promoted scientific and technical collaboration among the Allies.

Volterra was a brilliant scientist who became a member of almost every major scientific and mathematical society. He was elected to the Pontifical Academy of Sciences in 1936. He was also honored at many universities as a gifted teacher.

See also **Functional Analysis**; and **Integral Equation**.

J. M. I.

VOLUME (Critical). The volume occupied by one gram of a liquid or gaseous substance at its critical temperature and critical pressure.

VOLUME (Geometry). The volume of a parallelepiped is often represented as a scalar triple product of three vectors, the edges of the solid. In calculus, the volume of a solid may be found by means of definite integrals, as follows: (a) If a plane perpendicular to the X-axis at a distance x from the origin cuts, from a given solid, a section whose area is $A(x)$, then the volume of that part of the solid between $x = a$ and $x = b$ is given by the definite integral

$$V = \int_a^b A(x)\,dx$$

(b) Suppose the solid is that part of a right circular cylinder included between the XOY-plane and the surface $z = f(x, y)$, then its volume is given by the definite double integral

$$V = \int_{a1}^{a2} \int_{b1}^{b2} f(x, y)\,dx\,dy$$

where the base of the cylinder is bounded by the curves $x = a_1$, $x = a_2$, $y = b_1$, $y = b_2$. (c) If the solid is divided into volume elements, $d\tau = dx\,dy\,dz$ which are right prisms with base $dx\,dy$ and altitude dz, the volume of the solid is given by the triple definite integral

$$V = \int_{x1\,y1\,z1}^{x2\,y2\,z2} dx\,dy\,dz$$

where the limits are determined by the boundary of the given solid. In spherical polar coordinates $d\tau = r \sin\theta\, dr\, d\theta\, d\phi$ and in cylindrical coordinates $d\tau = p\,dp\,d\phi\,dz$.

Vector methods are often useful for expressing the volume of a solid (see also **Vector Integral**).

See also **Calculus**; and **Parallelepiped**.

VOLUME (Standard). The volume occupied by one gram molecular weight of a gas at 0 °C and a pressure of 1 standard atmosphere.

VON BAEYER, ADOLF (1835–1917). A German chemist who received the Nobel Prize for chemistry in 1905. He was recognized for his services in the advancement of organic chemistry and the chemical industry, through his work on organic dyes and hydroaromatic compounds. He was educated in Berlin under the direction of Bunsen and Kekule. He was a professor in Strasbourg and Munich. Many discoveries included barbituric acid and the molecular structure of indigo.

VON BEHRING, EMIL ADOLF (1854–1917). Von Behring was a German medical scientist who developed antitoxins against diphtheria and tetanus.

The son of a schoolteacher, Behring was born in Hansdorf, Germany (although the town is now part of Poland). In 1874, he became a cadet at the Friedrich Wilhelms Institute in Berlin, where students could receive a free medical education in return for promising to serve as military surgeons in the Prussian army for ten years. Behring received his MD in 1878 and passed his state board examinations in 1880. After an internship at the Charité hospital in Berlin, he was assigned to a cavalry regiment.

While serving in the army, in addition to his clinical duties Behring undertook researches on wound infection and experimented with the use of the chemical iodoform as a disinfectant. He concluded that iodoform did not kill bacteria, but neutralized their toxic effects. In 1887, he was sent to study pharmacology with Carl Binz in Bonn, where he improved his knowledge of chemistry and animal experimentation. He joined the staff of Robert Koch's Institute of Hygiene in Berlin in 1889 and also completed his army service that year. Behring remained Koch's assistant for six years, accompanying him to the new Institute for Infectious Diseases in Berlin in 1891, and did his pioneering work on antitoxins and serum therapy in this period. See also **Binz, Carl (1832–1913)**; **Drug Discovery (The History)**; and **Koch, Heinrich Hermann Robert (1843–1910)**.

By 1890 it had been established that the diphtheria and tetanus bacilli produce toxins which cause the symptoms of these diseases. Working in Koch's institute, Behring and Shibasaburo Kitasato injected experimental animals with increasing sub lethal doses of tetanus toxin and found that the blood serum of these animals developed an ability to neutralize the toxin. This serum could also produce short-term immunity in another animal. Behring and Kitasato, in a paper published in December of 1890, described this property of the serum as 'antitoxic'. A week later, Behring published a second paper in which he applied these same principles to a much more common disease, diphtheria. These two papers laid the groundwork for serum therapy and antitoxic immunity. See also **Immunology (The History)**; and **Kitasato, Shibasaburo (1852–1931)**.

Using guinea-pigs and then sheep, Behring worked to develop serum antitoxin into a useful therapeutic agent for the treatment of diphtheria. His colleague at Koch's institute, Paul Ehrlich, played a crucial role in developing a clinically useful, standardized preparation. As the antitoxin was introduced into medical practice, the mortality rate from diphtheria dropped from 48% to 13% in the children's hospitals of Berlin in 1892. Emile Roux and André Martin in Paris developed a method of immunizing horses in 1894, and Behring immediately adopted and extended this procedure, which greatly increased antitoxin production. Behring was hailed as the savior of the children, and in 1901 he was elevated to the Prussian nobility, thereafter being known as Von Behring. In that same year, he was awarded the Nobel Prize in Medicine or Physiology for his work on serum therapy, especially its application against diphtheria.

In 1894, Behring left Koch's institute to accept an appointment, secured with the aid of the Prussian government, as Professor of Hygiene at Halle. He was a mediocre teacher, and was transferred the following year to the chair of hygiene at the University of Marburg, despite opposition from the medical faculty there.

At Marburg, Behring continued research on tuberculosis begun earlier. One of his major contributions in this area was to point out the dangers to infants of drinking milk from cows infected with tuberculosis. He also developed a widely used vaccine for cows. His search for a vaccine against human tuberculosis, however, proved fruitless and he eventually abandoned it. See also **Tuberculosis**.

The major success of his later years was the development in 1913 of an active preventive vaccine against diphtheria, based on a toxin–antitoxin mixture rendered stable by formaldehyde. Unlike the diphtheria antitoxin, which was used to treat individuals who already had the disease, the vaccine provided long-lasting immunity against diphtheria. Behring's preparation was the vaccine of choice until the introduction of a superior product in 1924. Immunization for diphtheria is now routinely given to children in their first year in the United States and many other countries. See also **Vaccination**.

During World War I, preventive tetanus vaccination, based upon Behring's work, saved the lives of millions of German soldiers. As a result, he was awarded the Iron Cross, an unusual decoration for a non-combatant.

For many years, Behring was involved in a controversy with Elie Metchnikoff and others, defending his humoral theory of immunity (based on the principle of immune factors in the blood serum) against the cellular theory that was supported by Metchnikoff's discovery of the role of the 'phagocytes' or white blood cells in defending the body against disease. Both mechanisms actually play a role in the organism's defense system. In spite of his professional disagreement with Metchnikoff, the two were good friends. Behring maintained close ties with foreign scientists, especially Metchnikoff, Emile Roux, and other colleagues at the Pasteur Institute in Paris. See also **Metchnifoff, Elie (Ilya) (1845–1916)**; and **Roux, Pierre Paul Emile (1853–1933)**.

Behring had a taste for the good things in life. Thanks largely to profits based on the commercial success of his serum therapy, Behring found himself in comfortable financial circumstances. He owned a large estate in Marburg, where he entertained foreign visitors frequently, as well as a house in Capri, a favorite retreat. An authoritarian man with a strong ego, he alienated some of his German colleagues, such as Koch and Ehrlich. Behring was largely a solitary figure who never attracted a school of followers. In his later years, he suffered periodically from depression, occasionally seeking treatment in a sanatorium. His death in 1917 in Marburg was a result of pneumonia. See also **Ehrlich, Paul (1854–1915)**.

JOHN PARASCANDOLA, U.S. Department of Health and Human Services, Rockville, MD

VON BRAUN, WERNHER (1912–1977). Wernher von Braun is, without doubt, the greatest rocket scientist in history. His crowning achievement, as head of NASA's Marshall Space Flight Center, was to direct the mission to land the first men on the Moon in July 1969.

Wernher von Braun was born in 1912 in Wirsitz, Germany (now part of Poland), into an aristocratic Prussian family. His father was Baron Magnus von Braun and his mother was a direct descendent of Valdemar I of Denmark (1131–1182). At an early age Wernher developed a fascination for rockets, inspired by the ancient Chinese who invented fireworks. At the age of 12, he tried his first practical rocket experiment. He strapped six rockets to a small wagon and lit them up. The wagon performed beyond his wildest dreams and careened about crazily, trailing a tail of fire like a comet. When the rockets finally burned out, ending their sparkling performance with a magnificent thunderclap, the wagon rolled majestically to a halt. The police, who arrived late for the beginning of his experiment, but in time for the grand finale, were unappreciative. They took young Wernher into custody. Fortunately, no one was injured and he was released to the Minister of Agriculture, his father. So began a career in rocketry that changed human history.

Von Braun attended the French Gymnasium School in Berlin, but was not a star pupil. He spent much of his time building an automobile in his father's garage instead of studying books. Von Braun's grades improved after his father transferred him to a boarding school. Part of his education there involved working in small groups to develop technical skills. He would draw upon these lessons many times later in his career when working in teams. Before bedtime he was permitted to examine the stars with a small telescope that his mother bought him. Thus began his interest in astronomy.

One day in 1925, von Braun saw an ad in an astronomy magazine about a book called *The Rocket to the Interplanetary Spaces*, by Professor Hermann Oberth. He ordered the book at once and, when it arrived, opened it breathlessly. To his consternation, he could not understand a word. Its pages were a baffling conglomeration of mathematical symbols and formulae. Rushing to his teacher, he cried, "How can I understand what this man is saying?" To von Braun's dismay, his teacher told him to study mathematics and physics, but with the glamorous prospect of a life devoted to space travel, these subjects took on a new meaning. Von Braun was determined to master them and he began to bury himself in their mysteries, and after a few years, he succeeded in graduating a year ahead of his class.

After graduating from school, von Braun became a student at the Berlin Institute of Technology and worked in his spare time as an assistant for Professor Oberth at the German Society for Space Travel. Oberth was trying to prove that liquid fuels, instead of solids, offered the best approach to powering rockets for space vehicles. Oberth's other two assistants were Klaus Riedel and Rudolf Nebel. Their equipment was crude and the ignition system was perilous. Riedel would toss a flaming gasoline-soaked rag over the gas-spitting motor and duck for cover before Oberth opened the fuel valves, and then the motor would start with a roar!

Oberth and his assistants were allowed to conduct experiments as guests on the proving grounds of the Chemical and Technical Institute, the German equivalent of the U.S. Bureau of Standards. In August 1930, Oberth's little rocket engine succeeded in producing a thrust of seven kilograms for 90 seconds, burning gasoline and liquid oxygen. An official of the Institute certified the demonstration and the liquid-fueled rocket motor was, thus, recognized for the first time in Germany as a respectable member of the family of internal-combustion engines. This was a tremendous step forward but, because he had to support a large family, Oberth was forced to return to his teaching job in Romania.

After Oberth's departure, the team's guest status at the proving grounds expired and a new place to conduct the experiments had to be found. Nebel secured a lease on an abandoned 300-acre ammunition storage depot on the outskirts of Berlin. He persuaded the city fathers to let them use the site free-of-charge and for an indefinite period. One of the blockhouses was used as the laboratory and on this building was hung the sign "Raketenflugplatz Berlin" (Berlin Rocket Field).

Nebel did an amazing job of scrounging free materials, which were swapped for skilled labor, such as tin bending or welding. Riedel sketched out a design for a "Minimum Rocket," which they started to build. The motor was located in the nose, not for any scientific reason, but simply because Nebel had scrounged a truckload of aluminum tubing which could only be used if the motor dragged the tanks by the fuel lines.

In 1931, von Braun interrupted his studies at the Institute of Technology in Berlin to study for a semester at the Federal Institute of Technology in Zurich. He returned to Berlin in October for the first public firing of Riedel's rocket. Several local industrialists had been persuaded by Nebel and Riedel to pay one mark each to witness the demonstration. When the moment of truth came, the rocket moved halfway up the launcher tracks, then settled peacefully back on the pad. What an embarrassment, but the admission fees were not returned! The pressurization of the rocket's fuel tanks was unreliable and this problem was soon corrected. Within a few weeks, successful launchings became commonplace and the rocket reached an altitude of 1,000 feet. A small parachute carried the tail section gently back to Earth. Riedel would dash across the field in an old car, jump out, and sometimes catch the rocket before it struck the ground. After such a lucky "hand recovery," they could fire the rocket again immediately.

While taking part in these exciting activities in his spare time, von Braun continued with his formal studies, and graduated from the Berlin Institute of Technology with a bachelor's degree in aeronautical engineering in 1932. Von Braun's exposure to rocketry convinced him that the exploration of space would require far more than just applications of the current engineering technology. To this end he enrolled as a graduate student at the University of Berlin and gained his Ph.D. in physics in 1934. His thesis was about liquid rocket propulsion. Solid propellant rockets had been used for centuries, but liquid propulsion was new. Only miniature motors had been built and tested that used a liquid oxygen/alcohol propellant combination. Von Braun wanted to analyze some of the puzzling phenomena that take place in a rocket engine, such as atomization, combustion, and expansion of gases. Experimentation would be costly and von Braun considered himself fortunate when the research department of the German Army Ordnance Corps sponsored his research and permitted him to conduct dangerous experiments at the Kummersdorf Army Proving Ground.

After gaining his Ph.D., von Braun became a civilian employee of the Army and continued with this work. He designed the V-2 rocket that was used so effectively against Britain during World War II. At the end of the war, the von Braun team at Peenemunde on the Baltic Sea headed south and surrendered to U.S. forces rather than risk capture by the Soviet army.

With 120 of his associates, von Braun was brought to the U.S. as part of "Operation Paperclip" in order to demonstrate their achievements with

V-2 rockets. He arrived in the U.S. in September 1945 under contract to the U.S. Army. During the following five years, he directed high-altitude firings of V-2 rockets at the White Sands Missile Range in New Mexico and was project director of the guided missile development unit at Fort Bliss, Texas.

In 1950, the Fort Bliss rocket development group was transferred to Huntsville, Alabama, where the Army centered its rocket development activities. In Huntsville, the von Braun team worked on the ballistic rockets called Redstone, Jupiter C, Juno, and the Saturn 1B.

After the Soviets' Sputnik went into orbit in 1957 and the Navy's Vanguard rocket blew up on its pad, a version of von Braun's Redstone rocket, called Jupiter-C, put Explorer 1 into orbit in 1958, and another version carried Alan Shepard on the first U.S. sub-orbital flight in 1961.

Von Braun and his team were transferred from the Army's control to NASA's when the National Aeronautics and Space Administration was established in 1958. Von Braun became director of NASA's Marshall Space Flight Center (MSFC) in Huntsville, which was dedicated on July 1, 1960. The von Braun team members were given a choice whether to go to NASA or stay with the Army Ballistic Missile Agency. All elected to be transferred to MSFC on this same date.

Von Braun's management style was to let everybody on the team know that they were important to its success and that any work they did was a reflection on the team. The result was that every team member did his best.

When President Kennedy called for a Moon landing within the decade, von Braun was asked to lead the effort to design and build the rocket. The Saturn V, developed by MSFC, won the race with the Soviet Union to put the first men on the Moon in 1969. After the Moon landings, at the insistence of the NASA Administrator, von Braun, in 1970, went to NASA Headquarters in Washington, DC to serve as Deputy Associate Administrator and to promote space activities. But public interest and support had declined, and von Braun resigned in May 1972 to become vice president for engineering and development at Fairchild Industries, Inc.

In 1975, he founded and became the first president of the National Space Institute, a private group designed to increase public understanding and support of space activities.

VON FRISCH, KARL (1886–1982). Von Frisch was an Austrian ethologist and zoologist born in Vienna. His affiliation was Germany's Munich University Institute of Zoology. He did pioneering work in comparative behavioral psychology. His studies dealt with complex communication between insects particularly under natural conditions. In the 1940's, von Frisch first discovered the significance of the honeybees' dances. Von Frisch and his colleagues made careful accounts of the dance language. He noted with a stopwatch the time that movements lasted, the direction the bee faced while waggling, and how fast the bee dancer finished her circuits. He concluded that the honeybees' dance functioned as a language. Karl von Frisch won the 1973 Nobel Laureate in Medicine for discoveries concerning organization and elicitation of individual and social behavior patterns.

VON HIPPEL-LINDAU DISEASE (VHL). A genetic disorder, of abnormal growth of blood vessels that develop into angiomas or tumors. Angiomas can occur in various parts of the body but generally occur in areas rich in blood vessels, such as in the eye. Problems occur when the angioma grows causing the walls of the blood vessels to weaken and potentially leak. When leakage occurs, damage may result in surrounding tissues and affect organs. Overall, approximately one in 32,000 people in the world has VHL, but the disorder does not favor specific ethnic groups.

VHL is named after two doctors. Dr. Eugene Von Hippel described the genetic condition of the abnormal growth of blood vessels that develop into angiomas or tumors. His particular area of interest and research involved the eye, specifically angiomas in the retina. Dr. Arvid Lindau identified tumors of the spine and brain and is usually associated with VHL in the central nervous system.

As every person is different, so is the severity and onset of VHL, although it usually occurs in adulthood. Anyone with a history of VHL in his or her family should consult with a medical professional about what to do should the symptoms arise. Sometimes, VHL shows no signs or symptoms and the only definitive diagnosis is through DNA testing for the genetic marker, which is important because children can be affected.

An angioma in the eye may be one of the earliest signs of VHL disease. Such angiomas can occur beneath and on top of the retina and are identified by eye care professionals as lesions. If an angioma or blood vessels leak, the retina can detach and result in blindness. If no leakage is identified, careful monitoring of the tumor and its growth is essential in order to prevent retina detachment. Angiomas in the retina or optic nerve are usually not cancerous. These tumors tend to progress slowly, so early detection is key to preventing retina detachment.

The treatment of the retinal angioma depends on its severity and the diagnosis pertaining to any present lesions. Small lesions are easy to treat with laser surgery. For large tumors, eye care specialists may recommend cryotherapy. People with a history of VHL may undergo CT or MRI imaging scans to monitor tumor growth both in the eye as well as other parts of the body. So far, there is no cure for VHL. Research and studies continue in order to help people and professionals better manage VHL.

VON KLITZING, KLAUS (1943). Von Klitzing is a German physicist who began his career in physics with a dissertation of the electrical properties of indium antimonide, a compound of two semiconducting elements, indium and antimony. He was particularly interested in the effects of magnetic fields on the conducting properties of semiconductors and was awarded his Ph.D. for research in this field. He went to Oxford University because of the availability of superconducting magnets and then went to the High-Field Magnet Laboratory in Grenoble, France where he made his famous discovery of the quantized Hall effect. He was awarded the 1985 Nobel Prize in physics for his discovery. His discovery has made it possible to establish a new international standard for the ohm.

See also **Hall Effect and Quantized Hall Effect**.

J. M. I.

VON NEUMANN, JOHN (1903–1957). Von Neuman is recognized as an American mathematician. He was born in Budapest, Hungary. He received a Ph.D. in mathematics at the University of Budapest in 1926. He came to America in 1930 as a visiting professor at Princeton University and in 1933 he became professor of mathematics at the Institute for Advanced Study at Princeton, New Jersey, and remained in this position until his death. From 1943 until 1955 he was also associated with Los Alamos Scientific Laboratory. von Neuman was U.S. Atomic Energy Commissioner in 1954 and he received the Enrico Fermi Award of the Atomic Energy Commission in 1957.

Much of von Neuman's early work was in quantum theory. He made contributions to the study of periodic functions, the ergodic theorem, and the algebra of bounded operators. In 1928, he gave a presentation, which was the beginning of a new branch of science referred to as the theory of games. Later in 1944, he developed the analogy between games of strategy

and situations in economics. His theory of games has found a wide range of applications in social sciences.

Neu also remembered for his work in the pioneering of computer theory and design. In 1952, von Neumann and his colleagues designed and built the first computer, which was able to use a flexible stored program.

VORBIS. See **Data Compression**.

VORTEX LAWS. A vortex is defined in meteorology as a mass of fluid in which the flow is circulatory.

The filament or thread of the vortex is the locus of the centers of circulation. Hydrodynamic analysis of fluid flow, attributed to Helmholtz, has produced the following laws governing vortex flow:

1. The strength C of a vortex is constant along the filament.
2. The identity of the fluid in a vortex does not alter during the life of the vortex.
3. Filaments have no ending; they are either closed paths, or the ends extend to infinity.

VORTICITY EQUATION. A dynamic equation for the rate of change of the vorticity of a parcel, obtained by taking the curl of the vector equation of motion.

The vorticity equation takes on slightly different forms depending on whether height or pressure is taken as the vertical coordinate. With height as the vertical coordinate, and with friction terms omitted, the vertical component of the vorticity equation is

$$\frac{D\zeta}{Dt} = -(\zeta + f)\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) - \frac{2\Omega\cos\phi}{a}v + \left(\frac{\partial w}{\partial y}\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x}\frac{\partial v}{\partial z}\right) + \left(\frac{\partial p}{\partial x}\frac{\partial \alpha}{\partial y} - \frac{\partial p}{\partial y}\frac{\partial \alpha}{\partial x}\right),$$

where ζ is the vertical component of the relative vorticity; f the Coriolis parameter; u, v, and w the components of the wind velocity toward the east (x), north (y), and vertical (z); Ω the angular speed of the earth; p and α the air pressure and specific volume, respectively; a the earth's radius; and φ the latitude. The left-hand member of the equation represents the material rate of change of the relative vorticity of an air parcel. The first term on the right describes the effect of horizontal divergence. The second term on the right is the Rossby parameter times v and represents the change in vorticity resulting from latitudinal displacement. The third term on the right, often called the vertical shear, twisting, or tilting term, describes the influence of a horizontal gradient of vertical velocity in transforming vorticity about a horizontal axis to that about a vertical axis. The last term represents the generation of vorticity by pressure–volume solenoids. When pressure is taken as the vertical coordinate, and all differentiations are performed on an isobaric surface, the equation is simplified by the absence of the solenoidal term:

$$\frac{D\zeta_p}{Dt} = -(\zeta_p + f)\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) - \frac{2\Omega\cos\phi}{a}v + \left(\frac{\partial w}{\partial y}\frac{\partial u}{\partial p} - \frac{\partial w}{\partial x}\frac{\partial v}{\partial p}\right),$$

where ζ_p is the isobaric vorticity and $\omega = Dp/Dt$ is the material pressure change. If adiabatic processes are assumed, and potential temperature θ taken as vertical coordinate, all differentiations are performed on an isentropic surface, and the vorticity equation becomes

$$\frac{D\zeta_\theta}{Dt} = -(\zeta_\theta + f)\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) - \frac{2\Omega\cos\phi}{a}v.$$

VOYAGER MISSIONS TO JUPITER AND SATURN. The *Voyager* mission comprised a major thrust in the strategy of the U.S. National Aeronautics and Space Administration (NASA) for obtaining information on the outer solar system. The mission was officially approved in May 1972 and has returned more new knowledge about the outer planets than had existed in all of the preceding history of astronomy and planetary science. Objectives of the *Voyager* missions included the study of Jupiter and Saturn, including their satellites, as well as observations of interplanetary media between the Earth and these planets. The *Voyager* spacecraft were designed to take advantage of a rare geometric arrangement of the outer planets that occurs only once every 176 years. This configuration allows a single spacecraft to swing from one planet to the next without the need for large onboard propulsion systems. The two spacecraft were launched in 1977. *Voyager 2* was launched first, on August 20, 1977, followed by *Voyager 1*, which was put on a faster shorter trajectory to Jupiter on September 5, 1977. Both *Voyager* launches took place at the NASA Kennedy Space Center at Cape Canaveral, Florida. See Fig. 1. Eighteen months after launch, *Voyager 1* reached Jupiter, 650 million kilometers (400 million miles) away. The spacecraft made its closest approach on March 5, 1979, and *Voyager 2* followed with its closest approach occurring on July 9, 1979. The first spacecraft flew within 206,700 kilometers (128,400 miles) of the planet's cloud tops, and *Voyager 2* came within 570,000 kilometers (350,000 miles). On November 12, 1980 *Voyager 1* made its closest approach to Saturn followed by *Voyager 2* on August 25, 1981. *Voyager 1* flew within 64,200 kilometers (40,000 miles) of the cloud tops, while *Voyager 2* came within 41,000 kilometers (26,000 miles).

These spacecraft represented the technology of the 1970's. The very best hardware was incorporated into the spacecraft, not only to successfully complete the missions to Jupiter and Saturn, but also with the hopeful expectations that the systems would continue functioning satisfactorily and thus enable visits to Uranus and Neptune. After *Voyager 2's* successful Saturn encounter, it was shown that *Voyager 2* would likely be able to fly on to Uranus with all instruments operating. NASA provided additional funding to continue operating the two spacecraft and authorized the Jet Propulsion Laboratory (JPL) to conduct a Uranus flyby. Subsequently, NASA also authorized the Neptune leg of the mission, which was renamed to the *Voyager* Neptune Interstellar Mission. On January 24, 1986 *Voyager 2* made its closest approach to Uranus, coming within 81,500 kilometers (50,600 miles) of the planet's cloud tops. *Voyager 2* made its closest approach to Neptune, 5,000 kilometers (3,000 miles) on August 25,1989. Following *Voyager 2's* closest approach to Neptune, the spacecraft flew southward, below the ecliptic plane and onto a course that will take it to interstellar space. Reflecting the *Voyagers'* new transplanetary destinations, the project is now known as the *Voyager* Interstellar Mission. See also **Neptune (Planet)**; and **Uranus**.

Voyager 1 is now leaving the solar system, rising above the ecliptic plane at an angle of about 35 degrees at a rate of about 520 million kilometers (about 320 million miles) a year. *Voyager 2* is also headed out of the solar system, diving below the ecliptic plane at an angle of about 48 degrees and a rate of about 470 million kilometers (about 290 million miles) a year.

The Spacecraft

The *Voyager* mission module after injection weighed 826 kilograms (1,820 pounds), including a 105-kilogram (231-pound) scientific instrument payload. The propulsion module, with its large solid propellant rocket motor, weighed 1220 kilograms (2,960 pounds). The spacecraft adaptor joined the spacecraft with the *Centaur* stage of the launch vehicle. It weighed 47.2 kilograms (104 pounds) and thus the total launch weight was 2100 kilograms (4,360 pounds). To assure proper operation for the four–year flight to Saturn and beyond, the mission module sub-systems

Fig. 1. OUTWARD BOUND *VOYAGER* — A *Titan-Centaur* launch vehicle hurls *Voyager 1* from Cape Canaveral toward its rendezvous with Jupiter and Saturn. The launch took place at 5:56 A.M. (PDT) September 5, 1977. (*Jet Propulsion Laboratory*.)

were designed with high reliability and extensive redundancy. Like the *Mariners* that explored the solar system's inner planets and the *Viking* Mars Orbiters, the *Voyagers* are stabilized on three axes, using the sun and Canopus (a star) as celestial reference points. See Fig. 2.

Three engineering subsystems are programmable for onboard control of spacecraft functions. Only trajectory correction maneuvers must be enabled by ground command. These subsystems are the computer command subsystems (CCS), the flight data subsystems (FDS), and the attitude and articulation control subsystems (AACS). The memories of these units can be updated or modified by ground command at any time. Hot gas jets provide thrust for attitude stabilization as well as for trajectory correction maneuvers.

The science instruments required to view the planets and their moons are mounted on a two-axis scan platform at the end of the science boom for precise pointing. Other body-fixed and boom-mounted instruments are aligned for proper interpretation of their measurements. Data storage capacity on the spacecraft is about 536 million bits of information-the equivalent of about 100 full-resolution photos. Dual frequency communication links, S-band and X-band, provide accurate navigation data and large amounts of scientific information during planetary encounter periods (up to 115,200 bits per second at Jupiter; and 44,800 bits per second at Saturn). The dominant feature of the spacecraft is the 3.66-meter (12-foot) diameter high-gain antenna which points toward the Earth continually. While the high-gain antenna dish is white, most visible parts of the spacecraft are black-blanketed or wrapped for thermal control and micrometeoroid protection. A few small areas are finished in gold foil or have polished aluminum surfaces.

The basic mission module structure (see Fig. 3) is a 29.5-kilogram (65-pound), ten-sided aluminum framework with ten electronics packaging compartments. The structure is 47 centimeters (18.5 inches) high and 1.78 meters (5.8 feet) across. The electronics assemblies are structural elements of the ten-sided box.

Three Radioisotope Thermoelectric Generators (RTGs) are assembled in tandem on a deployable boom hinged on an outrigger arrangement of struts attached to the basic structure. See Fig. 4. The generators convert the heat released by the isotopic decay of plutonium-238 into electricity. Each isotope heat source has a capacity of 2400 thermal watts with a resultant maximum electrical power output of 160 watts at the start of the mission. Due to the natural radioactive decay of the Plutonium fuel source, the electrical energy provided by the RTGs is continually declining. By the time the spacecraft passed Saturn, the total power supply was reduced to about 384 watts. At the beginning of 1997, the power generated by

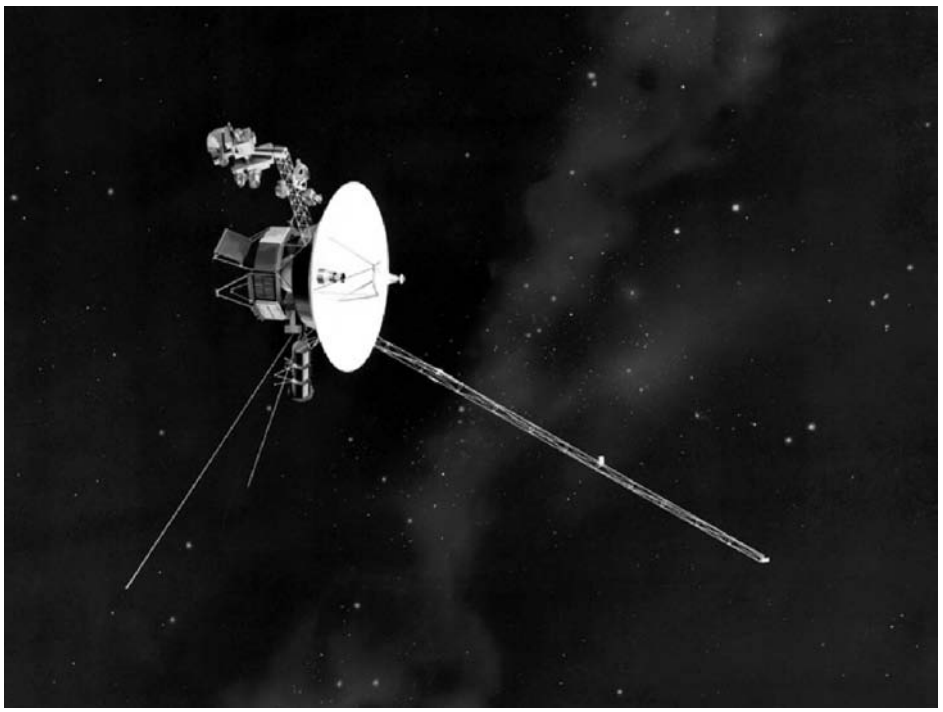

Fig. 2. Seen here is a full-scale model of one of the twin *Voyager* spacecraft, which was sent to explore the giant outer planets in our solar system. *Voyager 2* was launched August 20, 1977 followed by the launch of *Voyager 1* sixteen days later. (*Jet Propulsion Laboratory, Pasadena, California/NASA*.)

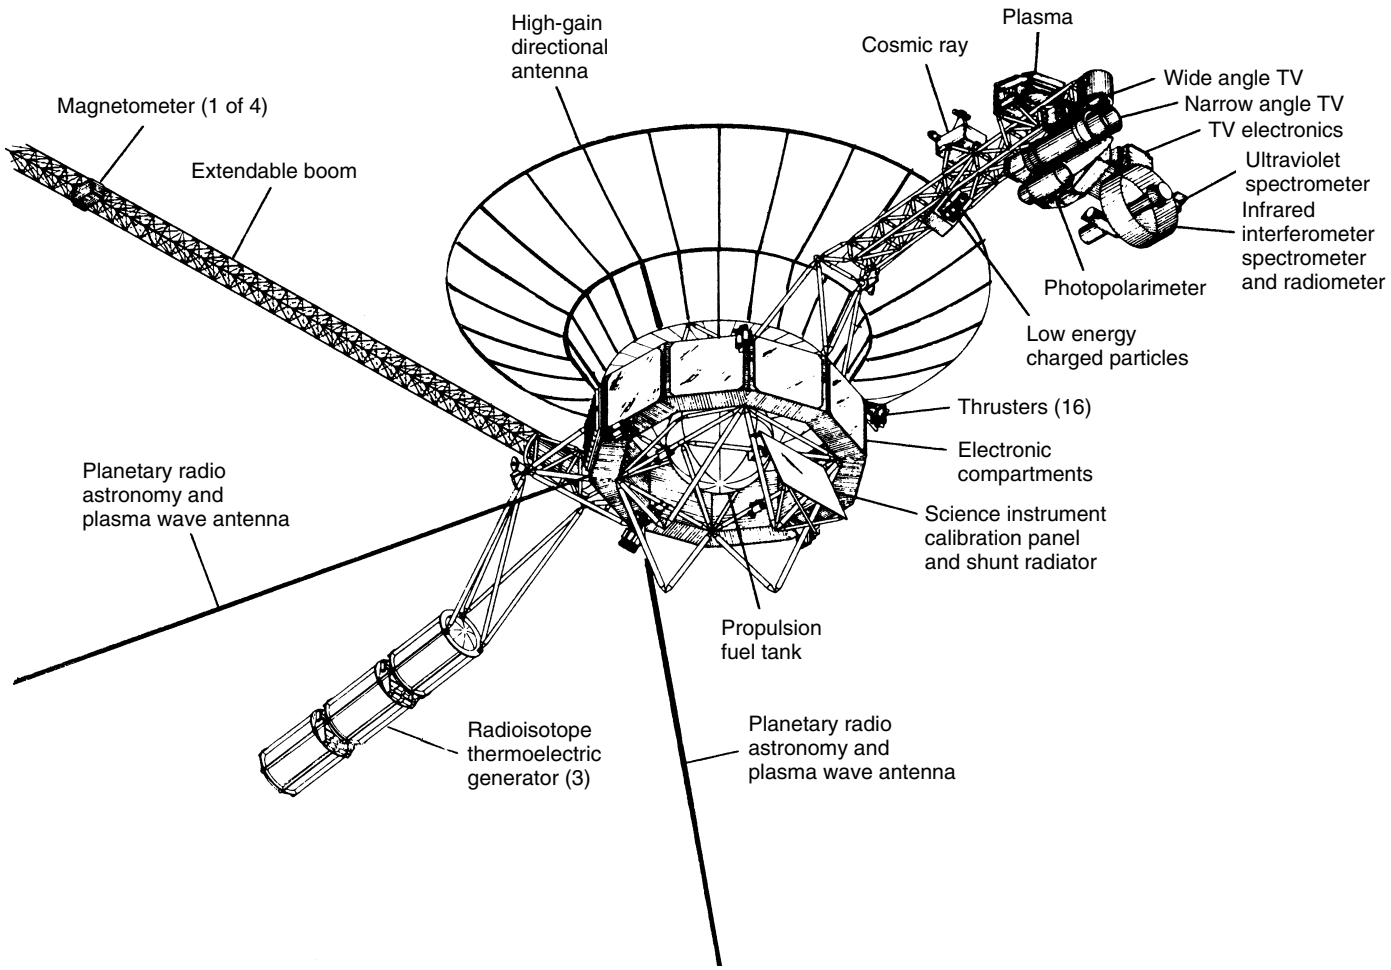

Fig. 3. Principal features of *Voyager* spacecraft. (*Jet Propupulsion Laboratory*.)

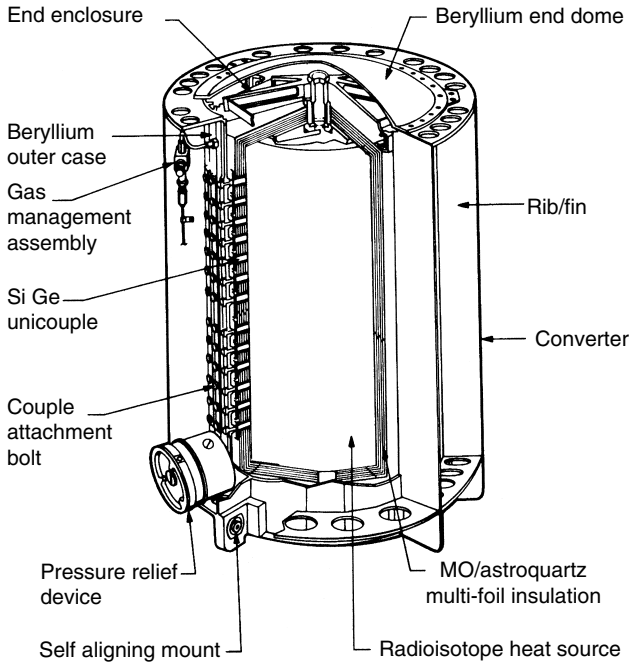

Fig. 4. Radioisotope thermoelectric generator aboard *Voyager* spacecraft. (*Jet Propulsion Laboratory*.)

Voyager 1 has dropped to 334 watts and 336 watts for *Voyager 2*. Both of these power levels represent performances higher than the pre-launch predictions. At the present time both spacecraft have adequate electrical power and attitude control propellant to continue operating until around 2020 when the available electrical power will no longer support science instrument operation.

The encounter geometry of *Voyager 1* and *2* with Jupiter are indicated in Figs. 5 and 6; that for Saturn is shown in Fig. 7.

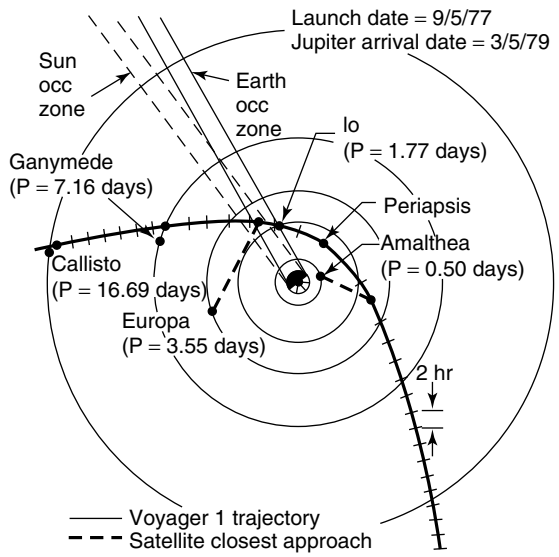

Fig. 5. *Voyager 1* Jupiter encounter geometry. This view from the planet's north pole shows the trajectory closest approach geometry to the planet and selected satellites, satellite periods, 2-hour tick marks along the trajectory path, and the Earth and Sun occultation zones through which the spacecraft proceeded. (*Jet Propulsion Laboratory*.)

Scientific Experiments Aboard *Voyagers*

The principal scientific investigations programmed for *Voyager* encounters included the following:

Imaging Science. High-resolution reconnaissance over large phase angles; atmospheric dynamics; geologic structure of satellites.

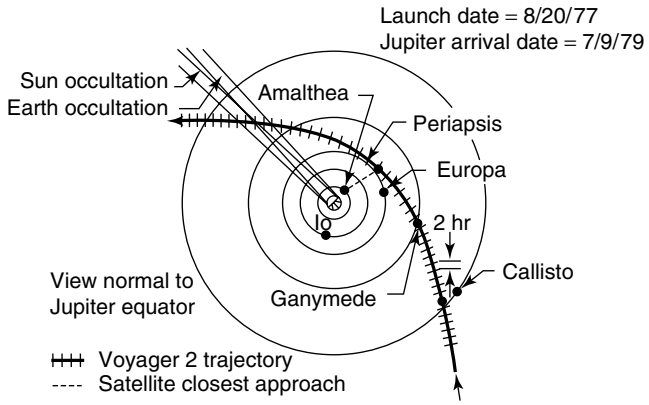

Fig. 6. *Voyager 2* Jupiter encounter geometry. This view from the planet's north pole shows the trajectory closest approach geometry to the planet and selected satellites, 2-hour time interval tick marks along the trajectory path, and the Earth and Sun occultation zones through which the spacecraft proceeded. (*Jet Propulsion Laboratory*.)

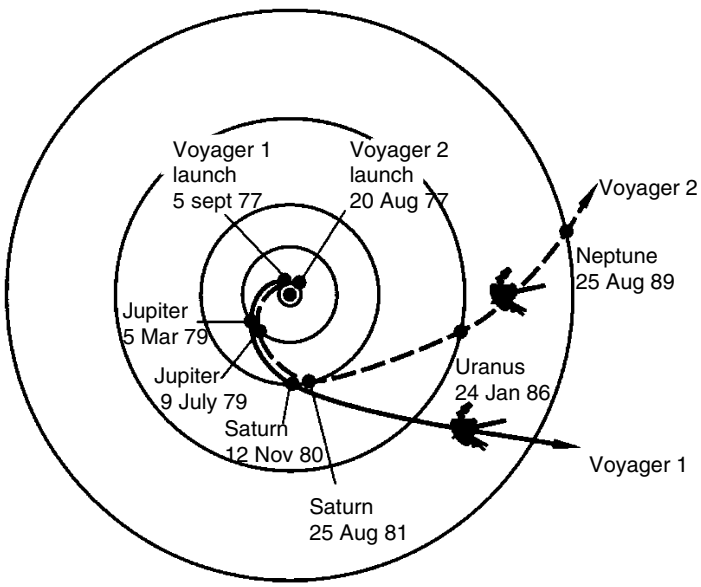

Fig. 7. *Voyagers 1* and 2 Saturn encounter geometry. As Saturn was the final planetary encounter for *Voyager 1*, its trajectory was designed to maximize the return of scientific information from the encounter with little regard to where the spacecraft would travel after Saturn. For *Voyager 2*, the aim point at Saturn was defined solely by the requirement to continue the trajectory to Uranus. The arrival time at Saturn, however was selected to allow closer approaches to several satellites which were viewed more remotely from *Voyager 1*. (*Jet Propulsion Laboratory*.)

Infrared Radiation. Atmospheric composition, thermal structure, and dynamics; satellite surface composition and thermal properties.

Photopolarimetry. Atmospheric aerosols; satellite surface texture and sodium cloud.

Radio Science. Atmospheric and ionospheric structure, constituents, and dynamics.

Ultraviolet Spectroscopy. Upper atmospheric composition and structure; auroral processes; distribution of ions and neutral atoms in planetary system.

Magnetic Fields. Planetary magnetic field; magnetospheric structure; Io flux tube currents.

Plasma Particles. Magnetospheric ion and electron distribution; solar wind interaction with planer; ions from satellites.

Plasma Waves. Plasma electron densities; wave-particle interactions; low-frequency wave emissions.

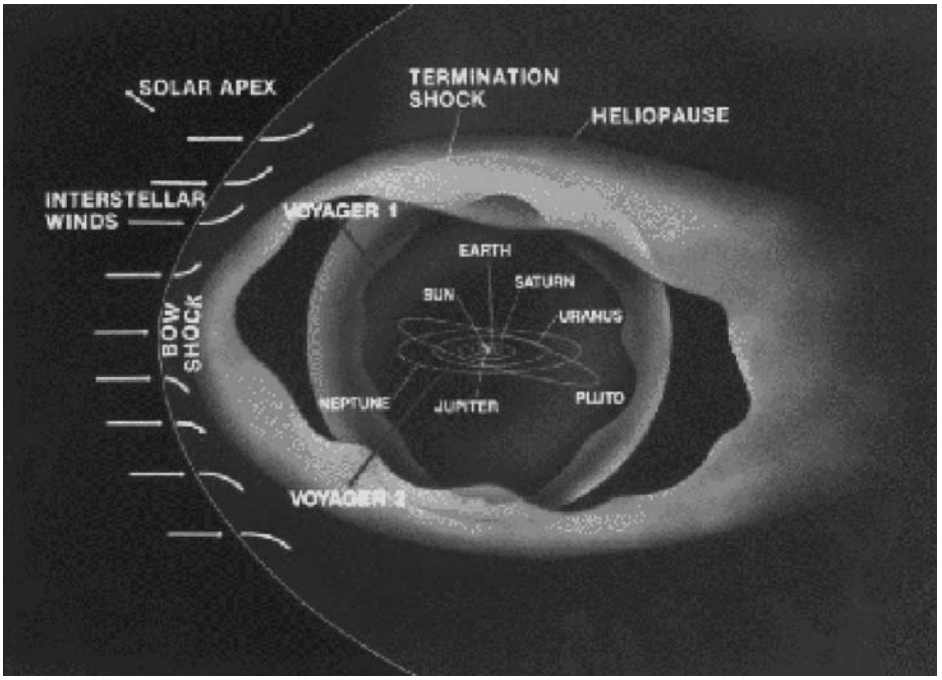

Fig. 8. Illustration showing the interstellar exploration by *Voyager*. (*Jet Propulsion Laboratory Pasadena, California/NASA*.)

Planetary Radio Astronomy. Polarization and spectra of radio frequency emissions; Io radio modulation process; plasma densities.

Low-Energy Charged Particles. Distribution, composition, and flow of energetic ions and electrons; satellite-energetic particle interactions.

Cosmic-ray Particles. Distribution, composition, and flow of high-energy trapped nuclei; energetic electron spectra.

Voyager's Interstellar Mission

At the start of the *Voyager* Interstellar Mission (VIM), the two *Voyager* spacecraft had been in flight for over 12 years. The objective of the (VIM) is to extend the NASA exploration of the solar system beyond the region of the outer planets to the outer limits of the Sun's sphere of influence, and possibly beyond. This extended mission is continuing to characterize the outer solar system environment and search for the heliopause boundary, the outer limit of the Sun's magnetic field and outward flow of the solar wind. Exactly where the heliopause is has been one of the great unanswered questions in space physics. By studying the radio emissions, scientists now theorize the heliopause exists some 90 to 120 astronomical units (AU) from the Sun. One AU is equal to 150 million kilometers (93 million miles).

We should consider the VIM as having three notable phases: the termination shock, heliosheath exploration, and interstellar exploration phases. The two *Voyager* spacecraft began the VIM operating, and are still operating, in an environment controlled by the Suns magnetic field with the plasma particles being dominated by those contained in the expanding supersonic solar wind. This is the characteristic environment of the termination shock phase. At some distance from the Sun, the supersonic solar wind will be held back from further expansion by the interstellar wind. One of the features to be encountered by a spacecraft as a result of this interstellar wind/solar wind interaction will be the termination shock where the solar wind slows from supersonic to subsonic speed and large changes in plasma flow direction and magnetic field orientation occur. Passage through the termination shock ends the termination shock phase and the heliosheath exploration phase begins. Since the exact location of the termination shock is not known, it is estimated that *Voyager 1* will complete the termination shock phase about the year 2000 or 2001 when it will be about 80 AU from the Sun. Once final passage through the termination shock, the spacecraft will be operating in the heliosheath environment which is dominated by the Suns magnetic field and particles contained in the solar wind. When the heliosheath exploration phase ends with passage through the heliopause which is the outer extent of the Suns magnetic field and solar wind. The thickness of the heliosheath is uncertain and could be tens of AU thick taking a couple of years to traverse. Passage through the heliopause begins the interstellar exploration phase with the spacecraft operating in an interstellar wind dominated environment. See Fig. 8.

Science Investigations

There are seven operating instruments on-board each *Voyager* spacecraft. Five of these instruments support the science investigation teams participating in the *Voyager's* Interstellar Mission (VIM).

Magnetic Field Investigation (MAG). NASA & Goddard Space Flight Center.

Low Energy Charged Particle Investigation (LECP). Johns Hopkins University/Applied Physics Laboratory.

Plasma Investigation (PLS). MIT Space Plasma Group.

Cosmic Ray Investigation (CRS). NASA & Goddard Space Flight Center.

Plasma Wave Investigation (PWS). The University of Iowa

These science teams are currently collecting and evaluating data on the strength and orientation of the Sun's magnetic field; the composition, direction and energy spectra of the solar wind particles and interstellar cosmic rays; the strength of radio emissions that are thought to be originating at the heliopause, beyond which is interstellar space; and the distribution of hydrogen within the outer heliosphere. In addition there are two science instruments that do not have official science investigation teams associated with them. These instruments are: *Planetary Radio Astronomy Subsystem* (PRA) and the *Ultraviolet Spectrometer Subsystem* (UVS). However the data captured by these instruments is made available to interested scientists.

VULCANIZATION. A physiochemical change resulting from cross-linking the unsaturated hydrocarbon chain of polyisoprene (rubber) with sulfur, usually with application of heat. The precise mechanism that produces the network structure of the cross-linked molecules is not completely known. Sulfur is also used with unsaturated types of synthetic rubbers; some types require use of peroxides, metallic oxides, chlorinated quinones, or nitrobenzenes. Natural rubber can be vulcanized with selenium, organic peroxides, and quinone derivatives, but these have limited industrial use; high-energy radiation curing is and important innovation.

See also **Rubber Chemicals**; **Rubber Compounding**; and **Rubber (Natural)**.

VULTURE *(Aves, Falconiformes).* A large, flesh-eating bird with a hooked beak but with claws less strongly developed than those of the

eagles, hawks, and owls. Vultures feed largely on carrion, but many species are also known to attack living animals.

The Old World vultures belong to a family distinct from the New World species. The latter differ in having the nostrils confluent, so that the beak is perforated transversely. With the exception of the lammergeier, an Old World species, all vultures have the head and neck almost bare of feathers and sometimes brightly colored.

The turkey vultures or turkey buzzards (Fig. 1), *Cathartes aura*, of North America are the most widely distributed representatives of the group, and the condor of South America is probably most widely known for its enormous size. It has been recorded with a length of 4 feet (1.2 meters) and a wingspread of 9 feet (2.7 meters). The California vulture or condor, *Gymnogyps californianus*, of the southwestern states and Lower California, has also been recorded with a maximum length of 4 feet (1.2 meters) or more, and its wingspread is said to reach almost 11 feet (3.3 meters). All these birds are magnificent fliers, soaring for long periods without flapping a wing. See also **Falconiformes**.

Fig. 1. Turkey buzzard (*Cathartes aura septembrionales*). Black with brown edging to feathers. Skin of head and neck bare and red.

W

WAD. The mineral wad, sometimes called *bog manganese*, occurs in amorphous masses, and consists of mixtures of manganese oxides, MnO_2 and MnO, and oxides of other metals such as copper, lead, cobalt, and iron. It is bluish- to brownish-black, usually soft enough to soil the fingers and often porous and light. It is not a distinct mineral species.

WADDEN ZEE. An inlet of the North Sea located in the Netherlands.

WADERS, SHOREBIRDS, AND GULLS *(Aves, Charadriiformes).* Among the many shore and wading birds making up this large order are the various species of auks, guillemots, and puffins; the sandpipers, ruffs, snipes, and woodcock; the plovers and killdeers; the gulls, skimmers and terns; the jacana, phalarope, water pheasant, and wrybill.

The *auks* have large, compressed beaks with oblique grooves toward the tip. One species, the razorbill (*Alca torda*) occurs on both sides of the Atlantic, nesting on rocky ledges. This species is related to the extinct great auk and to the murres, puffins, and guillemots, and is also known as the razor-bill auk. There are over 20 species of auks, which range from 7 to 30 inches (18–76 centimeters) in length. As a group, they are principally found in the North Atlantic and the Arctic regions. The color varies with particular species. Most are grayish, but some are black. Some species have ornamental head feathers. The feet are webbed and the legs are relatively short. The auk is considered to be quite gregarious. The garefowl (*Pinguinus (Alca) impennis*) is now extinct. *Guillemots* are birds with short legs, webbed feet, and upright posture. The several species are found chiefly about the northern oceans. The dovekie is a black guillemot (*Uria grylla*), a marine bird of the north Atlantic (also spelled dovekee and dovekey). The murres are moderately large marine birds closely related to the auks. To some extent, the name is synonymous with guillemot, but different species have been named as one or the other by ornithologists. The murres are powerful swimmers and divers. The murrelets are of a small species of marine diving birds and related to the murres. *Puffins* are marine birds of several species whose thick compressed beaks are almost as large as their heads. They are found on both sides of the Atlantic, nesting in northern latitudes and wintering south to New York and the Mediterranean. The related species of the Pacific are commonly called *shearwaters*.

Sandpipers are long-legged shore birds related to the snipes and plovers. They are named from their association with the bare margins of streams and ponds, where their clear piping calls are a familiar sound. There is a score or more of species in North America, some bearing other names, such as sanderling and knot. Other continents have representatives of the group during at least part of a year. *Snipes* are long-legged and long-beaked wading birds related to the sandpipers and woodcock. Snipes are found in marshy ground and occur on all continents. The principal species in North America is the Wilson snipe (*Capella delicata*) or jack snipe, which is regarded to a limited extent as a game bird. Its erractic flight makes it a severe test of marksmanship. The curlews are shore birds of several species with long legs, a moderately long neck, and a long, curved beak. They are related to the snipes. The *dunlin* (*Tringa*) is a common European shore bird, a type of sandpiper. It is also called the ox bird. The *godwits* are wading birds allied to the sandpipers, with long legs and a long slender beak. The several species nest in the far north, but migrate to the Southern Hemisphere in winter. The *greenshank* is a European sandpiper (*Tringa nebularia*), related to the willets of North America. The greenshank migrates into South Africa and Australia. The *redshank* is a Eurasian bird (*Tringa totanus*) related to the snipes and sandpipers, named from the red color of the bare part of the legs. The name is also applied to a larger related species of the European *T. erythropus*. The *ruff* is a European bird (*Philomachus* (*Machetes*) *pugnax*) related to the sandpipers. The name comes from the seasonal development of a large ruff about the neck of the male. The females are called *reeves*. Scales develop on the toes during winter months. The scales are long and help to support the bird as it walks on the snow. *Seed snipes* are South American birds resembling quails, but classes as intermediate between true snipes and the gulls. They are closely related to the *sheathbills*. The *tatler* is a North American sandpiper, *Heterocelus* (*Heteractitis icanus*), or wandering tatler, found along the Pacific coast of North America where it breeds in northern latitudes and on some of the Pacific islands. The *woodcock* is a woodland bird, *Scolopax minor*, of the northern and eastern part of the United States and related to the snipes. The woodcock has a long straight beak and short neck, tail, and legs, and its mottled brown plumage is a fine example of protective coloration. The woodcock is of limited interest as a game bird. Yellow-legs is an American bird related to the snipes and sandpipers. Two species, the greater, *Totanus* (*Tringa*) *melanoleucus*, and the lesser, *T.* (*Tringa*) *flavipes*, are widely distributed over North America and migrate into South America. The latter is sometimes seen in Europe.

The *plovers* are wading birds with moderately long legs and a moderate beak. Although usually found near water, many species frequent dry ground, such as meadows and pastures. Plovers average about 10 inches in length. In some species, the white plumage of the neck features two beautiful rings of black down. The common coloration for most species is black, with white and brown. Plovers are known for their rather raucous voices and also for their tricks when in trouble. They sometimes appear as though falling in flight as the result of a broken wing, or possibly feigning a broken leg when faced by intruders. The *killdeer, Oxyechus vociferus*, well named for its loud voice is the most common of several North American species of plovers. The *golden plover, Pluvialis dominica*, is remarkable for its long migrations between arctic breeding grounds and its winter home in Patagonia. The courser is a long-legged bird related to the plovers and is found in Africa and southern Europe. One species is a desert bird. *Dotterels* (*Eudromias*) represent several species of Old World birds related to the plovers. *Lapwings* (*Vanellus*) are birds of several species resembling plovers both in appearance and habit. The common European lapwing (*Vanellus vanellus*) also is known as the *peewit*. The *oyster catchers* are birds of few species, but of worldwide distribution. They are related to the *avocets*, from which they differ in being more stoutly built. Oyster catchers frequent the coasts and eat bivalve mollusks, among a much larger variety of food. The American oyster catcher is *Haematopus palliatus*. *Sheathbills* are related to the oyster catchers and derive their name from the horny sheath enclosing the base of the beak. Two species are known, both found in extreme southern latitudes and the Antarctic. *Turnstones* are shore birds related to the plovers and oyster catchers. They are found chiefly in the far north, migrating southward, chiefly along the coasts, in both the Old and New Worlds. They winter as far south as Patagonia. The *whimbrels* are northern shore birds with long legs and a long curved beak. They are related to the curlews and plovers. The term whimbrel applies to the European species. Species occurring in North America are called the *Eskimo*, *Phaeopus borealis*, and the *Hudsonian, P. hudsonicus*, curlews.

Gulls are water birds with webbed feet and long narrow wings. Their flight is powerful and easy, and they are more often seen in the air than on the water. They are common along the seashore and on larger bodies of fresh water, but Franklin gulls are often seen far from water, even following the plow to pick up insects. With exception of the sabine gully, they may be distinguished from the closely related terns by the square end of the tail. The *kittiwake* (*Rissa*) is a related species of the north Pacific and Bering Sea. The *jaegers*, also called *skuas*, are birds closely related to the gulls, from which they differ in the elongate middle tail feathers. Four species nest in the Arctic regions and migrate into Europe, the southern United

States, and some to the Southern Hemisphere. One species is found in the Antarctic and another lives along the west coast of South America. These birds hunt and fish like gulls. They range up to 2 feet (0.6 meter) in length. They fly with great speed and are known for rather nasty dispositions, even attacking people when too close to their nests. *Skimmers* are birds related to the terns and gulls, but distinguished by a peculiar beak. The entire beak is long and compressed and the lower mandible is much longer than the upper. The bird dips this lower mandible into the water as it flies. Of the few species, only one, the black skimmer, *Rhynchops nigra*, is known in North America. *Terns* resemble the gulls, but have a more slender and tapering beak. The tail is forked. Terns are very much like gulls in habit and are usually seen in flight over water, both on the coasts and near ponds and lakes. About 10 species are normally found in the United States. The common tern, *Sterna hirunda*, and the Arctic tern, *S. paradisaea*, breed within areas of the Arctic Circle. Four of the relatively few species breed in the Antarctic. Terns are well known for their very long-distant migrations. A tern banded in Labrador was recovered 11,000 miles (17,700 kilometers) away in Africa, only 3 months after the bird had learned to fly. Many of the terns have black heads with white bodies. The tail is deeply forked, wings long and pointed. They deposit 3 white eggs with dark flecks in a small cup rolled out in the sand. The eggs often are covered with sand. During courtship, the terns go through a ritual something like that of the *bower bird*. The tern is a beautiful and most graceful bird.

The *jacanas* are shore birds of South America, Africa, and the Oriental region. They have long legs and tail and very long toes. Depending upon species, they range in length from 6 to 12 inches (15–30 centimeters). Spurs on the wings are sometimes very sharp. In some species, the toes have nails up to 4 inches (10 centimeters) long. They help to hold them on to rafts of lilies or plants floating on the surface of ponds and lakes. Unlike most birds, the female jacana possesses the elaborate plumage instead of the male. Generally, the roles of sexes are reversed. The male makes the nest and cares for and incubates the eggs and tends to most of the rearing of the young. The female is also the more aggressive member of the family. The female entices the male during courtship through dances akin to the bower bird. Jacanas have a catlike cry. They have a red maroon coloration with a black head. They fly in beautiful pack formations. The eggs are 4 in number and often are submerged in warm sunlit water. Incubation period ranges from 22 to 24 days. The nails are long at birth. The young soon follow the male onto rafts for training in flying and hunting for food.

The *phalaropes* are wading birds of several species, with long legs, lobed toes, and a moderately long beak. The red (*Phalaropus fulicaris*) and northern (*Lobipes lobatus*) phalaropes breed throughout the northern part of the northern hemisphere. *Wilson's phalarope, Steganopus tricolor*, of North America is one of the most beautiful of wading birds. These birds are also unusual in the reversal of sex roles, the female being larger, more brightly colored, and taking the aggressive role in courtship.

The *water pheasant* is a large and beautiful water bird of India and Ceylon. Its nest floats on the water or is anchored to water plants. The bird is related to the jacana. The *wrybill* is a New Zealand bird whose beak is asymmetrical. The terminal half of the organ bends to the right. The bird is said to seek its food, consisting of insects and other small creatures, by reaching under the edges of stone. This habit is apparently well served by the peculiar adaption of the beak.

Pratincoles are birds of several species found on all continents of the Old World. Their long wings and forked tail give them the appearance of swallows when in flight, but their moderately long legs are a point of resemblance with the plovers. They live chiefly near water, but are insectivorous in habits.

Avocets are wading birds of several species found in the Old and New World. The beak is curved upward at the tip and the feet are fully webbed. Avocets are about 18 inches (46 centimeters) in length. Nests are found on the ground near water. Shallow pounds or muddy seacoasts are preferred habitats. The avocet catches its food by flinging its head from one side to the other with mouth open while in the water. It also gains food while wading. See also **Charadriiformes**.

WADI. A term used in desert regions for a stream bed or channel, a steep-sided and bouldery ravine, gully, or valley, or a dry wash that is usually dry except during the rainy season and that often forms an oasis. The word also may be used to designate an intermittent and torrential stream that flows through a wadi and ends in a closed basin, or a shallow, usually sharply defined closed basin in which a wadi terminates. Also spelled *wady* or *waddy*. See also **Arroyo**.

WADING BIRDS. See **Waders, Shorebirds, and Gulls**.

WAHOO. See **Mackerels**.

WAKE. The disturbed region behind a body placed in a stream of fluid. The flow derives its energy and momentum from the drag force on the body and measurements in the wake can be used to infer the force.

WAKSMAN, SELMAN ABRAHAM (1888–1973). Selman Abraham Waksman was born in the Ukraine (then part of Russia) in 1888. As a Jew he was denied a complete secondary education, so he immigrated to America in 1910. He entered Rutgers University, New Jersey to study agriculture. In 1916 he began his Masters degree with the soil chemist Jacob G. Lipman, himself an emigrant from Russia, and Director of the Agricultural Experiment Station at Rutgers. In this year Waksman became an American citizen, and married Bertha Mitnick. He completed his PhD in biochemistry at the University of California in 1918, and returned to Rutgers, where he would remain until his retirement in 1958.

Waksman was interested in the microbiology of the soil and sea, which involved the detailed study of bacteria and fungi, and a new group of soil organisms, the actinomycetes. These organisms were neither bacteria nor fungi, but were midway between the two. Initial work in the field led him to take up a part-time post in industry, working for a company that produced fungus enzymes and manufactured the arsenical compound Salvarsan, the first effective agent against syphilis. In 1921 he returned to Rutgers full-time and began to classify the actinomycetes. In 1925 he was appointed Associate Professor of Soil Microbiology, then in 1930 Professor of Microbiology. See also **Syphilis**.

During his study of the actinomycetes Waksman found that some cultures were able to prevent the growth of other microbes; actinomycetes had an antibiotic effect. In the late 1930s Waksman began a systematic search of the actinomycetes for antibiotic substances. Elsewhere researchers were screening fungi and bacteria for similar substances; only Waksman focused on actinomycetes. The first two substances isolated by Waksman, actinomycin and streptothyricin, proved to be highly toxic to experimental animals, and were therefore useless as therapeutic agents. The third agent, isolated from a soil actinomycete, *Streptomyces griseus*, proved more promising. It was effective against both Gram-positive and Gram-negative bacteria, unlike penicillin, and also had low toxicity. Successful clinical trials were carried out in 1944 at the Mayo Clinic. Streptomycin was the first chemotherapeutic agent active against tuberculosis; it was also used to treat diseases such as plague and meningitis. For his discovery Waksman was awarded the 1952 Nobel Prize for Medicine or Physiology. During the Second World War Waksman studied the role of bacteria in steel corrosion on behalf of the Government. See also **Antibiotics** and **Tuberculosis**.

Waksman's career was not without controversy. He was criticized by contemporaries for allowing streptomycin to be patented. In 1950 court proceedings found that Albert Schatz, a PhD student of Waksman, was a full collaborator in the discovery of streptomycin and was therefore entitled to a full share of the royalties derived from sales of the drug. Schatz was, however, overlooked by the Nobel Committee, and the discovery of streptomycin is still credited to Waksman.

WALDEN INVERSION. Inversion of configuration of a chiral center in bimolecular nucleophilic substitution reactions. See also **Rearrangement (Organic Chemistry)**.

WALKER CIRCULATION. A direct cell oriented along the equator; originally used by Bjerknes to refer to the cell induced by the contrast between the warm waters of the western Pacific and the cooler waters of the eastern Pacific. Variability in this cell is associated with the Southern Oscillation. The term is now sometimes used to refer to the entire chain of east–west equatorial circulation cells that stretches around the globe. See also **Trade Inversion**.

WALKING FERN. See **Ferns**.

WALKINGSTICK *(Insecta, Orthoptera)*. A slender wingless insect related to the grasshoppers. The walkingsticks are elongated in every part and closely resemble the twigs or stalks of the vegetation on which they live. Together with winged species found in the warmer regions of the world they make up the family Phasmidae. Some of the winged species resemble leaves. In the tropics, some of these insects measure 15 inches (38 centimeters) from end to end.

WALLABY. See **Marsupialia**.

WALLACE, ALFRED RUSSEL (1823–1913). Although Wallace's name is inseparably linked with that of Charles Darwin, the two were markedly different in background and intellectual commitments. Wallace was the third son and seventh child of Thomas and Mary Wallace, a couple with very reduced financial means. He was educated briefly at Hertford Grammar School and then, aged 14, joined his brother to learn the trade of surveying. The brothers worked all over the Midlands during the railway boom, and Wallace pursued his education by attending popular lectures at Mechanics' Institutes and other public venues. He read widely in the sciences. Hearing of Robert Owen's reformist views he became a committed early socialist; and soon abandoned whatever religious beliefs he had. He was particularly attracted by mesmerism (hypnosis) and phrenology, both of which gave him a lasting interest in mental phenomena. Wallace therefore had an eclectic self-education emerging out of the politically active, artisanal world of the manufacturing Midlands, which was grounded in the notion of individual progress and reform. In 1844 he taught mathematics at Leicester Collegiate School but abandoned it after a short while. In Leicester, however, he met Henry Walter Bates, who became a close friend. The two collected insects and corresponded about books. They were intrigued by the idea of evolution, as read in Chambers' *Vestiges of the Natural History of Creation*, which appeared in 1844. In 1848 they boldly decided to make a joint collecting expedition to the River Amazon, financing themselves with the sale of specimens. Wallace worked with and without Bates during these four years, pushing as far inland as Uaupes. He was deeply impressed by the lush diversity of the tropics and by his contact with indigenous tribes; and made several important observations about animal and plant distribution, as well as thinking about evolution. While returning to England in 1852, Wallace's ship sank. Although he was saved, he lost his cargo and all hope of financial profit. See **Bates, Henry Walter (1825–1882)**; **Owen, Richard (1804–1892)**.

In London, he wrote *A Narrative of Travels on the Amazon and Rio Negro*, which was published in 1853. By 1854 he decided to travel again, this time to the Malay Archipelago. This expedition lasted 8 years, always difficult and dangerous. Wallace estimated he covered 14,000 miles among the islands and collected some 125,660 specimens. His personal collection (not for resale) amounted to some 1,000 bird species, 7,000 beetle and butterfly species, besides quadrupeds and land shells. During the voyage he independently formulated the principle of evolution by natural selection. This was preceded by a careful analysis of the geographical distribution of closely related species, and written up in "On the Law which has Regulated the Introduction of New Species," and published in the *Annals and Magazine of Natural History* in 1855. Both Darwin and Charles Lyell read that article, and Lyell warned Darwin that Wallace's views were very similar to his own; subsequently Darwin corresponded with Wallace, complimenting him on his work. For much of the time, too, Wallace probed the question of human origins, thinking that so many indigenous peoples living in the area would provide a clue to ancestry. See also **Evolution (History)**; and **Lyell, Charles (1797–1875)**.

In February 1858, while on the island of Gilolo, close to Ternate, in the Moluccas, and ill with a passing bout of malaria, he realized that Malthus' principle of population could be applied to the animal and plant world, so that individuals which were unsuccessful or inadequately adapted would die out, leaving the better adapted individuals to survive and reproduce. He wrote an essay describing his views ("On the Tendency of Varieties to Depart Indefinitely from the Original Type") and sent it to Darwin from Ternate, asking Darwin that "if he thought it sufficiently important to show it to Sir Charles Lyell" (Wallace, *My Life*, vol. 1, p. 363). Darwin was astonished to see how closely Wallace's essay duplicated his own unpublished theories and passed the essay to Lyell on 18 June 1858, saying that he must give up his priority. But Lyell and Joseph Dalton Hooker hastily arranged a joint announcement of Darwin's and Wallace's views at the Linnean Society of London on 1 July 1858. Wallace was told about this only after the event. He responded with the greatest generosity: though there was indeed room for discreditable behavior in this episode, Darwin and Wallace always insisted that the other had, in their eyes, acted completely honorably. See also **Hooker, Joseph Dalton (1817–1911)**; and **Malaria**.

Wallace remained in Malaysia completing his collections until 1862. When he returned, much of the controversy over evolution had finished. Darwin had rushed out his *Origin of Species* in 1859 and there seemed little for Wallace now to do. He wrote many articles supporting adaptation by natural selection, especially on the protective coloration of animals and on sexual selection, disagreeing with Darwin on several important points. He was a prominent entomologist, becoming President of the Entomological Society. Later, in 1869, he published a magnificent account of his travels, *The Malay Archipelago*. He also made many significant contributions to biogeography, especially describing Wallace's Line, where two great biological provinces meet (and do not mingle) in Malaysia. His thoughts culminated in the classic study, *Island Life* (1880). See also **Biogeography (The History)**.

Turning towards human evolution and the development of mental attributes, he wrote important papers in 1864 and 1869, suggesting that natural selection acted on the human body only to push the different races apart, after which mental development alone took over. This proposal was not well received by Darwin who said "I hope you have not murdered too completely your own and my child" (F. Darwin (ed.), *More Letters of Charles Darwin*, vol. 2, p. 39). Nevertheless the two admired each other for the rest of their lives. Wallace was by far the most interesting author on Darwinian issues, producing his collected essays as *Darwinism* in 1889. He numbered Thomas Henry Huxley, Hooker, Lyell and Herbert Spencer among his closest scientific friends. See also **Huxley, Thomas Henry (1887–1975)**; and **Spencer, Herbert (1820–1903)**.

From about 1870 Wallace moved into different areas of research, becoming interested in spiritualism, mental physiology, technological advance and phrenology. He was politically engaged with land nationalization and the anti-vaccination cause. He believed fully in social progress, writing *The Wonderful Century* in 1898 and a utopian volume, *Man's Place in the Universe*, in 1903. Mild and modest by nature, Wallace was also vulnerable to difficult situations, such as rashly setting out in 1870 to prove the Earth was round. His antagonist pursued him relentlessly for years afterwards. Nor could he achieve secure employment, moving from position to position. In 1881 Darwin arranged a petition to the government for an annuity, which relieved the last years of his life.

WALLACH, OTTO (1847–1931). German chemist who received the Nobel Prize for chemistry in 1910 for recognition of his services to organic chemistry and the chemical industry by his pioneer work in the field of alicyclic compounds. His mentors were Hofmann and Wahler, and he worked at the University of Bonn under Kekule. He studied pharmacy and did work on terpenes, camphors, and essential oils. This was followed by research in aromatic oils, perfumes, and spices. His research of terpenes revealed their significance in sex hormones and vitamins. Ethereal oils and industrial uses were made possible by his work.

WALLOPS FLIGHT FACILITY. See **Spaceports U.S**.

WALNUT TREES. Members of the family *Juglandaceae* (walnut family), these trees are of several species. They are all termed walnut trees with exception of the butternut tree. Collectively, the Juglans may be described as deciduous trees, although some occur as large shrubs. They are best known for their hard-shelled nut which can be harvested in the autumn. See Fig. 1. Important species of the walnut family include:

American walnut	*Juglans nigra*
Black walnut	See American walnut
Butternut	*J. cinerea*
Chinese walnut	*J. cathayensis*
Circassian walnut	*J. regina*
Cut-leaved walnut	*J. regia "Laciniata"*
English walnut	*J. regia*
Manchurian walnut	*J. mandshurica*
Persian walnut	*J. regia*
Texas walnut	*J. rupestris*

The black walnut or American walnut is native to the United States and is found well distributed along the eastern seacoast and west to Michigan and throughout most of the Midwestern states. It is a large tree, with a height of 30 to as much as 65 feet (9 to 19.5 meters). The trunk is about 21/2 to 3 feet (0.8 to 0.9 meter) in circumference. As shown by Table 1, some specimens attain much larger dimensions. The branches are stout. The bark is sepia in coloration, rough with deep furrows that are perpendicular and

(**a**) (**b**)

TABLE 1. RECORD WALNUT TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Arizona walnut (1999) *(Juglans major)*	225	572	85	25.9	98	29.9	New Mexico
Black walnut (1991) *(Juglans nigra)*	278	706	130	39.6	140	42.7	Oregon
Butternut walnut (1998) *(Juglans cinerea)*	259	658	78	23.8	76	23.2	Connecticut
Little walnut (1980) *(Juglans microcarpa)*	160	406	50	15.2	80	24.4	Texas
Little walnut (1986) *(Juglans microcarpa)*	160	406	53	16.2	65	19.8	New Mexico
Northern California walnut (1986) *(Juglans hindsii)*	290	737	115	35.1	106	32.3	California
Southern California walnut (1973) *(Juglans californica)*	241	612	116	35.4	95	29	California

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

short. The leaf is compound and lance-shaped, with from 9 to 19 leaflets per leaf. They are pointed and downy. The nut is round, approximately 4 to 6 inches (10 to 15 centimeters) in circumference, with an outer thick hull. The hull is divided into 6 lobes and is dark green-brown in color. The sweet and oily kernel is inside a tough shell protected by the hull.

It requires about 80 years for walnut wood to mature and be used for timber. The specific gravity when kiln dried is 0.56; the shearing strength parallel to the grain is 1,000 psi (6.9 MPa). Compressive strength perpendicular to the grain is 1,730 psi (11.9 MPa). The strong, durable wood is rich brown in color, darker than European walnut and more uniform in color. The wood is closed-grained and aromatic. The wood is sometimes referred to as "Queen Ann's cabinet wood," and is particularly suited for carving, and especially valuable for furniture making and a leading wood for gun stocks.

Old walnut trees (a half century or more of age) are quite valuable even though facing death through diseases, such as *walnut dieback*, or suffering the effects of a lightning bolt. Owners of dying walnut trees will frequently send notices to walnut buyers asking for bids. For large trees (2 feet; 0.6 meter or more in diameter), the value will be in the thousands of dollars. The larger logs are frequently used for veneer. For example, the butt log from a large tree may have a volume of 1050 board feet,[1] which will produce approximately 80,000 square feet (7432 sq meters) or enough veneer to cover a wall 8 feet (2.4 meters) high and 13/4 miles (2.8 km) long. In processing, the log will be sawn into two pieces, lengthwise. Then, each half will be sawn in half (also lengthwise), making four quarters, known as *flitches*, from the single log. Each flitch is placed on a machine with a long knife blade that slices off the thin sheet of veneer. Much more detail on this topic is given by J. Birkemeir (*American Forests*, 13–15, September 1980). The processing of walnut wood and nuts is well covered by J.P. Jackson (*American Forests*, 18–58, October 1981).

Oil is obtained from pressing the nut kernel. The oil is fast-drying and yellow in color, and used for artists' paints. A walnut-shell flour made from walnut shells in California is used as a filler in plastics, providing strength.

The butternut tree is found from Maine to Minnesota and throughout the New England States. However, it does not occur in larger numbers. The tree is short-lived. The usual height is from 50 to 60 feet (15 to 18 meters), with a trunk of about 1 to 2 feet (0.3 to 0.6 meter) in diameter. The bark is furrowed and dark gray. The fruit is about 11/2 inches (3.8 centimeters) long, oval-shaped, with a brown, tough husk. The husk contains a yellowish liquid. The kernel is oily. Butternut wood takes a high polish and is considered quite valuable by cabinet makers.

WALRUS. See **Sea Lions and Seals**.

WANDERROO. See **Monkeys and Baboons**.

WARBLE FLY *(Insecta, Diptera; Hypoderma).* A bot fly whose larva migrates through the connective tissues of cattle to complete their development in small abscesses called warbles opening through the skin of the animal's back. The adult flies attach their eggs to the hairs of cattle and the newly hatched larva enters the skin by way of the hair follicle. During its development it migrates extensively before reaching its final position under the skin of the back. The perforations leading into the warbles damage the best part of the hide, and the insect is sometimes a source of economic loss as a cause of illness in cattle. The maggots can be pressed out of the warbles when they once become evident or can be destroyed by smearing an ointment over the openings in the skin.

WARBLER *(Aves, Passeriformes).* A small bird related to the thrushes. The warblers of the Old World are an extensive family (*Sylviidae*) represented in North America only by the *kinglets* and *gnatcatchers*. The birds commonly called warblers in America are more accurately distinguished as wood warblers and make up the family *Mniotiltidae*, more closely related to the vireos.

Both groups include species whose common names do not indicate their association. Among European examples are the *whitethroat*, the *hedge sparrow*, the *firecrest*, and among the American warblers are the *oven bird, water thrushes, chats*, and *redstarts*.

Many of these birds are beautiful. Their numerous species are a delight to bird lovers during the spring migration in the United States, and in the fall, due to the great variation of patterns and colors between the sexes and the immature individuals, they are as much a puzzle as a pleasure. See Fig. 1.

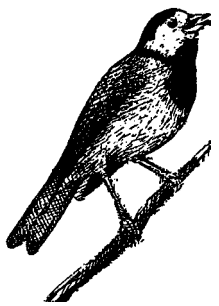

Fig. 1. Hooded warbler (*Wilsonia ciatrina*). Olive green above; yellow below. The male has a black hood covering the top of the head and running around the neck to the throat, giving the effect of a yellow mask across the face.

The *vireo* is a small, quietly colored bird of a family related to the warblers. The vireos are mostly gray to olive gray above and white below. Some species show traces of contrasting black or yellow. They construct beautifully cupped nests, suspended in the crotch of a twig.

The *whitethroat* is a European warbler. The common species, *Sylvia cinerea*, is a gray-brown color above and whitish below, and the lesser whitethroat, *S. curruca*, is gray above with dark brown ear coverts and tinged with pink on the breast. The *yellowthroat* is a North American warbler distinguished by its bright yellow front with black patch through the eyes and along the side of the head. Known as the Maryland yellowthroat in the eastern and central states and in its western varieties as the western, Pacific, tule, or salt-marsh yellowthroat. The bird frequents low thickets and marshy places.

WARBURG, OTTO HEINRICH (1883–1970). Otto Warburg was born at Freiburg in Breisgan, Baden, Germany on 8 October 1883. In 1896 the family moved to Berlin where his father had been appointed University Professor of Physics. At Berlin Warburg studied chemistry under Emil Fischer, thermodynamics with Walther Nernst and physics and photochemistry, including the quantum requirements of photosynthesis, with his father. Awarded a doctorate in 1906 he then studied medicine at Heidelberg, where he qualified in 1911. See also **Fischer, Emil Hermann (1852–1919)**; and **Nernst, Walther Hermann (1864–1941)**.

At Berlin Fischer taught him thoroughness in experimental work and, following Fischer's advice, Warburg would repeat his experiments many times before publishing the results. He trained his own technical assistants and was a pioneer in biochemical methodology, creating new methods and tools for investigations in spectrophotometry, the identification of cell constituents and enzymes, manometric measurements in cell metabolism studies, microanalytical techniques for the isolation of cell constituents and the crystallization of enzymes. From 1903 Warburg worked on cell metabolism, investigating cell respiration using iron compounds as catalysts. In the 1920s he developed a new tissue-slice technique coupled with biochemical manometry. In 1924 he discovered iron oxygenase and was awarded the Nobel Prize in Physiology or Medicine for this in 1931, the year when he became Head of the Max Planck Institute in Berlin.

While experimenting with yeast cells suspended in solutions containing iron oxygenase, with phosphates and glucose, Warburg observed that carbon monoxide inhibits cell respiration. The action is dependent on the ratio of the pressures of carbon monoxide and oxygen. He found that certain carbon monoxide/iron compounds are dissociated by light, releasing ferrous ions for oxygen attack. By alternating periods of light and darkness for cells respiring in mixtures of carbon monoxide and oxygen, Warburg determined the relationship between the number of Fe-CO groups split and the number of light quanta absorbed. Using monochromatic light of different wavelengths he showed that the absorption spectrum of the

[1] One board foot equals 2.36 cubic meters.

iron oxygenase–carbon monoxide complex was similar to that for carbon monoxide–hemoglobin, indicating that iron oxygenase is a hemin compound. By 1932 Warburg had also isolated the first of the flavoproteins (yellow enzymes), which take part in dehydrogenation reactions in cells. He discovered that they act together with a nonprotein component or coenzyme, flavin–adenine dinucleotide. In 1935 he discovered nicotinamide-adenine dinucleotide (NAD), another coenzyme involved in biological dehydrogenations. By 1950 Warburg was able to show that light energy conversion in plant cells proceeds in single-quantum stages, as predicted by Einstein's law of photochemical equivalence.

Warburg also investigated metabolism in cancer cells. In 1922 he discovered very high lactic acid production from glucose by cancer cells and concluded that they originate from normal body cells, replacing lost respiration energy by fermentation energy, which is morphologically inferior. Highly differentiated body cells then become cancer cells.

Warburg retired in 1969 at the age of 86. Throughout his life he devoted all his time and energy to experimental work, while Jacob Heiss of Kirn, southern Germany served as his administrator, monitor of scientific publications, financial adviser, consultant and close friend. Warburg died at Berlin-Dahlem on 1 August 1970 after a short illness. See also **Biochemistry (The History)**.

WART *(Verrucae)*. Warts are growths on the skin that occur in response to a viral infection. Warts come from the human papilloma virus, or from one of its 60 different subtypes, and enter the skin by direct contact. They thrive in moist environments but can occur anywhere. Once on the skin these viruses develop into raised skin lesions, gray, tan, brown, or black in color, having a piled up or horny surface that are highly contagious and easily spread by skin contact. Some warts will disappear over time if the immune system recognizes it as a virus and produces an antibody, but this is very rare. Warts are most effectively treated and removed by dermatologists.

Warts are found in multiples, do not bleed or itch, and with the exception of the plantar wart on the foot, do not cause pain. They are most commonly found on the fingers, hands, and soles of the feet. On the hands they are pale with a roughened appearance. Skin lines tend to go around them rather than through them. On the neck and face, warts tend to be small and smooth, while the painful plantar wart found on the ball or heel of the foot has the roughened look of a callus.

Children and teenagers are usually affected by warts because their still-developing immune system does not recognize or fight the wart virus. This changes as they age. The best precaution against plantar warts is not to go barefoot in locker rooms, poolside, or in hotels. The seemingly skimpy protection offered by wearing flip-flops or other sandals is actually all that is needed because it keeps the skin away from the wart virus.

Verruca vulgaris commonly occurs on the hands of children, as multiple, small warts over the fingers and back of the hand. Other forms are plantar warts on the soles of the feet, and venereal warts on the genitalia. It has been established that the types of warts appearing on children are caused by an identifiable filtrable virus. However, there is much to learn concerning the basic chemistry and mechanics of the behavior of these masses. Sometimes, on the one hand, they may disappear within a day or two after no attempt whatever to treat them. Other times, they stubbornly resist all attempts to remove them and, once removed, they may return to the exact spot on the body. Many warts disappear after varying lengths of time and thus do not require treatment. For stubborn cases where for cosmetic purposes it is highly desirable to remove the wart, various methods have been used with varying degrees of success. These include application of liquid nitrogen with a cotton-tipped applicator for freezing the lesion. This causes blisters and subsequent dissolution of the wart. Electrodesiccation and curettage are effective for persistent or recurrent lesions, but care must be exercised to avoid scarring.

The *Verruca plana* (skin-colored, flat wart), commonly seen on the face and back of the hand, or legs, is more difficult to cure. Freezing with liquid nitrogen, applying trichloracetic acid, or painting the lesions daily with 10% salicylic acid and 10% lactic acid in flexible collodion may be effective.

The *Verruca plantaris* (a more complex, mosaic-like lesion, often consisting of multiple discrete, or confluent lesions) is the most difficult to treat. These warts can be quite painful and, depending upon location, can be debilitating. After the wart is pared, 50% bichloracetic or trichloroacetic acid may be applied, or nightly applications of 40% salicylic acid plasters may be used. In unresponsive cases, surgical dissection and removal of the wart may be required.

Because of the similar appearance of some warts to much more serious skin lesions, the untrained person should not participate in diagnosis or treatment. Procedures such as those described should be limited to the physician.

Genital warts (*condyloma acuminata* or venereal warts) are caused by a group of viruses called human papilloma viruses (HPV). Genital warts are one or more painless, soft and fleshy growths that usually appear one or two months after exposure, but can take as long as nine months to incubate. Some warts are so small that they can be only identified with a colposcopic exam of the cervix and vagina or a Pap smear.

Genital warts are spread by sexual contact with an infected partner and are very contagious. Approximately two-thirds of all persons who have sexual contact with an infected partner will develop this sexually transmitted disease (STD). See also **Sexually Transmitted Diseases**.

Although much remains to be learned about how the papilloma virus progresses, doctors have observed that the warm, moist environment in the genital area seems to favor wart growth. Outbreaks appear to be exacerbated during pregnancy and in patients with defective immune systems.

Patients with a history of genital warts may be at increased risk for certain types of cancer. The human papilloma virus is associated with up to 90 percent of all cervical malignancies and may play a role in cancers of the vagina, anus, vulva and penis.

Cervical warts may be transmitted to the newborn via passage through the infected birth canal.

Like many other STDs, HPV infection often does not cause symptoms. One study sponsored by the National Institute of Allergy and Infectious Diseases (NIAID) reported that almost half of the all women with HPV had no visible symptoms. However, in many cases, small, hard spots (easily visible to the eye) can develop within three weeks to three months after exposure.

In women, the warts occur on the lips of the vagina, inside the vagina or around the anus. Anogenital warts may be itchy. Women also develop cervical warts, which are flat lesions invisible in their early stages. HPV infection is one of the most common causes of abnormal Pap smear tests.

It is important for a person who may have genital warts to see a doctor so other types of similar-looking infections or conditions can be ruled out or treated.

Genital warts are usually diagnosed by direct visual examination. When acetic acid (vinegar) is swabbed on the cervix or penis, HPV lesions appear whitish.

Colposcopy, a painless examination during which a lighted magnifying instrument is used to view the internal reproductive organs in women, can be performed in the doctor's office.

In some cases, it is necessary to do a biopsy of cervical tissue. This involves taking a small sample of tissue from the cervix and examining it under the microscope. Sampling cells with a biopsy and testing for HPV genetic material may be necessary to confirm a diagnosis.

Treatment. Genital warts often occur in groups and can accumulate into large masses on genital tissues. They often reappear after treatment. Depending on factors, such as their size and location, genital warts are treated in several ways.

A doctor may recommend treatment with a chemical, such as a 25 percent podophyllin solution, which is applied to the affected area and

washed off after several hours. Podophyllin should not be used during pregnancy, because it is absorbed by the skin and may cause birth defects.

Small warts can be removed by freezing (liquid nitrogen) or burning (electrodesiccation).

Imiquimod, a 5 percent cream that is an interferon inducer, has produced moderate activity in clearing external genital warts.

Surgery is occasionally needed to remove large warts that have not responded to other treatment. Doctors at some medical centers also use laser surgery to remove genital warts.

WASATCH WIND. See **Winds and Air Movement**.

WASHOW ZEPHYR. See **Winds and Air Movement**.

WASP *(Insecta, Hymenoptera)*. An insect related to the ants and bees. Some species are solitary and some social. Most species have four membranous wings, the front wings much larger than the hinder pair and both with few veins, joined to form closed cells. Some wasps burrow, some build nests of mud, and some use a coarse paper made by chewing wood from weathered surfaces. The last species are more commonly called hornets. Wasps are well known for their ability to sting; the more commonly known species inflict painful wounds because of their large size. See Fig. 1.

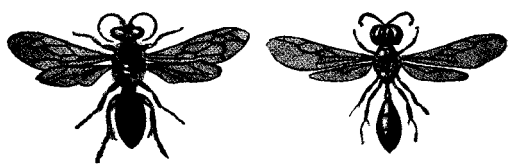

Fig. 1. Wasps.

From the scientific point of view, the term wasp is almost without value, since it applies to many different groups of insects. The members of one superfamily, the *Vespoidea*, include the spider wasps, the cuckoo wasps, the velvet ants, the true ants, the true wasps, and the potter wasps, each making up a different family, while the hornets and yellow-jackets, most familiar of wasps, are only one family of the group. Scientifically another superfamily, *Sphecoidea*, is made up entirely of insects called wasps according to some writers, but includes the bees according to others. The wasps of this division are represented by the giant cicada-killer, the largest of North American wasps, and the thread-waisted wasps.

Wasps have been extensively studied because of their complex behavior in making and provisioning nests for their young. In the works of the Peckhams and the Raus some remarkable and interesting records are preserved. See also **Dried-Fruit Insects**; **Hornet**; and "Fig Trees" in the entry on **Mulberry Family**.

WASTES AND POLLUTION. The approach to reducing waste and abating pollution is complex and sometimes even controversial among the experts. Differences arise because not all of the facts are on hand. The basic chemistry and physics of the Earth's three waste "sinks" — the atmosphere, the hydrosphere, and the lithosphere — remain poorly understood. Although there is consensus among both technologists and the lay public that serious environmental pollution problems exist and indeed are worsening, there are differences pertaining to details and priorities. Environmental scientists and engineers are influenced by factors that are not exclusively scientific, but that are of a societal and economic nature as well. The populace in general is slow to accept changes in life-style preferences and habits, and commerce and business interests frequently resist the concept that environmental costs must be added to the other costs of doing business. Such conflicting factors minimize the key ingredient of attaining success — *dedication*.

Even in view of the aforementioned difficulties, impressive pollution abatement successes have been made, but unfortunately the pace of these programs has not kept up with the rate of the worsening environment. To

TABLE 1. WASTE-POLLUTION OPTIONS AND STRATEGIES (Abridged)

PATHWAY 1

ELIMINATE OR GROSSLY REDUCE WASTES

Increase Life Span of Products
Reduce "junking" frequency. Design for corrosion and wear resistance; easy maintainability. Discourage frequent styling changes simply in interest of increasing marketing appeal.

Design Energy Efficiency into Products and Processes
Traditional processes for converting energy resources (fuels) into electricity, for example, are major polluters. Thus, end products and end processes should consume minimum energy to overcome "hidden" pollution costs. Considerable progress has been made to design more efficient heating and cooling systems (at manufacturing and consuming levels). New electric motor designs consume less energy. Electric lamp efficiency is increasing.

Use Less Pollutive Energy Sources
Check fuel BTU content vs. pollution generated. Also, pretreat fuels and design equipment to increase combustion efficiency.

Evaluate Nontraditional Energy Sources and Conversion Processes
Select least pollutive of common fossil fuels. Consider the feasibility of geothermal, hydro, solar, biomass, and other substitute energy resources. Nuclear power scores high as a non-polluter, with the exception of the radioactivity wastes. A new generation of nuclear reactors is underway that will increase safe operation manyfold. Much research on nontraditional energy resources continues, but generally technical problems have slowed the pace of progress. These efforts are addressed elsewhere in this encyclopedia. Check index.

Search for New Products and Processes (Substitutes)
Many existing products either generate excessive pollutants during their manufacture, require large amounts of energy (hence hidden polluters), or are adversely pollutive in their own right. Some agricultural chemicals and refrigerants exemplify the latter property. The techniques of organic synthesis provide an avenue to substitute product and process development. The recent development of new refrigerants to replace chlorofluorocarbons (ozone problem) and biological insecticides are examples. Some progress has been made in developing less-pollutive fuels for internal combustion engines and the substitution of new technology for traditional motive power, such as electric- and solar-powered vehicles.

De-emphasize Throw-Away Products
Although somewhat justifiable for certain hospital and medical products, these are very hazardous in wastes. This practice should be reevaluated. Other throw-away items, such as pens and cameras are designed because of marketing motivations and contribute to the waste-disposal load.

Eliminate Product Frills and Frivolous Products
Packaging engineers in recent years have contributed tremendously to waste creation. A substantial portion of household and restaurant wastes, for example, consist of packaging and shipping materials. The marketplace is full of junk merchandise.

Safely Transport Products
Moving polluting products from the manufacturing source to a consuming destination poses an environmentally damaging threat. Product containers must be designed to withstand forceful damage. In connection with petrochemical products, containers range in size from oil drums and chemical-containing carboys to ocean-going oil tankers.

J.S. Hirschhorn (Congressional Office of Technology Assessment) as early as 1988 presented a scholarly summary of waste reduction as the ultimate key to pollution abatement, "Waste reduction is the only way to save industry some of the escalating costs of the current waste-management system." The direct costs of waste disposal have increased some 50 times just over the past few years. Hirschhorn listed six steps to waste reduction:

1. Transfer the economic motivation for waste reduction to those engaged in the manufacturing process.
2. Motivate employees by crediting their performance records by meeting waste-reduction timetables established by management and for proposing waste-reduction concepts.
3. Seek technical assistance from outside sources to gain new viewpoints and incentives.
4. Conduct and maintain a waste-reduction audit.
5. Make waste reduction a lasting part of corporate culture. Approach waste-reduction goals today as energy conservation was stressed a decade or so ago.
6. Initiate a corporate-wide waste-reduction educational program.

TABLE 1. (*Continued*)

PATHWAY 2

RECYCLE WASTE MATERIALS

Design Containers for Recycling

Although not always desirable from a marketer's or consumer's viewpoint, throw-away containers of all kinds contribute massively to the waste-handling problem and to pollution.

Design Products and Components for Recycling

Whereas the aluminum beverage container cannot be reused as such, the aluminum in the can may be reprocessed. The recycling of aluminum is one of the current successes along these lines. The production of raw aluminum from ores consumes enormous amounts of electricity and thus contributes to pollution. Similarly, for years scrap and junk yards have specialized in recycling other metals and all manner of machine parts. From the viewpoint of pollution, this is an excellent practice. Nonmetallics have proved to be more difficult to recycle (most plastics, for example), but much technical progress in this area is underway. Recycled wood fibers in paper products has enjoyed much success. Product designers are in an excellent position to consider the recycling potential of materials after the useful life of the product itself has expired.

Design Processes for Recycling

Cooling water is a prime utility in manufacturing and most notably in the chemical and petrochemical industries. Excellent progress has been made in recycling water instead of continuously dipping into natural water reservoirs. Use is made of cooling ponds and relatively simple water treating at the plant site, thus bypassing pollutive procedures. This also avoids thermal pollution of water source.

Much more complex substances than water should be considered for recycling. These would include the reuse of solvents, cleaning compounds, and, in some instances, using traditional waste components as sources of raw materials. Recovery of valuable materials from wastes may prove less expensive than procuring the same substance from a supplier.

Consider Wastes as Energy Resources

Some industries that produce large amounts of combustible solid wastes have used such materials to augment solid fuels, such as coal, to generate utility steam and hot water. See article on **Wastes As Energy Sources**.

PATHWAY 3

NOTE: The actual disposition of waste into one of the Earth's "waste sinks" is the least attractive of pollution handling procedures. To date, however, dumping of waste remains the most widely used practice. Progress along Pathways 1 and 2 contribute to a progressive reduction in the tonnage of waste to be disposed and in the long term will alleviate the pollution problem in a major way.

In the advanced countries of the world, waste disposal is no longer a simple matter of venting gases and vapors into the atmosphere, or of finding the nearest creek or river, or of creating a landfill.

The carefree disposal of waste that took place several years ago resulted in a public outcry and the creation of numerous, often quite complex regulations. Thus, the polluting source today must take a number of costly actions prior to the ultimate disposal of the waste.

WASTE DISPOSAL — RELOCATING THE WASTE

Classify and Characterize the Waste

Regulations vary considerably, depending upon the nature of the waste. Hazardous (toxic) wastes are treated as a separate category by federal, state, provincial, and municipal regulatory agencies.

Pretreat Wastes Prior to Disposal

In addition to rigid requirements for hazardous wastes, other regulations may require various forms of pretreatment, such as sorting wastes into various categories in the interest of handling efficiency at waste sites, incinerators, and so on. Although they require handling as wastes, biodegradable wastes pose a lesser threat to long-term pollution and often require less stringent regulation.

Select an Appropriate Depository

Gases, vapors, and airborne particulates, unless present in minor amounts, generally will require postproduction treatment before venting to the atmosphere. Post-treatment is also frequently required for the disposal of liquid and solids. The topic of disposal site selection for liquids and solids is complex because there are so many classes of materials, including such diverse wastes as sewage, public building and household wastes, medical and hospital wastes, packaging wastes, transportation vehicle wastes, office wastes, and agricultural wastes. The lists numbers into the hundreds of categories.

In the case of fluids and solids, the Earth's hydrosphere or lithosphere are the only sinks available. For solids, some geological formations are much more appropriate than others. Some areas may appear suitable, but are found to exist over an aquifer (essentially an underground stream), and hence pollution can occur in the lithosphere and then pass along to the hydrosphere.

In the past, a number of polluters have used temporary waste storage means, such as aboveground tanks. Storage of radioactive wastes at nuclear power facilities is another example. In-plant storage or nearby polluter-owned sites must meet all current pollution regulations. These practices have been costly in retrospect. They have comprised many of the targets of the so-called Superfund.

Consider a Professional Waste-Handling Firm

Expert assistance (applying mainly to liquid and solid wastes) is available, but extreme caution must be taken in selecting such assistance. There have been several instances of fraudulent practices that have led to disastrous pollution and resulted in strict legal judgments against the initiating polluter.

Run Continuous Checks on Waste Disposal Costs

Where costs continue to spiral, this may provide the incentive to initiate actions along Pathways 1 and 2, which can lower pollution costs in the long term.

Consider the Inevitable Conflicts

Severe regulations are reasonably clear in terms of what a polluter can and cannot do. But tradeoffs do remain. A basic triangle of conflicting forces — that is, Energy vs. Economy vs. Environment — is described in article on Electric Power Production and Distribution.

Louis J. Thibodeaux (Louisiana State University and Director, EPA-Sponsored Hazardous Waste Research Center), in 1990, outlined the four *natural laws* of hazardous waste:

1. In converting thermal energy to useful work, a certain amount of waste (thermal) energy must be discharged into the environment.
2. It is impossible to recycle waste completely. Recycling is one aspect of waste minimization, not a solution.
3. Some fraction of the energy and material needed to drive processes and make products will always be degraded to waste that will have to be disposed of in an environmentally acceptable manner, such as incineration or some version of the solidification/fixation process.
4. Small waste leaks are unavoidable and acceptable. Ecosystems can handle small infusions of hazardous substance. Such discharges must, however, be made small so that there will be no harmful effects either locally or globally.

illustrate the partial successes to date, one need only to compare the environmental status in the advanced industrial nations with the environmental damage found in the former Soviet Bloc, where environmental problems essentially were ignored.

Pathways to Environmental Correction

From an idealistic viewpoint, one may place the efforts for restoring the purity of the natural environment as falling along three pathways. This is an approximation, and the pathways are not mutually exclusive. Table 1 essentially is included as a checklist of the numerous actions that are being taken.

Pathway 1 includes those actions that are directed more toward eliminating or drastically reducing waste production — that is, efforts made to correct the cause (waste) rather than the effect (pollution). Had actions along these lines been taken years ago, the massive pollution experienced today most likely would not have occurred.

Pathway 2 actions recognize that, with current technology and societal attitudes coupled with economic factors, a considerable amount of pollution must be accepted. Actions along this pathway, however, can reduce the amount of wastes produced and hence resulting pollution.

Pathway 3 actions recognize the current inevitability of mass pollution, but which are directed toward reducing the long-term effects of waste disposal. In the past, pollution has occurred in somewhat of a step-like fashion (i.e., creation of the wastes in the first place, sometimes followed by unscrupulous means taken to "hide" or simply "forget" abandoned wastes, followed by waste site clean up). These problems occur simply because wastes have been or are being disposed of improperly.

Establishment of Regulations

When it became apparent that environmental protection could not be accomplished strictly on a voluntary basis, several of the advanced industrial countries were forced to take regulatory actions (circa mid-1960s). The problem was too complex and not sufficiently understood at the outset to institute complete legislation at one time. Consequently in the United States, for example, numerous special acts were passed but stretched out for several years. See Table 2 on p. 3701. This has resulted in difficult compliance and enforcement procedures.

TABLE 2. WASTES AND POLLUTANTS REGULATORY STATUTES

(United States — Partial List)
Clean Air Act
Clean Water Act
Comprehensive Environmental Response, Compensation, and Liability Act (popularly known as the Superfund)
Federal Insecticide, Fungicide, and Rodenticide Act
Food, Drug, and Cosmetic Act
Hazardous Materials Transportation Act
National Environmental Policy Act
Occupational Safety and Health Act
Resource Conservation and Recovery Act
Safe Drinking Water Act
Superfund Amendments and Reauthorization Act
Toxic Substances Control Act

Note: Most of these statutes have been enacted since the early 1970s.

Numerous scholars of the environment have noted several major differences between the way some of the advanced European industrial nations and Japan approach the problems of waste reduction and pollution abatement, and the general approach adopted by the United States over the years. The European countries referred to here notably are the Netherlands, Sweden, and Germany and, of course, do not include the former Soviet Bloc countries.

In the United States, *regulation* is by far the predominant controlling tool. The U.S. system is highly legalized. In the European countries and Japan, regulation is but one tool used.

Government regulators in the United States infrequently provide specific professional assistance to a firm with pollution problems. In the European countries mentioned and in Japan, regulatory personnel frequently work closely and cooperatively with industrial personnel in seeking solutions. In fact, in some cases, government grants are made available for remedial implementation.

The principal incentive for regulators in the United States is that of *developing* and *enforcing* regulations. Less emphasis is directed toward finding better methods for achieving improved results. In connection with the Superfund program, regulators are credited when pollution sites are cleaned up, but emphasis is given to *initiating* the action, with less accountability required where the cleanup has been found inadequate.

In Japan and the European countries mentioned, regulators are rewarded for eliminating waste streams and cleaning up pollution. Regulators contribute technical expertise. In some cases, research is conducted in government laboratories in an effort to solve a particular pollution problem. The emphasis is on cooperation, rather than adjudication.

In the United States, regulations are highly detailed, sometimes overburdened with detail. They are drawn up so that they can withstand litigation and with little practical latitude in enforcement. Industry has no greater access to the regulators than does any other interest. This, unfortunately, tends to create a climate of confrontation rather than one of cooperation.

In the European countries mentioned and in Japan, polluting firms are not required to pay for past practices that did not break former law, with the exception of sites that the polluter continues to own. In the United States, industrial polluters are liable for cleanup costs for sites to which they have contributed waste, even though no laws were broken when the pollution was created.

A more thorough examination of these policy differences is given in the Beecher/Rappaport reference listed.

Particular Attention Given to Hazardous Wastes. In addition to toxicity, hazardous wastes include materials that may become chemically reactive, including ignitability and explosibility, or that may be corrosive. Some toxic materials require extensive pretreatment prior to dumping. See Table 3 on p. 3701.

TABLE 3. REGULATOR'S CHARACTERIZATION OF HAZARDOUS WASTES

Toxicity

Definition of Extract: The liquid component of a solid waste and deionized water at a pH 5.0 that has been in continuous contact with the solid phase of the waste for a minimum of 24 hours.

Permissible Upper Limit of Contaminant:

	Milligrams/Liter
Arsenic	5.0
Barium	100.0
Cadmium	1.0
Chromium	5.0
Lead	5.0
Mercury	0.2
Selenium	1.0
Silver	5.0
Endrin insecticide	0.02
Lindane insecticide	0.4
Methoxychlor insecticide	10.0
Toxaphene insecticide	0.5
2,4-D (2,4-Dichlorophenoxyacetic acid)	10.0
Silvex 2-(2,4–5 Trichlorophenoxy propionic acid)	1.0

Reactivity

Any substance that:

- Is normally unstable and readily undergoes violent changes with detonations.
- Reacts violently with water.
- Reacts with water to generate toxic gases, vapors, or fumes in a quantity that is dangerous to human health or the environment.
- Is capable of detonating or undergoing an explosive reaction when subjected to a strong initiating source or if heated when confined.
- Is capable of detonation or explosive decomposition or reaction at standard temperatures and pressures.
- Is normally considered explosive and that meets transportation regulations.
- Forms potentially explosive mixtures with water.
- Is a cyanide or a sulfide-bearing material that, when exposed to a pH between 2 and 12.5, can generate toxic gases, vapors, or fumes that are dangerous to human health or the environment.

Ignitability

Any substance that:

- Is a liquid with a flash point of less than 60 °C (140 °F).
- Is a solid and is capable of causing fire through friction, absorption of moisture, or spontaneous chemical changes that, when ignited, burns so vigorously as to create a hazard.
- Is a compressed gas or oxidizer that does not meet transportation regulations.

Corrosiveness

Any aqueous liquid with a pH less than or equal to 2.0 or greater than or equal to 12.5.

Any liquid that corrodes steel at a rate greater than 0.006 meter (1/4-inch) per year.

With the growing use of throwaway products in the hospital and medical field, there is an increasing danger stemming from *infectious wastes*. The ultimate disposal of millions of needles and condoms becomes a part of municipal wastes. The virulence of microorganisms under such conditions is poorly understood. Throwaway diapers not only contribute immensely to the volume of wastes to be handled, but also contain hosts of living microorganisms, the survival rate of which, under disposal conditions, have not been documented. The common childhood intestinal pathogens, such as retoviruses, hepatitis A virus, and the protozoans *Giardia* and *Cryptospordium*, have not been ruled out.

Incineration of Hazardous Wastes

One authority has commented that the greatest public health danger with medical waste in the United States is *substandard* incineration practices

at local hospitals. It has been estimated that in the early 1990s there were about 6000 substandard medical-waste incinerators throughout the United States. The congressional Office of Technology Assessment (OTA) has estimated that air emissions of dioxin and heavy metals from these incinerators average from 10 to 100 times more per gram of waste burned than emissions from well-controlled municipal waste incinerators. Also, hospital incinerators produce toxic remains in the ashes that can contaminate surface and groundwater when dumped in landfills.

The problem is exacerbated in large and crowded communities. For example, there are well over 50 hospital incinerators in New York City. Most local hospital incinerators are not equipped with acid-gas scrubbers, which convert harmful airborne substances into harmless calcium salts. Nor are most incinerators equipped with electrostatic precipitators to capture particles that have adsorbed toxic flue gases.

Authorities report that quite the contrary conditions exist in several parts of Europe, notably Switzerland and Germany. Legislation in the early 1980s in Germany mandated the closing of hospital incinerators, requiring that medical wastes be sent to regional facilities, at which the latest in technology is deployed. Incinerator operators are given special training and require certification of their skills. Particular precautions are used in feeding such incinerators to protect plant workers. The incinerated remains are disposed of in specially lined landfills.

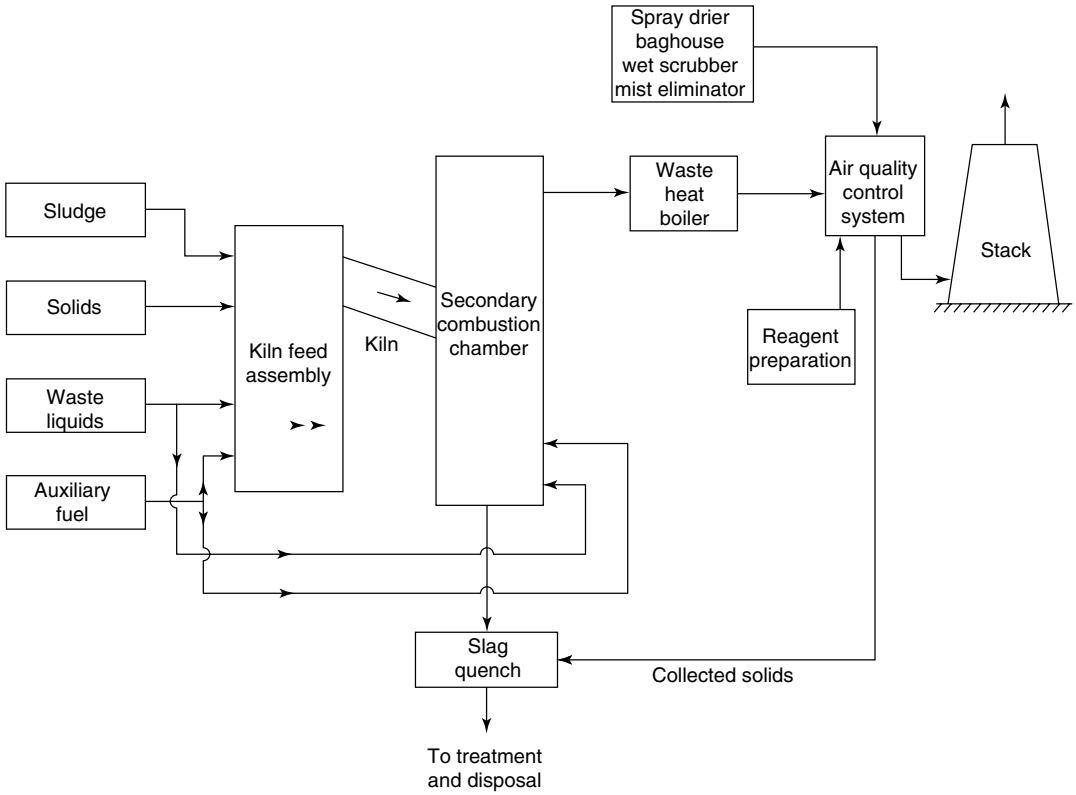

Fig. 1. Simplified flowsheet of incineration train in a hazardous waste treatment complex. (*After Tillman.*)

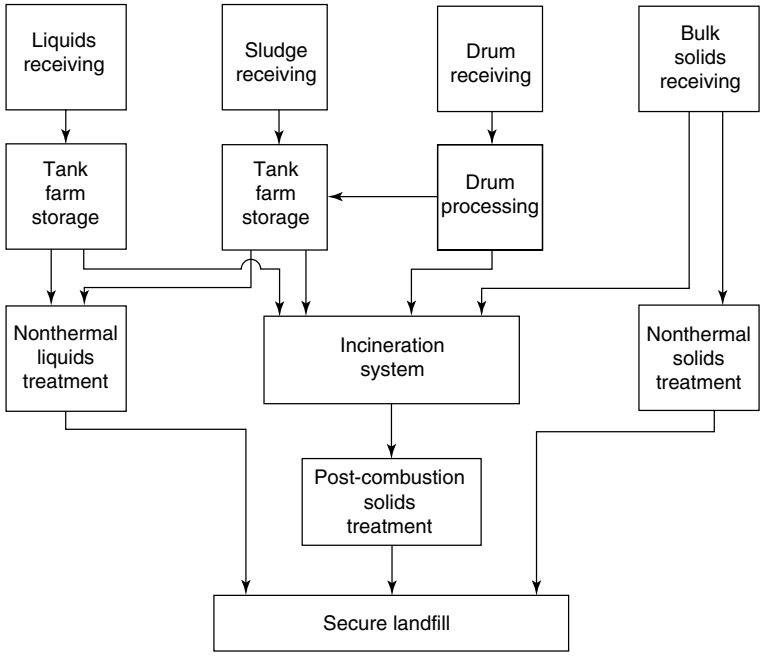

Fig. 2. Generalized flowsheet of a hazardous waste treatment system complex that utilizes a rotary kiln incineration system. (*After Tillman.*)

Recently, the technology of autoclaving instead of incineration has been proposed. Disinfection is achieved through the use of high-pressure steam, which assists in breaking the refuse down and ready for compacting.

German authorities also mandate strict regulations over the transport of medical waste, disallowing the transport of foodstuffs in trucks that also are used to handle medical wastes. Hospitals also are required to "tag" all refuse, designating such categories as "office, cafeteria, and general," "infectious" (including pathological body parts, syringes, needles), "radioactive," and "dangerous to handle" (such as scalpels, which must be placed in unopenable containers).

Considerable design effort has been invested in the improvement of incineration systems. D.A. Tillman (Ebasco Environmental) and associates report that "Rotary kilns have become the incinerators of choice for eliminating hazardous wastes in accordance with the U.S. Resource Conservation and Recovery Act, Superfund, and related legislation."

The Ebasco team points out, "A rotary kiln is basically a rotating cylinder that, typically, is refractory lined. The cylinder is tilted slightly (i.e. 3°) and the feed material goes into the upper end. A heat source is applied to the material, usually by combusting liquid or gaseous fuel within the kiln. Gravity moves the material through the cylinder, and it is discharged from the lower end. When rotary kilns are used for hazardous waste incineration, the gaseous products from the kiln are ducted to a secondary combustion chamber for subsequent destruction." Several overall system design configurations are possible. Generalized configurations are illustrated in Figs. 1 and 2. See Tillman reference listed.

J.F. Mullen (Dorr-Oliver Inc.) reports that fluidized bed incinerators have been used for municipal sludge and industrial waste incineration since the early 1960s for a variety of wastes (petroleum tank bottoms, sludge from pharmaceutical, pulp and paper, and nylon manufacturing operations), waste plastics, waste oils, and solvents. Fluid beds were first considered for incinerating hazardous wastes in the 1980s.

Advantages claimed for fluid bed technology include efficient combustion, ease of control for handling a variety of feeds, and reasonably low capital and operating costs. Specific advantages claimed for incinerating hazardous wastes include fuel savings and lower emissions of nitrogen oxides (NO_x) and metals. The principles of a fluid bed incinerator are illustrated in Fig. 3. Among the primary organic hazardous constituents (POHCs) of waste, the fluid-bed has successfully demonstrated its effectiveness in achieving 99.99% efficiency in removal of aniline, carbon tetrachloride, chloroform, chlorobenzene, cresol, para -dichlorobenzene, methyl methacrylate, naphthalene, perchloroethylene, phenol, tetrachloroethane, 1,1,1-trichloroethane, trichloroethylene, and toluene.

Soil-Washing Technology

Tons of earth per hour can be sifted and scrubbed clean of hazardous materials by using what may be called a heavy-duty industrial *washing machine*. Soils contaminated with hazardous or radioactive materials may be removed by washing. Contaminating material that "comes out in the wash" so to speak, such as copper, then can be recycled and reused by industry. Although not widely publicized, soil washing is not a new technology. It has been estimated that nearly 100,000 tons of contaminated soils are remedied in this manner each year in Europe. The bulk of these soils are sands contaminated with hydrocarbons and/or heavy metals. Westinghouse has developed a commercial unit.

The soil-washing process itself is environmentally benign. It is a closed-loop system, and thus no contaminants are discharged into the air or land. It is a permanent solution to many hazardous problems because it physically removes contaminants from the soil. Examples of tests made on the process are graphed in Fig. 4. Soil washers are mounted on truck trailers for mobility. A flow sheet of the process is given in Fig. 5.

In a particular application, Westinghouse unveiled in late 1992 equipment for removing lead particles from the residue created when bridges and other metal structures are sand-blasted to remove old lead-containing paint. This problem is commonly encountered by highway construction and maintenance personnel, but the system is not limited to such applications. It has been estimated that the method has achieved a two-thirds reduction in disposal costs as compared with burial or smelting

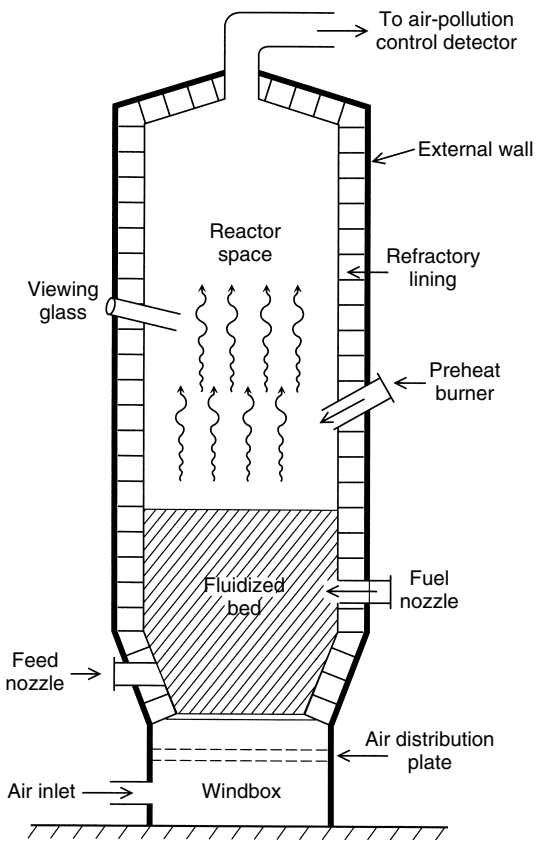

Fig. 3. Schematic diagram of a fluid-bed incinerator. Waste is injected into a bed of inert material that is fluidized by large quantities of air flowing upward through the unit. (*After Mullen.*)

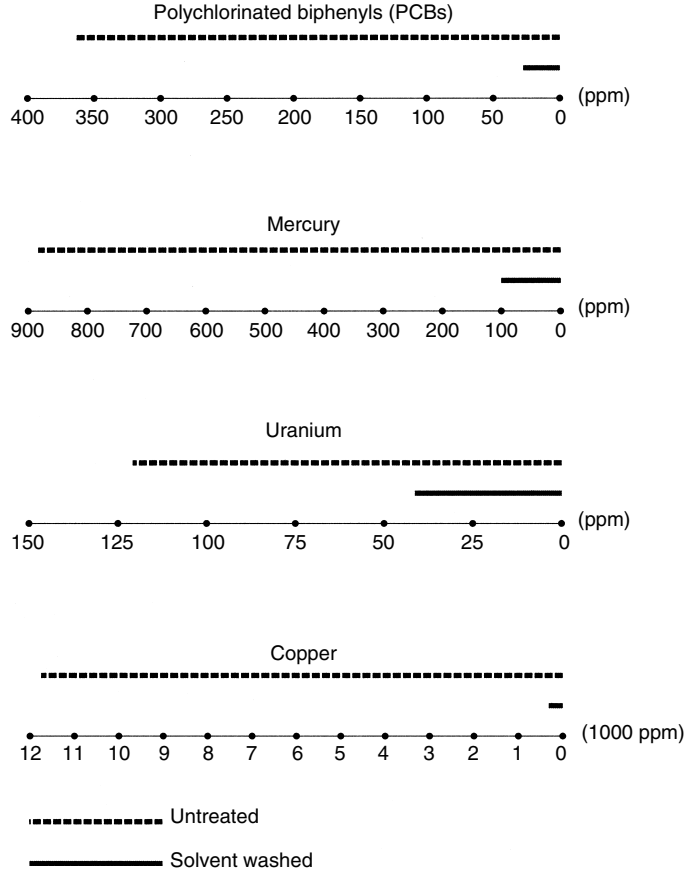

Fig. 4. Examples of performance of soil-washing process. (*Westinghouse Electric Corporation.*)

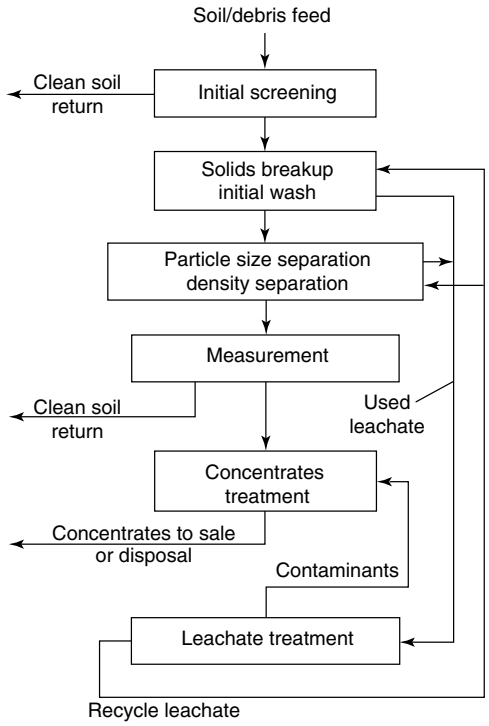

Fig. 5. Soil-washing process flowsheet. (*Westinghouse Electric Corporation.*)

without pretreatment. One of the first large-scale tests of the equipment was conducted by the Minnesota Department of Transportation. A portable soil-washing machine for highway work is shown in Figs. 6 and 7.

Fig. 6. Portable soil-washing machine shown here at a highway maintenance site used for removal of lead particles from the residue created when bridges and other metal structures are sand-blasted to remove old paint containing lead. There are numerous applications for such portable plants. (*Westinghouse Electric Corporation.*)

Soil washing is based on the use of water-based leachates, which are recycled continuously in the machine. The end products are a relatively clean, coarser soil fraction and a wash water containing finer soil particles and most contaminants. The small levels of organic contamination remaining in the coarser materials are removed readily with heat. The wash water, depending upon the specific contaminants, responds to various traditional treatment methods, such as bioremediation, air stripping, chemical precipitation, or membrane separation.

Recycling Plastic Wastes

Although plastic wastes in refuse are highly visible to the public, and thus have caused considerable consumer pressures on plastics manufacturers to take anti-pollution measures, disposal of plastics creates special problems in municipal incinerators because of the formation of some toxic gases.

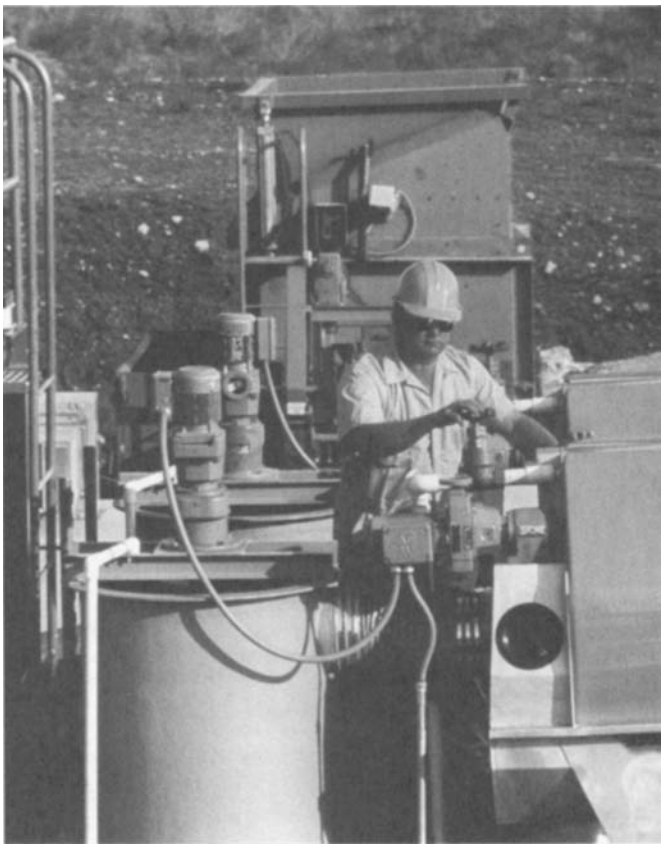

Fig. 7. Operator at controls of portable soil-washing machine used at highway reconstruction site. (*Westinghouse Electric Corporation.*)

In terms of dumpsite disposal, the absence of biodegradability results in long-term solids buildup. Actually, on a weight basis, however, plastics only comprise 7% of municipal wastes, as shown in Table 4.

TABLE 4. MAJOR MATERIALS IN MUNICIPAL WASTES

Material	Percent by Weight
Paper products	40
Yard waste	18
Food waste (garbage)	12
Glass	8
Plastics	7
Steel/metals	7
Other	8
	100
Principal Classes of Plastics	
Low-density polyethylene (LDPE)	24
High-density polyethylene (HDPE)	19
Polystyrene	14.5
Polypropylene	14.5
Polypropylene terephthalate (PET)	4.5
Other plastics	23.5
	100.0

The principal plastics that show up in municipal wastes are the polyethylenes, polystyrenes, and polypropylenes. These include polyethylene terephthalate (PET) used in soft drink containers, high-density polyethylene (HDPE), used in milk jugs, and polystyrene, used in fast-food containers, which, incidentally, were first banned in Oregon (1989).

As early as 1989, 7 billion plastic soft drink containers were produced in the United States and nearly an equivalent tonnage in Europe. As of early 1991, it was reported that about 28% of the PET bottles produced in the United States were recycled, yielding over 20 million pounds of PET for subsequent use in making carpet yarn, fiberfill for clothing, nonfood

containers, automobile parts, fencing, and industrial strapping. A doubling of these amounts was expected by 1995.

A principal plastic reclaiming process used was developed in the Netherlands by a resin manufacturing firm. In this process, after removal of labels and base cups by machine, the bottles (clear or green) are color sorted and granulated. The PET flake is then washed to remove glue. Closure material is separated by flotation from the PET. The remaining PET is dried and sifted for fines and then is ready for reuse.

In 1989, seven of the leading plastics producers in the United States formed the National Polystyrene Recycling Company, with a 1995 target for achieving a minimum of a 25% recycling rate for polystyrene. A pilot recycling center was set up in Leominster, Massachusetts.

A joint venture of a leading plastics manufacturer and a major waste management firm was established in 1990 to recycle PET and HDPE materials. The plan was that two existing plants would be joined by three additional recycling operations by 1994. Jointly, the plants would recycle about 200 million pounds of these plastics per year. Taken in perspective, however, this is a small quantity of the total of 1.5 billion pounds (PET) and 6.5 billion pounds (HDPE) disposed each year in the United States.

Still another leading plastics manufacturer commenced operation recently for recycling 400 million pounds/year of plastic film and rigid containers. Following a pilot-plant test run, a wide variety of polyethylene materials can be processed. These include polyethylene wrap, lawn and grocery bags, and containers (detergent, bleach, and motor oil), as well as plastic milk and juice bottles and PET soft drink and liquor containers. When in full operation, the plant will serve a 500-mile (~800-km) radius area. It is projected that new applications for the recycled materials will displace some of the requirements for virgin plastic and nonplastic materials. Food applications of recycled material are not in the current plans because of the special problems involved in altering the color and other physical properties of the recycled resins.

Plastic materials recycling poses a serious problem when plastic refuse is received in a commingled state. Because of the great variety of plastic products, only a comparatively few can be presorted before delivery to a recycling plant. These few exceptions would include plastic milk and other beverage containers. Impressive research has been underway at Rensselaer Polytechnic Institute, and a patent has been obtained for a process that dissolves shredded plastics (as described by a researcher), "one polymer at a time in a chip-filled vat" where a solvent (xylene) is used to dissolve five groups of plastics at five separate temperatures, ranging from room temperature to 138 °C (280 °F). For example, polystyrene dissolves first, while the other plastics remain unaffected. The top solubility temperature required is well below the boiling point of the xylene solvent. As pointed out by the researchers, the xylene polymer solution (for a specific polymer) drains to a separate part of the system, where it is heated under pressure to near the boiling point of xylene. Pressure is required to keep the xylene-polymer solution in liquid form. The solution then is sent through a valve into a vacuum chamber to undergo flash devolitization. The sudden change from high to low pressure, researchers say, causes the xylene to vaporize instantly, leaving behind the pure polymer.

After the recovered polymer is removed, the same xylenes are recompressed and cooled to return to its liquid state. It again is heated to a different temperature and reintroduced into the vat to dissolve another of the polymers, and the interim steps are repeated until all polymers present have been separated.

Genetic Engineering and Pollution

Research on the genetic engineering of microbes to degrade toxic wastes has been underway for at least two decades. Progress has been relatively slow, partially attributed to societal concerns over the possible release of new, untested microorganisms that in themselves could create environmental and health threats. As one researcher in the field has pointed out, "No one wants to release organisms before the possible consequences are known, but the possible consequences will remain unknown until the organisms are released."

A very cautious approach has been taken thus far concerning the possible use of engineered microbes in connection with the Superfund dumpsite cleanup program. Budget allocations for genetic engineering in the pollution field have not exceeded a few million dollars annually for the past several years.

Pseudomonas putida, a common soil microbe, has been the target of several researchers. A few years ago, scientists at the University Medical Center (Geneva, Switzerland) created a microbe that eats 4-ethylbenzoate (4-EB), a toxic synthetic chemical. The researchers attempted to find all the "right" genes and combine them into one organism. As early as 1980, researchers in the United States designed a microorganism to break down crude oil. This also involved research with *Pseudomonas* bacterial species. Other engineered microbes have been created that break down much of the sulfur in coal. Research at Johns Hopkins University also has yielded engineered microbes that can metabolize sulfur.

Microorganisms have been used successfully to clean up contaminated wastewater of such substances as pentachlorophenols (PCPs), polychlorinated biphenyls (PCBs), iron cyanide, and leachates containing chlorinated compounds, phenols, and formaldehydes. A dry cleaning solvent, tetrachlorodiphenylethane (TCE), which is a suspected carcinogen, has been degraded through the use of enzymes released by a strain of the bacterium, *Pseudomonas cetacia*. A wastewater treatment plant has used a mutant strain of *Pseudomonas*, which consumes mine-generated cyanide wastes. A process has been developed that uses naturally occurring microbes to concentrate phosphorus for easy removal. It has been estimated that 99.3% of phosphorus in wastewaters can be removed by the process. One firm has developed a bioreactor that uses an aerobic microorganism (naturally occurring in white-roto fungus) to break down toxic substances, such as 2-chlorophenol.

Other researchers have designed a microorganism for breaking down crude oil, and some experience has been gained from testing the product for cleaning up oil tanker spills. Several proprietary engineered microbes have been announced, but with little detail given. Research firms in the field are delaying commercialization, pending clarification of federal, state, and provincial regulations. See also **Water Pollution**.

Fermentation. In 1990, a bioprocessing research center was opened at Penn State University. A pilot plant demonstrates various processes for converting (recycling) agricultural and food processing wastes into dietary supplements for animals. The pilot plant is designed with versatility and flexibility for testing and processing a wide variety of substances. One example of agricultural and livestock wastes that can occur during abnormal situations is an estimated 1 million tons/day of chickens that die of natural causes and are buried at a site on the Delmarva Peninsula, which borders on the Chesapeake Bay. In extremely hot weather, this figure can increase to 4 million tons/day. Also, it has been estimated that 600 tons/day of fish wastes are dumped off Kodiak Island. The Netherlands is estimated to produce 100 million tons/year of poultry manure, twice the amount that the land can absorb naturally. Researchers at Penn State have applied for patents on one of the fermentation processes developed. A type of marine yeast converts protein-bearing waste into a slurry of water-soluble proteins. The process destroys all pathogens. Thus, when the slurry is dried, it is suitable as a dietary supplement. Researchers note that the same principles could be applied to cesspool wastes. Although centralized sewer systems collect *un*sanitary wastes in most urban areas today, there remain multi-thousands or millions of cesspools used in less-populated areas of the country.

Recycling/Regenerating Paper Wastes

Considerable progress has been made during the past decade for recycling paper wastes, which according to Table 4 constitute well over one-third of the typical municipal waste produced.

Investigators at Texas A&M University (Austin, Texas) are targeting on improved processes for regenerating paper wastes. One of the key problems is the cellulose content in newspapers and paper products. Cellulose is very difficult to "digest." The researchers have developed an ammonia fiber explosion (AFEX) technique that more efficiently utilizes enzymatic digestion of cellulose. Researchers explain that ground-up municipal waste is placed in a tank and soaked with ammonia for about one-half hour, after which high pressure is applied. When this pressure is released abruptly, cellulose fibers are literally blown apart, making it much easier for enzymes to digest them. The enzymes break down the cellulose into individual glucose molecules, after which yeast can convert them to ethanol. The researchers have noted an improvement of up to 150% in digestion as the result of the AFEX process. Researchers also forecast that 180 billion tons of municipal wastes could be converted into over 8 billion gallons of ethanol fuel for automotive consumption.

In many communities, prescribed routines for consumers to separate paper from other items of trash have been highly successful and, in fact, in recent years there has been more paper ready to recycle than there are facilities to process it. Consequently, a lot of newsprint and other paper products still go to the dumpsite. Paper in the household trash is a highly visible waste to the average consumer — hence, much cooperation from the populace has been evidenced. In recognition of an imminent "glut" of newsprint to recycle, some municipalities and states have lowered their targets. One example is Wisconsin, which had set a goal of 50% recycled fiber by 1995 to 17% by 2001.

As mentioned earlier in this article, there is a continuing conflict (triangle) of forces that come into play in numerous decisions that interlock the factors of energy, environment, and economy. Newsprint as of the early 1990s is an example. Publishers, particularly in the northeastern United States, can obtain paper of high quality and made of virgin fibers from nearby Canada at an attractive cost, not much in excess of the cost of recycled newsprint. Canadian paper is imported duty-free. Approximately 58% of the paper consumed in the United States (overall) is imported from Canadian mills from trees grown in Canada. Expected lower timber prices in the southeastern United States may make that region more competitive with Canada over the next decade or two.

Average use by newspapers of recycled fibers seldom exceeds 50% of the total. However, the publishers of the *Los Angeles Times* use approximately 80% recycled fiber.

Recycled newsprint does pose problems to publishers, notably those of books and magazines. Some virgin pulp is required to hold the paper together. Magazine publishers usually purchase what recycled paper they do use from pulp-substitute suppliers — that is, firms that process only selected used paper, such as envelope trim and cuttings, ledgers, business forms, and computer printout paper. A long-range recycling program also poses the problem of dealing with shorter fibers. Each time paper is reprocessed, the fibers are shortened. The present use of recycled fiber in newspapers is, on the average, about 20%.

The processing of recycled paper is essentially the same as the production of paper from virgin fibers once the feed slurry is made. See article on **Papermaking and Finishing**; and **Pulp (Wood) Production and Processing**.

In preparing the slurry for recycled newsprint, first all trash must be removed from the waste paper (some manual labor assisted by machine metal detectors, etc.). The paper then passes to a pulper, where water and some reagents are used to accomplish de-inking. In the pulper, the waste paper is shredded by rotating cutting blades to produce a slurry. This slurry is passed through a continuous pulper, similar to that used in making virgin paper slurry after the natural fibers have been processed in a digester. The slurry then passes through screens and onto a three-stage washer, where ink particles are fully removed and the paper adjusted for the proper consistency prior to being introduced onto the paper machine.

Considering the numerous errors that have appeared in the environmental literature, Stephen Strauss, a science writer for the *Toronto Globe and Mail*, points out how easy it is to draw conclusions regarding environmental measures when raw data have not been gathered, calculated, or presented with exacting care. Strauss makes the serious but amusing observation, "When historians of technology reflect on the final quarter of the twentieth century, they may well surmise that the archetypal public debate (over pollution) centered around the throw-away (paper or foam) cup."

See Strauss reference listed.

Several other articles in this encyclopedia address the topic of waste and pollution. See also **Pollution (Air)**; **Water Pollution**; and alphabetical index. Global warming concepts are described in article on **Climate**; radon is covered under **Radon**; and ozone is described in article on **Polar Research**.

WASTES AS ENERGY SOURCES. Initially, *biomass* was defined as the amount of living organisms in a particular area, stated in terms of the weight or volume of organisms per unit area or of the volume of the environment. This definition still applies very well to ecological and geophysical assessments of land areas or regions and depths of the seas and lakes.

In modern technology, the term also may be used to describe the exploitation of living terrestrial materials, such as plants or marine plants, all or parts of which may be combusted directly for the thermal energy that they yield or, more indirectly, as raw materials for processes that can convert the biomass into fuels.[1] Very generally, biomass may be considered the total amount of living matter within a given unit of area, volume, or mass. When biomaterials serve as foods or provide fibers and items of construction, for example, waste is created. These materials are typified by straw, sawdust, sewage sludge, and so on, which possess value as energy sources. That aspect of biomass is the topic of this article.

Generally, the pace of research and construction of facilities for transforming solid wastes into energy forms, such as methane, or to recover heat from combusting the wastes, slowed during the late 1980s and early 1990s. There are several causative factors, but of course a breakthrough could reverse these trends. In the 1970s, during the time of the oil embargo and energy crisis, finding new sources of energy was a major incentive. The fervor of the former energy programs has largely deteriorated in the presence of what is now considered by many a severe environmental crisis. This latter incentive has not been sufficient to foster extensive research programs in transforming garbage and other trash into energy because the *primary* advantages remain as an energy source and not as a means of pollution abatement. Nevertheless, progress has been made. Simply combusting municipal rubbish as a means of waste disposal is described in the preceding article.

Considerable research is being conducted on a variety of biomass feedstocks that contain cellulose, from which ethanol can be produced. Again, ethanol as a transportation fuel component has not been widely accepted, even though aggressively promoted in some areas. Brazil usually is cited as a prime example of progress in this area. L.R. Lynd (Dartmouth College) and a team of researchers have been studying the impacts of alternative fuel use on carbon dioxide (CO_2) accumulation, energy security, and economic effects on the United States as a whole. The team observes, "Production of ethanol from cellulosic biomass is believed to be an emerging energy technology with particularly great potential for the U.S. transportation sector. Research to improve conversion processes and to develop cellulosic energy crops is necessary to reduce costs and to increase production potential. Success can reasonably be expected in both these areas in light of the immature state of current technology and the powerful approaches available." In terms of their potential for yielding ethanol, in order of diminishing production potential, are agricultural wastes, forest sources, and municipal solid waste.

The majority of agricultural, commercial, industrial, and urban or municipal wastes are of a biological rather than mineral nature and thus fall under the umbrella of biomass. The simple burning of wood for heat illustrates one of the simplest ways to convert biomass to energy. All biomass represents an indirect form of solar energy. Biomass, as a source of energy, differs from coal, natural gas, and petroleum in one major way — biomass is renewable. Some potential biomass energy crops can be renewed as frequently as two or three times per year, depending upon location, while other materials such as trees have a renewable cycle of several years. Anthropogenic wastes are renewed on a daily basis. Interest in biomass over the last several years has stemmed from the overall concern with ultimate exhaustion of nonrenewable energy sources, as well as gaining a degree of political independence by many nations that either do not have any fossil fuel resources, or that have insufficient supplies to maintain a strong economic and industrial position.

Urban Wastes as Energy Sources

Urban waste includes household, sewage, commercial, institutional, manufacturing, and demolition waste. The availability of this waste is directly related to the population living in urban areas of adequate size to support a given size system.

Manufacturing and processing wastes include all residuals generated from material inputs that leave the plant as product output. Office and packaging wastes associated with this sector are included in the urban waste sector. The majority of these wastes are from pulp and paper manufacturing, primary and secondary wood manufacturing, and the construction industry.

The energy recovery system selected dictates the extent that solid waste must be prepared. Some systems require nothing more than the removal of massive noncombustibles, such as kitchen appliances from the refuse, while other processes require extensive shredding, air classification, reshredding, and drying. In conjunction with fuel preparation, it is usually worthwhile to reclaim metals and glass for recycling.

One-stage shredding is often used to reduce waste to a nominal size as small as 1 inch (2.5 centimeters). When finer-sized fuel is required, a second shredding step is usually used after air classification has removed many of the noncombustibles. Both vertical and horizontal air classifiers depend on the heavy noncombustibles settling out by gravity in a moving air stream, while the lighter combustibles are pneumatically transferred through the air classifier. Denser combustibles, such as rubber and leather, may be removed with the heavy fraction, while some of the fine glass and metal foils are carried with the combustibles. Thus, desired separation may not always be achieved on one pass through an air classifier.

Some energy recovery systems require drying to remove excess moisture in the waste. This is required when sewage sludge is used as a fuel. Usually, waste heat from the total process can be used for the drying system.

Pyrolysis. In one system, municipal refuse is charged at the top of a shaft furnace and is pyrolyzed as it passes downward through the furnace. Oxygen enters the furnace through tuyeres near the furnace bottom and passes upward through a 1425 to 1650 °C combustion zone. The products of combustion then pass through a pyrolysis zone and exit at about 93 °C. The off-gas then passes through an electrostatic precipitator to remove flyash and oil formed during pyrolysis. The latter are recycled to the furnace combustion zone. The gas then passes through an acid absorber and a condenser. The clean fuel gas has a heating value of about 300 Btu/cubic foot (2670 Calories/cubic meter) and a flame temperature equivalent to that of natural gas. The solid waste that remains is a slag at the furnace bottom.

Biological Methane Production. This process involves the anaerobic digestion of a solid waste and water or sewage sludge slurry at 60 °C for five days to produce a methane-rich gas. Solid waste is prepared by shredding and air classification, followed by blending with water to produce a mixture of 10 to 20% solids concentration. The slurry is heated and placed in a mixed digester at 60 °C for 5 days detention. The digester gas is drawn off and separated into carbon dioxide and methane. The spent slurry from the digester is pumped through a heat exchanger to partially heat the incoming slurry prior to filtration. The filtrate is returned to the

[1] The generation of biomass from carbon dioxide is called "primary production" because it is the first fundamental step in turning inorganic material into organic compounds and cell constituents. This reduction of carbon dioxide uses sunlight as the source of energy. See also **Photosynthesis**.

blender and the sludge is used for landfill. Heat addition to the refuse slurry is required to maintain the required digester temperature. The process is well suited for use on sewage sludge, animal manures, and other high-moisture-content solid wastes. It is estimated that the process can reduce the volume of volatile solids by 75%, while producing about 3000 cubic feet (85 cubic meters) of methane per ton of incoming solid waste. The major residue is used for landfill or incinerated. About 10% of the methane is required to heat the digester feed.

Direct Steam Process. One process uses a rotary kiln pyrolizer followed by an afterburner and boiler to produce steam from shredded waste. The pyrolysis process in a kiln is operated countercurrently. Solid waste enters at one end and pyrolyzed residue is discharged at the other. External fuel and air are introduced at the residue discharge area and combustion products and pyrolysis gases leave the kiln at the feed opening. This arrangement causes the solid waste to be exposed to progressively higher temperatures as it passes through the kiln. The kiln off-gases pass through a refractory-lined afterburner into which air is introduced to allow complete combustion prior to passing through the waste heat boiler. A wet scrubber is used for air pollution control, while an induced draft fan is used to draw the gases through the system. One ton of solid waste, augmented by 1.25 million Btu (0.3 million Calories) from auxiliary fuel and 55 kilowatt-hours of electricity will produce about 4800 pounds (2177 kilograms) of steam at 330 psig (22.4 atmospheres) along with 200 pounds (91 kilograms) of char.

Waterwall Incinerators. These devices generate steam by burning unprepared solid waste on a grate and passing the hot products of combustion through a boiler. Numerous waterwall incinerators have been built in Europe and the United States. Unprepared refuse is taken from storage pits and charged directly into the incinerator feed hopper. From there, the refuse drops onto a feed chute and then is fed automatically onto the stoker by means of a hydraulic feed ram. Temperatures in the 870 °C range effectively burn the solid waste. Before the flue gas enters the boiler, secondary air is added to produce a temperature near 1090 °C. The boiler is constructed of membrane waterwalled tubes with extruded fins. After passing through the boiler, the gases travel through an economizer section and then into an electrostatic precipitator for particle removal. A typical 1000 tons/day (900 metric tons/day) waterwall incinerator produces about 300,000 pounds (136,080 kilograms) of steam per hour.

Additional engineering is required where toxic wastes may be present.

Principal Biomass Materials for Energy

Biomass-to-energy systems fall into two principal categories: (1) materials for direct combustion that will generate heat for processing, for warming living and working spaces, for steam and hence also for generating electricity; and (2) materials from which both fuels and chemicals can be obtained through biochemical or thermochemical conversion processes. Resulting fuels must have ample caloric content per unit of weight and thus rich in carbon and hydrogen and poor in the content of atoms, such as oxygen and nitrogen, which do not contribute to the caloric value of the fuel. In searching for new biomass raw materials, scientists have found it helpful to study the various biosynthetic pathways followed by plants from seed to maturation.

Direct Wood Burning. Wood was the major fuel of the United States until about 1886 when the consumption of coal equaled that of wood. Oil did not appear on the chart until about 1900 and gas in 1910–1920. The use of wood tapered off while other fuels climbed at amazing rates, but wood never ceased as a factor, even if small. It is interesting to note that about a million modern woodburning stoves are in use and that about 40% of the wood products industry is furnished by combusting bark and mill wastes. This amounts to about 1 quad (10^{15} Btu). Wood burning has been sufficiently extensive during the past few years to cause environmental concerns in some regions. Although wood has a low sulfur content and produces minimal amounts of nitrogen oxides even by the hottest fires (1370 °C; 2500 °F), it contains air pollutants in the form of particulates, gases, and tars. Environmentalists in the New England region have estimated that the 300,000–400,000 tons of wood burned per year (New Hampshire only), if the fuel is very dry red oak, will add 1000 tons of particulates to the air; if dry white pine is burned, the total may be over 5000 tons. Since a mixture of woods usually is used, the figure lies somewhere between the two aforementioned quantities.

Agricultural Wastes. In the absence of an energy crisis, with a few exceptions, attention to the use of agricultural wastes has waned. These materials continue to represent an essentially untouched source of energy in most countries. In the course of extensive scientific research in the early 1970s, at a time when renewable energy sources were being aggressively sought, evaluations were made of various materials for their caloric content and availability. Included were corn (maize), sorghum, wheat, sugar beats, sugarcane, pineapple, and cassava, among others. Several of these crops were considered as sources for the production of alcohol for admixture with gasoline (gasahol) as an automotive fuel. Brazil has had considerable success in this regard with sugarcane as a raw material.

Although burning and incineration offers means for disposing some waste products, these processes do contribute to air pollution and thus must meet the requirements now followed for the common fossil fuels.

WASTEWATER TREATMENT. See **Water Pollution**.

WATCH. See **Clocks**.

WATER. [CAS: 7732-18-5]. Water (from the Old English word *wæter*; c.f German "Wasser", from Proto-Indo-European language (PIE) **wod-or*, "water") is a tasteless, odorless, and nearly colorless (it has a slight hint of blue) substance in its pure form that is essential to all known forms of life and is known also as the most *universal solvent*. Water is an abundant substance on Earth. It exists in many places and forms. It appears mostly in the oceans and polar ice caps, but also as clouds, rain water, rivers, freshwater aquifers, and sea ice. On the planet, water is continuously moving through the cycle involving evaporation, precipitation, and runoff to the sea.

Water fit for human consumption is called *potable water*. This natural resource is becoming scarcer in certain places as human population in those places increases, and its availability is a major social and economic concern.

Water takes many different shapes on earth: water vapor and clouds in the sky, waves and icebergs in the sea, glaciers in the mountain, aquifers in the ground, to name but a few. Through evaporation, precipitation, and runoff, water is continuously flowing from one form to another, in what is called the *water cycle*. See also **Clouds and Cloud Formation**; **Evaporation**; **Ocean Resources (Energy)**; **Polar Research;** and **Precipitation and Hydrometeors**.

Because of the importance of precipitation to agriculture, and to mankind in general, different names are given to its various forms: while rain is common in most countries, other phenomena are quite surprising when seen for the first time. Hail, snow, fog or dew are examples. When appropriately lit, water drops in the air can refract sunlight to produce rainbows.

Similarly, water runoffs have played major roles in human history as rivers and irrigation brought the water needed for agriculture. Rivers and

seas offered opportunity for travel and commerce. Through erosion, runoffs played a major part in shaping the environment providing river valleys and deltas which provide rich soil and level ground for the establishment of population centers. See also **Irrigation**; and **Ocean**.

Water also infiltrates the ground and goes into aquifers. This groundwater later flows back to the surface in springs or more spectacularly in hot springs and geysers. Groundwater is also extracted artificially in wells. See also **Hydrology**; and **Groundwater**.

Because water can contain many different substances, it can taste or smell very differently. In fact, humans and other animals have developed their senses to be able to evaluate the drinkability of water: animals generally dislike the taste of salty sea water and the putrid swamps and favor the purer water of a mountain spring or aquifer. See also **Ocean Water.**

Biological Aspects. From a biological standpoint, water has many distinct properties that are critical for the proliferation of life that set it apart from other substances. Water carries out this role by allowing organic compounds to react in ways that ultimately allows replication. It is a good solvent and has a high surface tension, and thus allows organic compounds and living things to be transported in it. Fresh water has its greatest density at 4°C, then becoming less dense as it freezes or heats up from this point. As a stable, polar molecule prevalent in the atmosphere, it plays an important atmospheric role as an absorber of infrared radiation, crucial in the atmospheric greenhouse effect without of which, the average surface temperature would be −18° Celsius. Water also has an unusually high specific heat, which plays many roles in regulating global and regional climate, such as the Gulf Stream climate, allowing life to survive. See also **Greenhouse Effect**.

Water is a very good solvent, chemically not unlike ammonia, and dissolves many types of substances, such as various salts and sugar, and facilitates their chemical interaction, which aids complex metabolisms.

Some substances, however, do not mix well with water, including oils and other hydrophobic substances. Cell membranes, composed of lipids and proteins, take advantage of this property to carefully control interactions between their contents and external chemicals. This is facilitated somewhat by the surface tension of water.

Water drops are stable due to the high surface tension of water caused by the strong intermolecular forces called cohesive forces. This can be seen when small quantities of water are put onto a nonsoluble surface such as polythene: the water stays together as drops. On extremely clean glass the water may form a thin film because the molecular forces between glass and water molecules (adhesive forces) are stronger than the cohesive forces. This property plays a key role in plant transpiration.

In biological cells and organelles, water is in contact with membrane and protein surfaces that are hydrophilic, that is, those surfaces that have a strong attraction to water. Langmuir observed a strong repulsive force between hydrophilic surfaces. To dehydrate hydrophilic surfaces - to remove the strongly held layers of water of hydration — requires doing substantial work against these forces, called hydration forces. These forces are very large, but decrease rapidly over a nanometre or less. Their importance in biology has been extensively studied by Parsegian. They are particularly important when cells are dehydrated by exposure to dry atmospheres or to extracellular freezing.

A simple but environmentally important and unique property of water is that its common solid form, ice, floats on the liquid. This solid phase is less dense than liquid water, due to the geometry of the strong hydrogen bonds which are formed only at lower temperatures. For almost all other substances and for all other 11 uncommon phases of water ice except ice-XI, the solid form is denser than the liquid form. Fresh water is most dense at 4°C, and will sink by convection as it cools to that temperature, and if it becomes colder it will rise instead. This reversal will cause deep water to remain warmer than shallower freezing water, so that ice in a body of water will form first at the surface and progress downward, while the majority of the water underneath will hold a constant 4°C. This effectively insulates a lake floor from the cold.

While this behavior may seem obvious, even intuitive, it should be noted that almost all other chemicals are denser as solids than they are as liquids, and freeze from the bottom up.

Life on earth has evolved with and adapted itself to the important features of water. The existence of abundant liquid, vapor and solid forms of water on Earth has been an important factor in the abundant colonization of Earth's various environments by life-forms adapted to those varying and often extreme conditions.

Civilizations have historically flourished around rivers and major waterways; Mesopotamia, the so-called cradle of civilization, is situated between two major rivers. Large metropolises like London, Paris, New York, and Tokyo owe their success in part to their easy accessibility via water and the resultant expansion of trade. Islands with safe water ports, like Singapore and Hong Kong, have flourished for precisely this reason. In places such as North Africa and the Middle East, where water is scarcer, access to clean drinking water was and is a major factor in human development.

A common misconception about water is that it is a powerful conductor of electricity. Any electrical properties observable in water are due to the ions of mineral salts and carbon dioxide dissolved in it. Water does self-ionize (two water molecules become one hydroxide anion and one hydronium cation), but only at a very slight, almost immeasurable level. Pure water can also be electrolized into oxygen and hydrogen gases but without any dissolved ions, this is a very slow process and thus very little current is conducted. Many bottled water companies exploit another common misconception, advertising both purity and taste, even though pure water is tasteless.

Astronomical Impact. The coexistence of the solid, liquid, and gaseous phases of water on Earth is vital to the origin, evolution, and continued existence of life on Earth. However, if the Earth's location in the solar system were even marginally closer or further from the Sun (ie, a million miles or so), the conditions which allow the three forms to be present simultaneously would be far less likely to exist.

Earth's mass allows gravity to hold an atmosphere. Water vapor and carbon dioxide in the atmosphere provides a greenhouse effect which helps maintain a relatively steady surface temperature. If Earth were less massive, a thinner atmosphere would cause temperature extremes preventing the accumulation of water except in polar ice caps (as on Mars). According to the solar nebula model of the solar system's formation, Earth's mass may be largely due to its distance from the Sun.

The distance between Earth and the Sun and the combination of solar radiation received and the greenhouse effect of the atmosphere ensures that its surface is neither too cold nor too hot for liquid water. If Earth were more distant, most water would be frozen. If Earth were nearer to the Sun, its higher surface temperature would limit the formation of ice caps, or cause water to exist only as vapor. In the former case, the low albedo of oceans would cause Earth to absorb more solar energy. In the second case, a runaway greenhouse effect and inhospitable conditions similar to Venus would result.

It has been proposed that life itself may maintain the conditions that have allowed its continued existence. The surface temperature of Earth has been relatively constant through geologic time despite varying solar flux, indicating that a dynamic process governs Earth's temperature via a combination of greenhouse gases and surface or atmospheric albedo. This proposal is known as the *Gaia hypothesis*.

Properties. A colorless liquid, H_2O or HOH, odorless, tasteless, melting point 0°C (one of the standard temperature points), boiling point 100°C at 760 millimeters of mercury pressure (another standard temperature point).

The boiling point of water increases with increasing pressure: 100.366°C at 770 mm; 120.6°C at 1,520 mm; 180.5°C at 7,600 mm. The boiling point decreases with decreasing pressure: 99.360°C at 750.0 mm; 99.255°C at 740.0 mm; 98.877°C at 730.0 mm; 81.7°C at 380 mm; 46.1°C at 76.0 mm.

At 0°C, the density of water is 0.99987 gram per milliliter. At 8°C, 0.99988; at 15°C, 0.99913; at 16°C, 0.99897; at 17.5°C, 0.99871; at 20°C, 0.99823; at 25°C, 0.99707; at 40°C, 0.99224; at 50°C, 0.99807; at 75°C, 0.97489; at 100°C, 0.95838; at 120°C, 0.9434.

The critical temperature of water is 374.15°C; critical pressure, 218.4 atmospheres; critical density, 0.323 gram per cubic centimeter.

The viscosity at 0°C is 0.01792 poise (dyne second per square centimeter), specific viscosity, 1.000. At 20°C the viscosity is 0.01005 poise, specific viscosity, 0.561. At 50°C, the viscosity is 0.00549 poise, specific viscosity, 0.307. At 75°C, the viscosity is 0.00380 poise, specific viscosity, 0.212. At 100°C, the viscosity is 0.00284 poise, specific viscosity, 0.158.

The surface tension of water against air at 0°C is 75.6 dynes per centimeter. At 10°C, the surface tension is 74.22; at 20°C, 72.75; at 30°C, 71.18; at 60°C, 66.18; and at 100°C, 58.9.

The specific heat of water is 1.000000 at 15°C (standard of specific heat). At 0°C, the specific heat is 1.00874; at 25°C, 0.99765; at 35°C, 0.99743 (minimum); at 50°C, 0.99829; at 65°C, 1.00001; at 80°C, 1.00239; at 100°C, 1.00645; at 120°C, 1.016; at 180°C, 1.04.

The electrical conductivity of water at 18°C is 0.04×10^{-6} reciprocal ohms (measurements of Kohlraush and Heydweiller, 1902); of pure water in equilibrium with air, 0.8×10^{-6}; of ordinary distilled water, about 5×10^{-6}.

The dielectric constant of water (specific inductive capacity) is 81.07 at 18°C.

Pure water, when free of dissolved gases, may be heated above 100°C (even up to 180°C) without boiling, but upon further heating, boiling with explosive violence may occur. Steam at 100°C occupies a volume 1,700 times greater than water at 100°C. Pure water, when not agitated, may be cooled somewhat below 0°C without freezing, but upon further cooling it congeals with an increase of volume (density of ice, 0.917) exerting great force, when confined, but if in intimate contact with water at atmospheric pressure, the freezing temperature is 0°C. The vapor pressure of ice and water is 4.579 millimeters at 1 atmosphere pressure and 0°C. The triple point (ice, water, and water vapor) occurs at a saturation vapor pressure of 6.11 millimeters and at a temperature of 273.16 K. When water is compressed to about 20,000 atmospheres and then cooled, other varieties of ice, all denser than water, are formed. Ice II is 12% denser; Ice III is 3% denser. At least six varieties of ice are known.

In ice I, ice II, and ice III, each oxygen atom is surrounded tetrahedrally by four other oxygen atoms, the difference between the three forms being largely in some distortion of the linkages, since the O — O distance varies little from the 2.76 value of ice I. Each oxygen atom has 2 hydrogen atoms quite close (about 1 Å) to it. At lower temperatures, and presumably higher pressures (forms V, VI, and VII, the water molecules with four hydrogen bonds are more in evidence.

Liquid water exhibits the same tendency toward increased bonding at lower temperatures. While individual water molecules have a nonlinear structure, there is association between H_2O molecules by hydrogen bonding, the degree of association being greater at lower temperatures. Based upon the statistical mechanical treatment of Frank and Wen, liquid water may be regarded as a mixture of hydrogen bonded clusters and unbonded molecules. Other research characterizes this model in terms of 5 species: unbonded molecules, tetrahydrogen bonded molecules in the interior of cluster; and surface molecules connected to the cluster by 1, 2, or 3 hydrogen bonds.

The chemical properties of water change with temperature at high temperatures. The reaction, $2H_2O \longleftrightarrow 2H_2 + O_2$, shows an appreciable shift to the right, reaching 0.8% at 2,000°C, and increasing rapidly above that temperature. At ordinary temperatures, the equilibrium, $2H_2O \longleftrightarrow H_3O^+OH^-$, is important because it enables water to act either as a proton donor or acceptor. With stronger acids, water can act as a proton acceptor:

$$HCl + H_2O \longleftrightarrow H_3O^+ + Cl^-$$

$$HBr + H_2O \longleftrightarrow H_3O^+ + Br^-$$

$$HSO_4^- + H_2O \longleftrightarrow H_3O^+ + SO_4^{2-}$$

With stronger bases, water can act as a proton donor:

$$H_2O + CO_3^{2-} \longrightarrow HCO_3^- + OH^-$$

$$H_2O + NH_3 \longrightarrow NH_4^- + OH^-$$

Although the ions shown are written as CO_3^{2-}, HCO_3^-, Cl^-, etc., they of course are more or less solvated by the water, i.e., they have water molecules attached to them by ion-dipole bonds, since water is a polar compound. One of the most strongly marked properties of water is its behavior as an electrolytic solvent, which is due to its high dielectric constant. The energy of separation of two ions is an inverse function of the dielectric constant of the solvent. Some of the parameters of water are shown in diagram of Fig. 1.

Molecular Architecture. Greatly oversimplified, the water molecule may appear as shown in Fig. 2, which indicates the equilibrium position of the oxygen atom and the hydrogen atoms, i.e., the equilibrium position

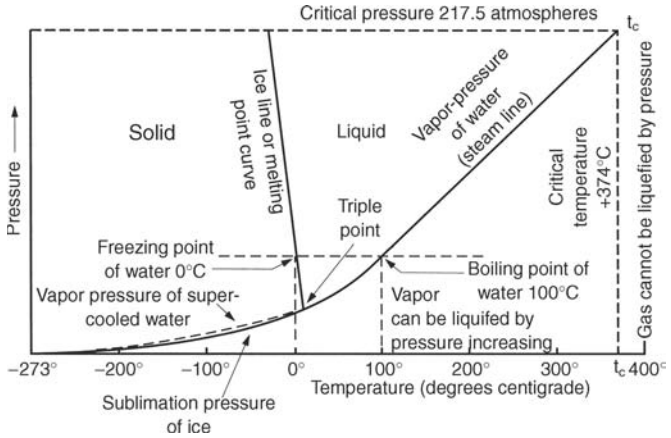

Fig. 1. Pressure-temperature diagram for water.

of the positive and negative charges of the molecule. Because of this orientation, the water molecule has a strong tendency to be oriented in an electrical field. The dipole moment depends upon the magnitude of the charge separation within the molecule, and in the water molecule, the separation is large. Thus, water may be described as having an exceptionally large dipole moment and consequently a large dielectric constant. On the basis of ascribing a dielectric constant of 1 for a vacuum, the dielectric constant of water is 80; i.e., in water, 2 electrical charges will attract or repel each other with only 1/80th as much strength as would be the case in a vacuum. This accounts, at least in part, for the remarkable ability of water to dissolve substances, particularly materials whose molecules are held together primarily by ionic bonding. The bonding arrangements within the water molecule also account for the exceptional cohesive power exhibited in water's high surface tension and the outstanding ability of water to adhere strongly to a variety of materials (the property of wetting). Bonding also accounts for the manner in which water crystals, e.g., snowflakes, are formed and for the maximum density of water (4°C), below which water assumes less dense forms, causing ice to float. Bonding is responsible for the exceptional heat capacity and exceptionally high latent heats of fusion and evaporation of water.

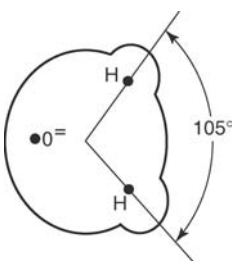

Fig. 2. Schematic representation of arrangement of electrical charges in water molecule.

The molecular behavior of various molecular types in electrolytes is shown in Fig. 3. This behavior is of particular significance to the role of water in biological systems. See also **Molecule**.

Although of continuing interest, research on the structure of water is exceptionally difficult. X-ray crystallography has provided a good picture of the stable hydrogen-bonded structure of ice, but thus far the structural imaging of liquid water has escaped investigators, and hence blackboard theorizing and computer modeling are the principal research techniques followed. In the *Journal of the American Chemical Society* (*JACS*) of May 20, 1992, water scientists present a complex new theory that may account for so many of the physical properties of liquid water.

Heavy water, also known as deuterium oxide, D_2O, is water in which the hydrogen of the water molecule consists entirely of the heavy-hydrogen isotope having a mass number of 2. The density of heavy water is 1.1076 at 20°C. Heavy water has been used as a moderator in nuclear reactors as well as a coolant.

Uses. Water is such a common substance that its importance and versatility are usually taken for granted. Included among the major ways in

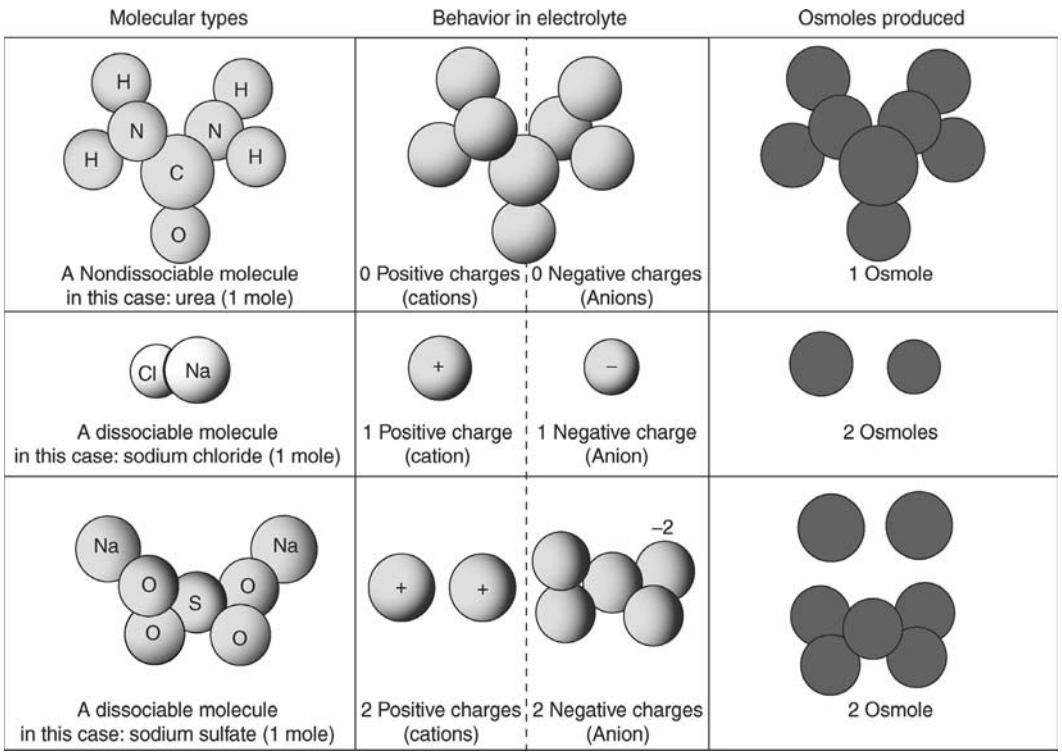

Fig. 3. Behavior of various molecular types in electrolytes. (*After Maffy*.)

which water is important would be: (1) as a raw material for incorporation into final products without chemical change; (2) as a raw material for undergoing chemical change; (3) as a transport and conveyance medium with water acting as a solvent or carrier of solutions and suspensions in and out of reactions and physical-change operations — at an industrial as well as biochemical level; (4) as a heating and cooling medium over the wide temperature range from below normal freezing temperature (brine solutions, for example) to those of superheated steam; (5) as an energy-storage medium; (6) as a gathering medium for waste products; (7) as a cleaning medium; (8) as a shield against heat and nuclear radiation (heavy water); (9) as a convenient standard in terms of temperature, density, viscosity, and other units; and (10) with exception of a few situations where the presence of water is hazardous, as a fire-fighting medium.

Water Metabolism in Vertebrates. Those vertebrates that now inhabit land, seas, brackish and fresh waters have survived because they have developed homeostatic mechanisms that enable them to cope with considerable variation in the content and availability of water, sodium, potassium, and chloride in their external environment. These mechanisms prevent life-threatening changes in their internal environment by (1) assuring that the cells are bathed by fluid with the same osmotic concentrations as themselves; and (2) by preventing major qualitative changes in the intra- and extracellular content of these ions or water. Regardless of species, one is impressed not by the differences, but by the similarities in the ionic composition of their intra- and extracellular fluids. The water content of the fat-free tissues of all vertebrates ranges between 70 and 80%. Water diffuses freely along its concentration gradient (osmosis) throughout all body tissues. Therefore, any deviation of the osmotic pressure of intra- or extracellular fluids, by either withdrawal or addition of water, causes an immediate movement of water from the more dilute to the more concentrated solution until osmotic equilibrium is reestablished.

Water is lost from the body of mammals by evaporation across the skin and in the expired air, urine, and feces. The more arid the environment, the more a mammal must be able to reduce water loss and tolerate longer periods of water dehydration and hypertonicity of its body fluids.

According to Chew, vertebrates fall into several groups in terms of how they maintain their water balance. *Fishes and amphibians* in fresh water are very hypertonic to their medium and must counteract a continual dilution of their body fluids. Water influx is reduced by the relative impermeability of the skin, and is balanced by diuresis. Electrolytes lost in this urine are replaced in food eaten and by absorption through gill surfaces (fishes) and skin (amphibians). *Marine elasmobranches* are unique in maintaining themselves slightly hypertonic to sea water by retention of urea (2±%) in their body fluids, making their osmotic pressure more than twice that of marine teleosts. *Marine teleosts* and terrestrial tetrapods face the continual problem of counteracting desiccation due to osmotic loss to a hypertonic medium or to evaporation. Mammals are the most effective of vertebrates in conserving urine water by concentrating the urine, which is achieved by reabsorption of water in the kidney tubules.

Terrestrial tetrapods adjust by avoidance of evaporative stress, reduction of evaporative and urinary water losses, and temporary toleration of hyperthermia or hypernatremia. Antidiuretic hormone (ADH) from the neurapophysis is very important in enhancing uptake of water through the skin (amphibians), reduction in glomerular filtration (amphibians, reptiles, birds), and increase in tubular reabsorption of water (mammals).

Water balance processes are best developed in species inhabiting deserts, where little drinking water is available and climatic conditions accentuate evaporation.

Certain toads and frogs survive in deserts, needing open water only for breeding, largely by remaining dormant during dry periods. Evaporation is greatly retarded in a cool damp burrow, and urine volume is reduced by 98–99% (filtration antidiuresis), but urine remains hypotonic. Urinary water may be recycled through the body by reabsorption from the bladder. Dormant animals tolerate a loss of 50–60% of their body water. They emerge during rains, and in their dehydrated state quickly reabsorb water through the skin.

Terrestrial reptiles also avoid considerable evaporation by being quiescent in burrows much of the time. Also, their skin is more impermeable than that of amphibians, although water is still lost in expired air. Hydrated lizards have low urine filtration rate (urine always hypotonic), and may become almost anuric when dehydrated. During dehydration, electrolyte wastes are retained in the body and tolerated in concentrations fatal to birds and mammals, until water is available for their excretion. A carnivorous diet (70±% water) provides adequate water intake while food is available. Water can be reabsorbed osmotically from the cloaca, reabsorption being particularly effective because of the nature of the principal nitrogenous waste, uric acid, which has a very low solubility. As uric acid precipitates in the cloaca, its osmotic effect is removed, and further water can then be absorbed by osmosis. This is probably the major value of uric acid excretion. Precipitated wastes are excreted en masse, with very little fluid loss.

Birds, being homeothermic, cannot reduce their evaporative loss by becoming dormant. Being diurnally active and exposed to radiant energy, they must often expend water for cooling, by panting. Consequently, in arid regions the distribution of birds is limited to areas within flying distance of water. Some water expenditure is avoided by allowing hyperthermia (up to 3°C) in the daytime.

Desert rodents lead the most water-independent life of all vertebrates. Kangaroo rats can so reduce their evaporation that they are able to maintain water balance on only metabolic water. Other species survive on only metabolic water plus free water in air-dry seeds. Respiratory water loss is reduced by cool nasal mucosal surfaces, which condense water from warm air coming from the lungs, before it can be expired. Skin impermeability involves a physical vapor barrier in the epidermis, plus unknown physiological factors.

Many larger mammals are exposed to daytime radiant energy and need to dissipate heat by sweating, panting or wetting themselves with saliva (marsupials). These water expenditures must be balanced periodically by drinking. A dehydrated camel is particularly physiologically adapted to store heat (rather than dissipate it by evaporation), undergoing a temperature rise of up to 6° in the daytime.

Water in the Human Body. The adult male human body contains about 60% (weight) of water and the adult female body about 50%. The large amount of body water is compartmentalized, each compartment being bounded by membranes. It has been estimated (Edelman and Leibman, 1959) that 55% of this water is contained within cells and that it is bounded by cell membranes. The remaining, extracellular water or fluids (ECF) is made up of a relatively small volume of plasma (7.5% of total body water in the vascular tree), with the remaining 37.5% in nonplasma and located outside the vascular tree. The latter includes interstitial water (20%), another 15% in bone and dense connective tissue, and 2.5% in secretions. These numbers are shown graphically in Figs. 4 and 5.

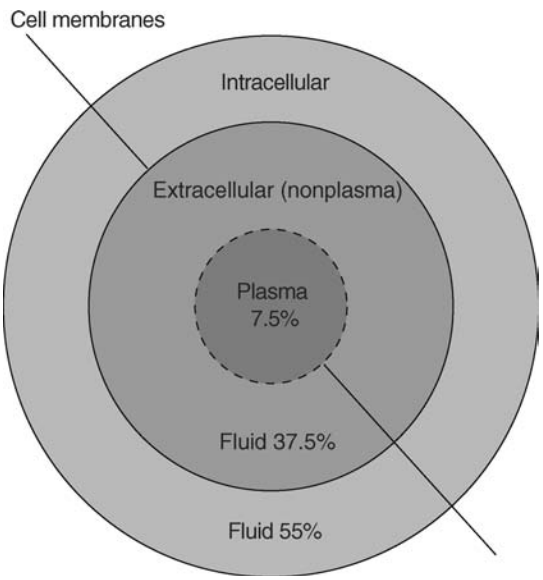

Fig. 4. The three principal categories of body water.

Two driving forces control the movement of water in the body, namely, hydrostatic pressure and osmotic pressure. Because transmembrane pressures are so low, it is not believed that hydrostatic pressure plays a role in the movement of water across cell membranes. On the other hand, hydrostatic pressure resulting from heart action creates a gradient of about 20 millimeters of mercury pressure across the capillary walls. The principles of osmosis are described in the entry on **Osmotic Pressure**. Normally, in describing osmotic pressure, reference is made to salt solutions of differing concentrations separated by a membrane. Concentrations are expressed in terms of solute in solvent (water). When thinking in terms of body water, one usually considers the addition of solute to the water as a dilution of the pure water rather than as an increase in solute content of the water. For example, pure water contains 55.5 moles per kilogram (about 55,500 mmoles/liter). Body fluids, that is, intracellular fluid (ICF) and

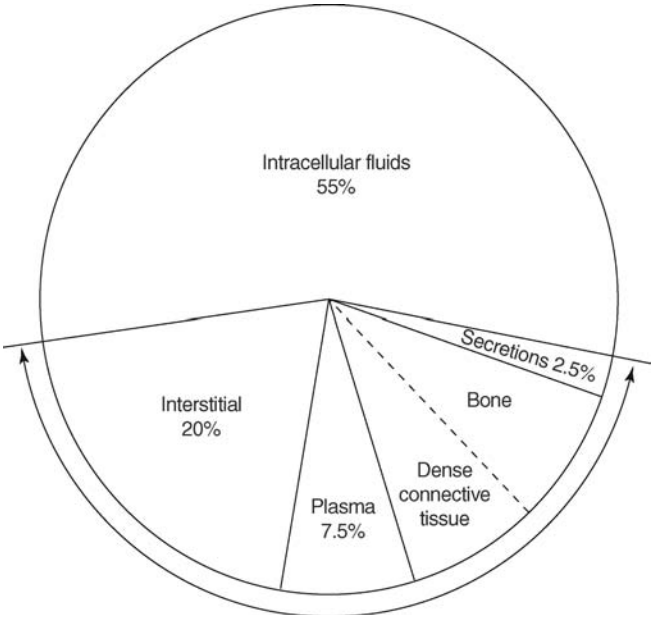

Fig. 5. Pie chart showing approximate volumetric proportions of body fluids.

extracellular fluid (ECF) contain approximately 99.5% water molecules and 0.5% solute molecules. This equals about 55,200 mmoles of water per liter; and 300 mmoles of solute per liter. Osmolality is a measure of the concentration of osmoles present in the water. If the osmolality is low, the concentration of water is high; if the osmolality is high, the concentration of water is low. Movement of water across the cell membranes occurs because of differences in concentration, the movement always being from a phase of high water concentration to one of lower concentration. Movement is "downhill" so to speak and the motivating force is called osmotic pressure. This movement can be counteracted by the application of an opposing force, notably hydrostatic pressure.

It is interesting to note that the main cation present in ICF is the potassium ion, whereas the principal cation in ECF is the sodium ion. The role of potassium and sodium ions in the biological system is described in the entry on **Potassium and Sodium (In Biological Systems)**.

Water Intoxication. Either an increased intake of water or a decreased output of water can cause an excess of body water. Because healthy kidneys have outstanding ability to increase water excretion, a condition of water intoxication usually occurs because of a disability to excrete water (*hyponatremia*). Frequently impairment may not be the result of disease or damage to the kidneys per se, but rather due to faulty processing of stimuli by the kidneys. Excessive renal reabsorption of water can result from the action of antidiuretic hormone (ADH) or by the excessive reabsorption of sodium in the proximal tubules. Under such conditions, the excretion of water and sodium will be low. Retention of salt and water causes an expansion of the ECF, usually resulting in edema and effusions.

Water Deficiency. This condition occurs when water output exceeds intake. Water is continually lost by way of the lungs, skin, and kidneys and thus a deficiency of body water will occur if a critical minimal supply is not maintained. Decreased intake when water is available is uncommon. Very rarely, a brain malfunction may interfere with one's sense of thirst. Increased output of water can result from many causes. For example, a person with diabetes insipidus who lacks ADH (antidiuretic hormone) or a person whose kidneys do not respond normally to ADH, as in instances of nephrogenic diabetes insipidus, will increase water output. Other diseases which may cause excess excretion of water include osmotic diuresis, hypercalcemia, hypokalemia, chronic pyelonephritis, and sickle cell anemia, among others. Excessive water losses are also experienced in some cases with advanced age and in some burn cases. Two clinical features are good measures of dehydration — weight loss of the patient and an elevation of the serum sodium concentration. In situations of dehydration, the body initiates mechanisms which manipulate the transfer of water from one compartment to the next, retaining water in those cells and organs where it is most needed.

In cases of severe dehydration, rehydration must be brought about carefully and in steps. The usual practice is to make an initial estimate of water or electrolytes that require replacement and then to administer one-half the amount of the deficit, after which another series of measurements is made, followed by replacement of one-half of the estimate — until a satisfactory ultimate balance has been attained. If rehydration is not gradual, some organs, such as the brain, may take up water beyond normal requirements and this can result in cerebral edema. Also, in the case of acute dehydration, permanent brain damage can occur as the result of a shrinking brain tearing away vessels, causing cerebral hemorrhages.

Water and Macromolecules. Over eons of time, processes have appeared for making the great variety of macromolecules required by living organisms. Most of these developments have occurred in a water medium, or in one having a high water vapor content. So it is not surprising that the majority of the macromolecules involved in the life processes are hydrophilic, in different degrees. One may find minor exceptions in the cases of certain fats and lipids. It should be noted that in living organisms, the hydrophilic macromolecules of one kind often join with those of other kinds to produce the useful structures required in the life process, i.e., membranes.

Decades ago, biochemists recognized that it was difficult to remove all water from a large number of macromolecular materials. The term "bound water" was coined to explain the great affinity many of these materials showed for water, particularly the proteins. Biochemists were convinced that biological behavior, at least in part, resulted from the amount of "bound water" contained in the macromolecular structure. As an example, water held in plant structures so that it did not freeze in below-freezing temperatures was considered to be bound. At the time these ideas found favor, the method of lyophilization or quick freeze-drying had not been perfected. Lyophilization removes the bulk of the water held in biological substances without destroying their structures or their activity.

In more recent years, lyophilized proteins have been further dried to a constant weight in a high vacuum and then studied as they adsorbed water vapor. The heats of adsorption of the first water vapor molecules were considerably higher than the values obtained as the adsorption approached that of the saturated vapor. These results indicated that the first molecules to be adsorbed were on the most water-loving or active sites. Such adsorbed molecules on the higher-energy sites would be desorbed last in a high vacuum. Without going into considerable detail, the results of this line of research led to the conclusion that the earlier concept of "bound water" was unfounded.

Many biological systems depend in part on their degree of hydration. Most biological membranes are hydrophilic, but should the membrane be a multi-layered one, the hydration of the different layers may well differ markedly. A great many of the membranes used by living organisms are known to be selective in what passes through them. For many years the theory of the role of some membranes in pumping water into the cells they surround even against high osmotic gradients due to salt concentration has maintained among most biologists. The fascinating field of membrane biophysics has shed much light concerning the hydration of biological macromolecules.

As pointed out by Kolata, a primary difference between living and dead cells is that living cells selectively retain certain ions, such as potassium, and exclude others, such as sodium. The water in dead cells reflects the conditions of the solution around them. The conventional explanation is that this difference is due to ion "pumps" in membranes, pumps purported to use cell energy to transport some ions into and other ions out of the cell. There is another school of thought, however, which denies that such pumps exist. This school claims that ions are excluded from cells on the basis of their low solubilities in cellular water, except when specific charged sites with which the ions can associate are available. It is maintained that cell water has a different structure than either liquid water or ice and that it is this special structure that affects the solubility of various ions in it. This school also suggests that there is evidence that ion pumps are thermodynamically impossible, requiring more energy than is available to the cell. The school also claims that nuclear magnetic resonance (NMR) studies show that cell water is more structured than liquid water and less structured than ice. This, it is believed, would affect the solubilities of ions in the cell and could account for selective ion exclusions. A number of investigators, including advocates of pumps, have agreed that cell water may have some ordered structure that makes it different from liquid water. Most investigators do not question that cell water is likely to be structured, but do ask to what extent it is structured and what the physiological importance of this structure may be.

Degassed Water. It is interesting to note that during the past several years, Russian scientists have raised some intriguing points concerning water, not all of which have held up under intensive scrutiny. Some readers may recall the discussions of the early 1970s concerning the "discovery" of polywater or so-called anomalous water by some Russian scientists. Observations of this water did not meet with accepted criteria for physical properties. For a while, it was considered by some scientists to be of a polymeric nature, but as the result of subsequent numerous exchanges of views and a careful scrutiny of the water it was found to be ordinary water which had a large concentration of dissolved minerals.

In 1978, other Russian scientists proposed that meltwater (from freshly melted snows) carries certain biological properties not known in ordinary water. The Russian scientists theorized that meltwater retains some of the order that is characteristic of frozen water and that this increased order alters vital reaction rates within cells. This tends to tie in with the concept of structured water discussed briefly later.

In the course of investigation at the Institute of Fruit-Growing and Vine-Growing (Kazakhstan, Russia), investigators tested the relative growing rates, qualities, and yields of various plants subjected to meltwater, tap water, and boiled water. Although the plants responded in a superior way to the meltwater, as compared with tap water, it was found (more or less accidentally) that the plants responded even better to quickly cooled boiled water. Thus, the experimenters concluded that the superior action on plants derived from the fact that some of the waters tested (meltwater and quickly-cooled boiled water) contained less dissolved gases. In other words, the claim was made that any degassed water is superior when administered to plants. Igor Zelepukhin suggests that the conductivity of degassed water is decreased considerably and there are comparative increases in density, viscosity, surface tension, energy of intermolecular interaction, and internal pressure, factors that may enhance the value of water. Zelephuhkin thus observed further that degassed water bears a closer resemblance to the fluid in cells than does ordinary tap water. Experiments in utilizing degassed water for cattle and livestock are proceeding. Other Russian investigators have observed that concrete prepared with degassed water is from 8 to 10% stronger than when ordinary water is used. It should be stressed that, as of the early 1990s, these observations have not as yet been accepted by the general scientific community. Considerably more research is required toward the development of hard, convincing data.

Raw Water and Treatment

Aside from desalinators used in some regions of the world that have severe insufficiencies of rain and freshwater and thus must depend upon purified saline waters, drinking water and the water required by industry for a plurality of reasons come from two classes of natural sources. The first is *surface waters* from ponds, streams, rivers, lakes, waterfalls, and glaciers. Natural water precipitation (rain and snow) is the result of Earth's natural hydrologic cycle. Precipitation also reaches below the surface to collect or flow in aquifers and thus is referred to as groundwater. See also **Climate**; **Desalination**; and **Hydrology.**

Prior to the great increases in world population and the development of extensive industrialization and modern agriculture, nature provided a number of built-in processes by which flowing streams essentially can be self-purifying, provided, of course, that pollution of any significant magnitude or intensity did not reach the natural water source. Today, with the exception of very few locales, such pristine conditions do not occur, and, in fact, some form of raw water treatment has existed for nearly five centuries. Traditionally called *waterworks*, or *pumping plants*, the earliest plant is believed to have been one designed by Peter Maurice and located near London Bridge in 1562. Its capacity exceeded 300,000 gallons (1136 cubic meters) for furnishing water to London. The first municipal plant installed in the United States was built in Boston in 1652. Only 15 more plants had been built in the United States by 1800, all located in the northeastern part of the country. The presence of bacteria in public water supplies was the major incentive for treating as well as filtering and pumping water to large municipalities. In terms of the treating operations performed at water treating plants, treating chemicals (including chlorine introduction methods) have grossly improved, and the

various processes have increased in size and numbers to handle much greater quantities of water. One of the major factors that distinguishes the water treating plants of the last few decades from their earlier counterparts is the availability of much more sensitive instruments to measure water quality and the automatic control means introduced to accelerate processing reaction time. Public concern and the consequent great expansion of regulatory requirements are the result of raw water supply pollution. Water consumers today also are much more demanding for controlling water taste and odor. Controls over the introduction of toxic wastes (see also **Wastes and Pollution**) have been mandated.

In an average situation, water will be pumped from a natural source, passed through bar screens to remove any large pieces of debris, and moved on to a raw water storage tank for temporary holding. Treating boiler feedwater requires customized methods. See also **Water Treatment (Boiler)**. Raw water treatment plants are found in nearly all municipalities throughout the U.S., Canada, and other advanced countries. Traditionally, these plants have operated under strict regulations and guidelines. Additionally, some industrial firms will re-treat municipal water for a variety of special reasons. Ultrapure water, for example, is required by the semiconductor industry, and means used to obtain ultrapurity include reverse osmosis processes, decarbonators, distillation, deionization, ultraviolet sterilization, and ultrafiltration.

Principal Impurities. Substances that must be removed in order to meet required standards for municipal water fall into three general categories:

1. Suspended matter, color, and organic matter — sediment, turbidity, microorganisms, taste, odor, and other organic matter.
2. Dissolved mineral matter — bicarbonates, sulfate, chlorides of calcium, magnesium, and sodium. Small amounts of silica and alumina commonly are present. Other constituents frequently present are iron, manganese, fluorides, nitrates, potassium, and sulfuric acid. (The presence of mine drainage components [common in some regions] and components of trade wastes are less frequently encountered today because of severe pollution restrictions. Severely toxic wastes also are controlled, with current regulations in most advanced industrialized nations mandating pretreatment to eliminate or neutralize all such substances prior to disposing of them in public reservoirs. However, municipal water treatment plant managers require the analysis of incoming raw water for the presence of toxic substances.)
3. Dissolved gases — Usually, these are present as oxygen, nitrogen, carbon dioxide, and, less frequently, hydrogen sulfide and methane.

Major Water Treating Operations

The principal operations required to remove and alleviate the undesirable components of raw water include the following.

Sedimentation. With waters containing large amounts of coarse, easily settled, suspended matter, sedimentation (plain sedimentation) is often of value in reducing the load on the filters and effecting economies in amounts of chemicals used for coagulation. Sedimentation may be carried out in sedimentation tanks or basins or in reservoirs. Detention periods vary over a wide range — from a few hours up to one or more months.

Coagulation. Coagulation is employed to form, by cataphoresis and entanglement, larger aggregates with the turbidity, color, microorganisms, and other organic matter present in the water. These larger particles, known as the "floc," may then be removed by filtration through a sand or Anthrafilt filter or by settling and filtration. The coagulant employed is either an aluminum or iron salt, usually the surface. Aluminum sulfate is the most widely used coagulant. Others are ferric sulfate, ferrous sulfate (must be oxidized by air or chlorine) and sodium aluminate. Most favorable pH values for aluminum coagulants usually range from 5.5 to 6.8 and for iron from 3.5 to 5.5 and above 9.0 but there are exceptions. Coagulation aids are ground clay (not too finely pulverized) and activated silica.

Filtration. Filtration is effected by flowing the coagulated or coagulated and settled water downward through a bed of fine filter sand or Anthrafilt is either a pressure type or gravity type filter. Flow rates in industrial practice range up to 3 gpm per sq. ft. (122 liters/min/sq. meter) of filter bed area while in municipal practice maximum flow rate is usually 2 gpm per sq. ft. (81.5 liters/min/sq. meter).

Chlorination. Chlorination is the most widely used disinfecting or sterilizing process. Where daily water requirements are not large, it is common practice to use a hypochlorite, but for large plants liquefied chlorine gas is used. Chlorination may be practiced before filtration (prechlorination), after filtration (post-chlorination), or both before and after.

Taste and Odor Removal. Except for sulfur waters, most tastes and odors are organic in nature. Activated carbon is widely used for their removal. In powdered form, it may be added to the water being treated in coagulation and settling equipment. In such installations, aeration is frequently used as preliminary treatment. In granular form, it is used in filters (activated carbon filters or purifiers). As substances producing tastes and odors are usually extremely small in amount, activated carbon filters are frequently operated for 6 months to one or more years before replacement of bed is necessary.

Optional Treating Operations

These may include improving water quality for domestic and industrial purposes.

Hardness Removal (Water Softening).

Sodium Cation Exchanger (Zeolite) Process. This is the most widely used water-softening process in industrial, commercial, institutional and household applications. Hard water is softened by flowing it, usually downward, through a bed (2 feet to over 8 feet in thickness) of a granular or bead type sodium cation exchanger in either a pressure-type (most widely used) or gravity-type water softener. As water comes in contact with sodium cation exchanger, hardness (calcium and magnesium ions) is taken up and held by the exchanger which gives up to the water an equivalent amount of sodium ions. At end of softening run (4 to over 24 hours in industrial practice and 1 to over 2 weeks in household use), softener is cut out of service, regenerated and returned to service (1/2 to 11/2 hours). Regeneration is effected in 3 steps: (1) backwashing to cleanse and hydraulically regrade the bed (2) salting with specified amount of common salt (sodium chloride) solution, usually 10 to 15% in strength, which removes calcium and magnesium from the exchanger and restores sodium to it and (3) rinsing to remove calcium and magnesium chlorides and excess salt.

Hydrogen Cation Exchanger Process. Calcium, magnesium, sodium and other cations are removed by flowing water (usually downward) through a bed (2 feet to over 8 feet in thickness) in an acid-proof pressure-type (most widely used) or gravity-type shell. As water comes in contact with hydrogen cation exchanger, calcium, magnesium, sodium and other cations are taken up by the exchanger which gives up to the water an equivalent amount of hydrogen ions. At the end of operating run (4 to over 24 hours), unit is cut out of service, regenerated and returned to service (11/4 to 2 hours). Regeneration is effected in three steps: (1) backwashing to cleanse and hydraulically regrade the bed; (2) acid treatment with sulfuric or hydrochloric acid which removes metallic cations from the bed and restores hydrogen to it; and (3) rinsing to remove salts (sulfates or chlorides) and excess acid. The carbon dioxide formed from the bicarbonates may be reduced to below 5 to 10 ppm by aeration. The sulfuric and hydrochloric acids formed from chlorides and sulfates may be (1) neutralized with an alkali (usually caustic soda), (2) neutralized by sodium bicarbonate content of a sodium cation exchanger softened water (in which case aeration follows neutralization), or (3) removed by an anion exchanger.

Cold Lime (or Lime Soda) Process. Chemicals used may be (1) lime plus a coagulant or (2) lime plus soda ash plus a coagulant. Dosages vary according to composition of raw water and result desired such as (a) calcium alkalinity reduction, (b) calcium and magnesium alkalinity reduction, (c) reduction of total hardness without excess chemicals and (d) excess chemical treatment. Precipitates produced are calcium carbonate and magnesium hydroxide. Rated residuals without excess chemicals are 35 ppm for calcium and 33 ppm for magnesium, both expressed as calcium carbonate. Operating results will range between these and theoretical solubilities. With excess chemicals, total hardness may be lowered to 16 ppm. The process is best carried out in the sludge blanket-type of equipment in which the treated water is filtered upward through a suspended blanket of previously formed sludge. Detention periods range from one to two hours. Usually, treated water is filtered before going to service but where small amounts of turbidity are unobjectionable, filters may be omitted.

Hot Lime Soda Process. In this process, treatment with lime and soda ash is carried out at temperatures around the boiling point in closed, steel

pressure tanks. Heating is usually accomplished with exhaust steam and pressures most widely used range from 5 to 10 psig, but higher pressures up to but seldom above 20 psig are also used. At these temperatures, the reactions proceed swiftly and precipitates formed are larger than those in cold lime soda process so no coagulant is needed. Detention period is one hour and de-aeration effected in primary heater is sufficient to lower dissolved oxygen content to 0.3 milliliter per liter which is sufficient for low-pressure boilers. For high-pressure boilers, either an integral or separate de-aerator is used and this will bring the dissolved oxygen down to less than 0.005 ml/l. With 20 to 30 ppm excess soda ash, the hardness will be reduced to 25 ppm. Softening to practically zero hardness may be effected by either (1) two-stage hot lime soda phosphate treatment in which effluent from hot lime soda softener is treated with sodium phosphate, or (2) the filtered effluent is passed through a sodium cation exchanger. Anthrafilt filters are usually employed with hot process softeners.

Fluoridation. See entry on **Fluorine**.

Demineralization (Deionization). Metallic cations are removed by a hydrogen cation exchanger. Anions are removed by an anion exchanger. Depending on the hookup used, the carbon dioxide formed from the bicarbonates may be removed mechanically by an aerator, degasifier or vacuum de-aerator, or chemically by a strongly basic anion exchanger. Strongly basic anion exchangers will remove both strongly ionized acids, such as sulfuric and hydrochloric, and weakly ionized acids, such as silicic and carbonic. Weakly basic anion exchangers will remove only strongly ionized acids.

Iron and Manganese Removal. In clear, deep ground waters, iron and/or manganese may occur as soluble, colorless, divalent bicarbonates. These may be removed (1) by oxidation plus settling (if necessary) plus filtration (2) by cation exchange with sodium or hydrogen cation exchangers or (3) filtration through an oxidizing (manganese zeolite) filter. In (1) addition of an alkali or lime may be needed to build up the pH value so as to speed up the oxidation. Iron and/or manganese in organic (chelated) form may usually be removed by coagulation, settling and filtration. In acid waters, these metals may be removed by neutralization (plus increase of pH), aeration, settling and filtration.

Fluoride Removal. Fluorides may be reduced to below 1 ppm by filtration through a bed of a specially prepared, granular bone char (bone black). Regeneration is effected with caustic soda solution followed by treatment with dilute phosphoric acid.

Dissolved Gases. Oxygen and Nitrogen may be removed (1) hot in a deaerating heater (de-aerator) or (2) cold in a vacuum de-aerator. Carbon dioxide may be removed in (1) an aerator, (2) a de-aerating heater or (3) a vacuum de-aerator or it may be neutralized with lime or an alkali or by filtration through a bed of granular calcite. Hydrogen sulfide may be removed by (1) aeration followed by chlorination, (2) treatment with flue gas plus aeration followed by chlorination or (3) filtration through an oxidizing manganese zeolite filter (household use). If sulfur content and pH values are high, (1) may effect but little removal but, in some cases, with fairly long detention periods, sulfur bacteria may effect notable reductions.

Treatment of Wastewater (Sewage)

Wastewater may be defined as the spent or used water from a community or industry that contains dissolved or suspended matter. Toxic wastes must receive pretreatment by the polluter prior to introduction into a water reservoir or municipal used-water return lines. Most wastewater is 99.94% water by weight. The remaining 0.06% is material dissolved or suspended in the water. Water chemists differentiate *suspended solids* and *dissolved contaminants*. The concentration of dissolved or suspended matter usually is expressed as milligrams of pollutants per liter of water (mg/l), or as parts per million (ppm) (weight). On another scale, 1 ppm can be visualized as being equivalent to 1 minute of time in 1.9 years. Although pollutants may be so minute, innumerable studies have shown their adverse effects on human and other animal life.

A generally accepted estimate is that each individual, on a national (U.S.) average, contributes approximately 265 to 568 litres of water per day to a community's wastewater flow. While most people think of wastewater as only "sewage," wastewater also comes from other sources — commercial, industrial, and storm and ground water. Generally, each house or business has a pipe or sewer that carries the wastewater to the wastewater treatment plant. **Sanitary sewers** carry only domestic and industrial wastewater, while **combined sewers** carry wastewater and storm water runoff. Every reasonable effort is made to exclude storm (inflow) and ground (infiltration) water from the sanitary sewer system. These efforts are usually less successful on older sewer systems that leak.

The wastewater from the sewer system either flows by gravity or is pumped into the treatment plant. Usually, treatment consists of two major steps, primary and secondary, along with a process to dispose of solids removed during the two steps.

In **primary treatment**, the objective is to physically remove suspended solids from the wastewater, either by screening, settling, or floating. The major goal of **secondary treatment** is to biologically remove contaminants that are dissolved in wastewater. In secondary treatment, air is supplied to encourage the natural processes of growth of bacteria and other biological organisms to consume most of the waste. These organisms and other solids are then separated from the wastewater. Before discharge to the **receiving stream**, the water usually passes through a tank where a small amount of chemical (usually chlorine) is added to disinfect the treated water.

In primary and secondary treatment, solids are settled and removed for further processing. Solids, usually referred to as sludge, are normally processed in three steps — digestion, dewatering, and disposal. The digestion step reduces the volatile solids and prepares the sludge for further processing. Dewatering involves the application of a variety of processes that reduces the water content of the sludge and, in turn, its volume. The final step is the ultimate management of this treated material, or biosolids, which can be used beneficially through methods such as land application. See Figs. 6 and 7.

Screening removes large floating objects from the incoming wastewater stream. Treatment plant screens are sturdily built to withstand the flow of untreated wastewater for years at a time. Rags, wood, plastics, and other floating objects could clog pipes and disable treatment plant pumps if not removed at this point. Typically, screens are made of steel or iron bars set in parallel about one-half inch apart. Some treatment plants use a device known as a comminuter, which combines the functions of a screen with that of a grinder.

Sand, grit, and gravel flow through the screens to be picked up in the next stage of primary treatment — the grit chamber. Grit chambers are large tanks designed to slow the wastewater down just long enough for the grit to drop to the bottom. Grit is usually washed after its removal from the chamber and buried in a landfill.

After the flow passes out of the grit chamber, it enters a more sophisticated settling basin called a sedimentation tank. Sedimentation removes the solids that are too light to fall out in the grit chamber. Sedimentation tanks are designed to hold wastewater for several hours. During that time the suspended solids drift to the bottom of the tank, where they can be pushed into a large mass by mechanical scrapers and pumped out of the bottom of the tank. The solids removed at this point are called primary sludge. The primary sludge is usually pumped to a sludge digester for further treatment. During the sedimentation process, floatable substances, such as grease and oil, rise to the surface and are removed by a surface skimming system. The skimmed materials are either sent to the sludge digester for treatment along with the primary sludge or are incinerated. Sedimentation marks the end of primary treatment. At this point, most of the solids in the stream that can be removed by the purely physical processes of screening, skimming, and settling have been collected. An additional set of techniques using biological processes must be employed next. (*After Water Environment Federation.*)

There are several different ways to optimize biological conversion. Secondary treatment promotes the growth of millions of microorganisms, bringing them into close contact with the wastewater on which they feed. Care is taken to make sure that the temperature, oxygen level, and contact time support rapid and complete consumption of the dissolved wastes. The final products are carbon dioxide, water and more microorganisms. Three widely employed types of secondary treatment are common: activated sludge, trickling filters, and lagoons.

The most common is the activated sludge process. Activated sludge processes are much more tightly controlled than either trickling filters or lagoons. In this form of treatment, wastewater and microorganisms are mixed for a few hours in a large tank by constant aeration and agitation. Once the aeration is complete, the mixture of water and microorganisms

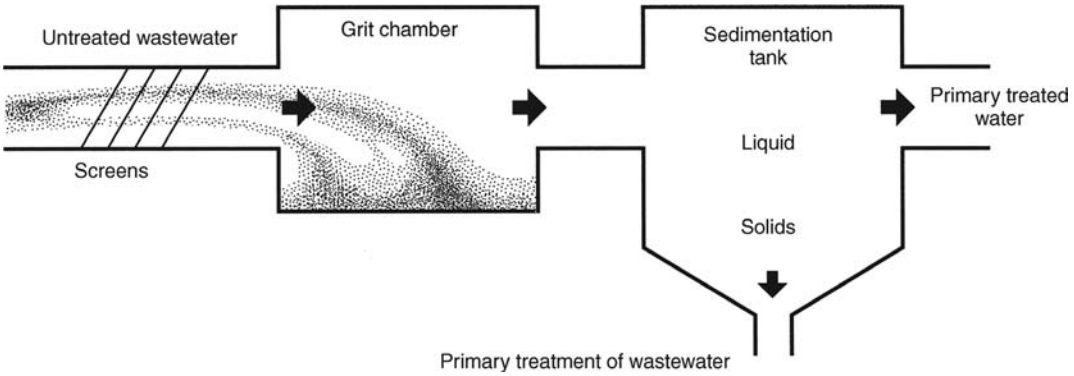

Fig. 6. Wastewater entering a treatment plant receives primary treatment first. In this state, a series of operations removes most of the solids that can be screened out, will float, or will settle.

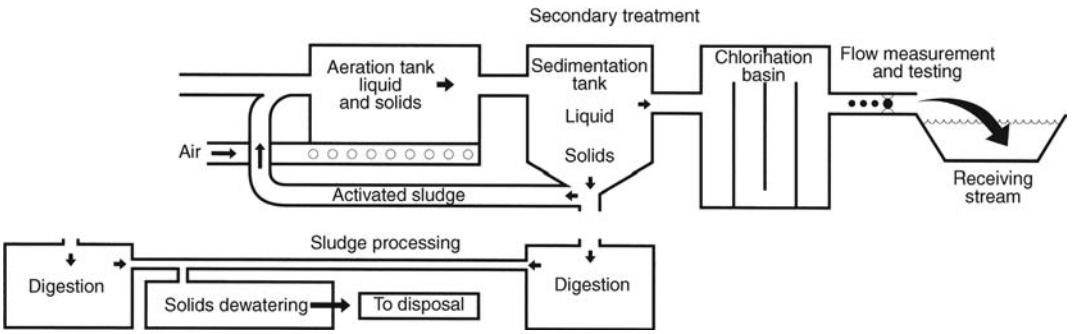

Fig. 7. Wastewater flowing out of primary treatment still contains some suspended solids and other solids that are dissolved in the water. In a natural stream, such substances are a source of food for protozoa, fungi, algae, and hundreds of varieties of bacteria. The secondary treatment stage is a highly controlled artificial environment in which these same microscopic organisms are allowed to work as fast and efficiently as they can. The microorganisms biologically convert the dissolved solids in the wastewater to suspended solids that will physically settle out at the end of secondary treatment.

flows to a sedimentation tank similar to the one used in primary treatment. The microorganisms and other solids settle to the bottom of the sedimentation tank. Since activated sludge is a continuous process, a portion of the settled solids (return activated sludge) are circulated back to the beginning of the process to serve as "seed" organisms. The part not needed for "seed" is commonly called waste activated sludge and is sent to a sludge digester for further treatment. (*After Water Environment Federation.*)

Sludge Handling. Treatment professionals refer to solids in general as **sludge**. Beneficial sludges are called "biosolids." But these solutions are not the thick, molasses-like substances that most people think of when they hear the word "sludge." Wastewater sludges are slurries of water and solids that are roughly 100 times more concentrated than untreated wastewater. That is, they contain about 3% solids compared to the. 03% (or less) concentration of the initial flow into a treatment plant. The various techniques for handling these flows are designed to increase the solids concentration even further, to as much as 50%.

As a rule of thumb, higher degrees of wastewater treatment produce larger volumes of sludge. For example, primary treatment usually produces 2500 to 3500 gallons of sludge for every 1 million gallons of wastewater. Secondary treatment usually produces 15,000 to 25,000 gallons for every 1 million gallons treated. To try to dispose of or recycle such volumes of waste is practical. Thus, sludge handling methods are designed to remove as much water from the mixture as possible.

The spectrum of sludge handling techniques is divided into processes that condition, thicken, stabilize, and dewater the sludge flow. Conditioning operations usually employ chemicals or heat to make the sludge release water more easily. Thickening techniques use gravity, flotation, and chemicals to separate water from the solids. Conditioning and thickening are usually the first steps in handling primary and secondary sludges.

Stabilization converts the organic matter in the sludge so that the biosolids can be disposed of or used as a soil conditioner without posing a health hazard in the general environment. Sludge stabilization can occur with (**aerobic**) or without (*anaerobic*) oxygen in special tanks called digesters. Sometimes chemicals such as lime are used for stabilization.

Dewatering is done by mechanical means. Filters, centrifuges, and presses remove even more water from the biosolids. Biosolids dewatered by such equipment have the consistency of wet mud and can have a solids concentration of up to 20%. Other techniques, such as drying beds or special presses, can be used to dewater the sludge, producing up to 50% solids — about the consistency of dry soil. At the end of a sludge handling process, the concentrated solids can be placed in landfills, incinerated, applied to land, or composted for use as a soil conditioner.

Alternatives to Sludge Process. For some wastewater treating situations, the complexities of the sludge process may not be required. In such instances, trickling filters or lagoons may be used.

Trickling filters. These are large beds of coarse, loosely packed material — rocks, wooden slats, or shaped plastic pieces — over which the wastewater is sprayed or spread. The surfaces of the filter material (also known as the "medium") become breeding grounds for the microorganisms that consume the wastes. A common trickling filter is a bed of stones 3 to 10 feet deep. Under the bed, a system of drains collects the treated wastewater and diverts it to a sedimentation tank or back over the filter medium for additional treatment. In the sedimentation tank, suspended solids settle and are pumped to a sludge digester. Trickling filters are relatively simple to construct and operate. Many communities in the United States rely on them for secondary treatment.

Lagoons. These are used by some communities to achieve secondary treatment. Lagoons generally treat the total wastewater from a community until the biological oxidation processes have consumed and converted most of the wastes present. This form of treatment depends heavily on the interaction of sunlight, algae, and oxygen. Sometimes the wastewater is aerated to speed the process, since these interactions are relatively slow. There is usually no sedimentation tank associated with a lagoon. Suspended solids settle to the bottom of the lagoon, where they remain or are removed every few years. Generally speaking, lagoons are simpler to operate than other forms of secondary treatment, but are less efficient.

At the end of a secondary treatment process, the wastewater is disinfected to remove disease-causing organisms. Usually, an agent such as chlorine is added to the stream of wastewater before it is discharged

to receiving waters. Sometimes other techniques are used if the receiving waters are sensitive to the addition of chlorine.

An alternate to secondary and higher levels of treatment is land application of wastewater. The wastewater is usually sprayed over natural or specially sloped and seeded land. The wastewater seeps into the soil where natural solid microorganisms consume the wastes. The treated water is either used by plants, stays in the ground, or is collected and routed to a receiving stream.

Role of Sunlight as a Detoxifying Agent

In the late 1980s, Sandia National Laboratories announced the development of a solar-powered reactor to generate low-cost electrical power and recently have found an alternative use for it, namely, for the detoxification of polluted water. As stated by the project leader, C. Tyner, "We believe this process will destroy most organic materials, including industrial solvents, pesticides, dioxins, PCBs, and munitions chemicals." The process breaks down toxic chemicals into smaller, safer molecules. Current methods remove organic wastes from water by bubbling air through the water and thus volatilizing them for release into the atmosphere (not attractive) or by running the polluted water through carbon filters. The researchers have set up a troughlike arrangement (similar to sunlight collectors used for solar furnaces) along which runs a radiation-transparent tube holding the flowing water, which thus receives a maximum concentration of solar radiation. The future of the project will be determined largely by cost considerations.

WATER BOATMAN *(Insecta, Hemiptera)*. An aquatic bug of the family *Corixidae*. These insects are flattened, broad at the head and tapering bluntly at the opposite end of the body. The fringed posterior legs project like a pair of oars and are used in swimming. Water boatmen breathe air but they are able to descend to considerable depths, carrying a film of air on the ventral surface of the body. They feed on ooze containing plant matter and minute animals.

WATER CYCLE. The water cycle — a series of steps through which virtually all water on earth is constantly cycling. The names of these steps vary, but they generally follow this order: storage, evaporation, transpiration, condensation, precipitation, infiltration, and runoff.

Due to the nature of the water cycle, there is really no "beginning" or "end", but for simplicity, the cycle can be said to begin at the storage stage. Storage is the storing of water on, in, and above the earth. There are about 340 million cubic miles of water on the earth. This water is stored in many places: glaciers, seas, rivers, lakes, polar ice caps, and all living things on the planet. The largest percentage of water, approximately 97.25%, exists as salt water in the ocean. Water is also stored in the earth's atmosphere and as groundwater. Groundwater in the top few miles of the earth's crust is easily obtainable, whereas groundwater further down is chemically attached to rocks and usually cannot be accessed.

Evaporation is an essential way in which water is transferred from the earth to the atmosphere. During evaporation, water molecules change from a liquid state directly into a gaseous state, known as water vapor. Changes in temperature and air pressure on the earth cause millions of gallons of water to evaporate into the atmosphere each day. The majority of the water that is transferred into the atmosphere is primarily in a liquid state before the change; however, a small percentage of new water vapor comes from ice. The process of water changing state from a solid directly to a gas is called sublimation. Sublimation occurs on glaciers and polar ice sheets. When the sun strikes these massive ice structures, the temperature and pressure allow no room for a liquid, only a solid and a gas.

Transpiration is another way that water is transferred into the atmosphere. Although similar in process to evaporation, transpiration differs

because the medium from which the water comes is not earth, it is plants. Transpiration is the process through which water absorbed from the ground by plant roots evaporates into the atmosphere. After the plants absorb the water from the soil, the water moves up through the veins of the plant, eventually reaching the leaves (or the plant's equivalent). These leaves have pores, or stomata, which allow water to evaporate. Large forests can release massive amounts of water into the atmosphere through transpiration.

Once the water has been transferred into the atmosphere by either evaporation or transpiration, the molecules will eventually condense. This process is called condensation. Condensation is the reciprocal process of evaporation. During condensation, water changes state from a gas to a liquid. Once again, a change in either temperature or pressure initiates the change. Condensation is most visible in the formation of dew, fog, and clouds. Dew usually appears in the morning and is water that has condensed on any solid object during the rapid temperature change that occurs from day to night. If the water vapor is dense enough around objects when the temperature change happens, dew is formed. Fog is really a low level cloud formation. When the conditions are right, fog is formed on or near the ground. The only difference between fog and cloud formations is their locations with reference to the earth. Clouds form when water vapor in the atmosphere encounters a critical temperature or air pressure, causing the water vapor to change state into a liquid. Water molecules then "stick together" causing physical cloud structures to emerge. When the molecules in the cloud that are stuck together reach a certain critical mass, they release the moisture causing precipitation to begin.

Precipitation is the process by which water is transferred from the medium of the atmosphere to the medium of the earth. Precipitation literally comes in all shapes and sizes, including rain, snow, and ice. The differentiating factor that determines the form water takes when precipitating is air temperature. The lower the temperature, the more likely it is that the precipitation will be either snow or ice (the closer the temperature is to the freezing point of water, 32 °F or 0 °C the more likely). Droplets of rain form around small particles of dust or dirt to form a cohesive raindrop as a vehicle for the trip to the earth.

Regardless of the form it takes on its descent, water will take one of two paths once it arrives on the earth's crust. It will either seep into the ground or flow into larger bodies of water such as streams, seas, oceans, and rivers. The former process is infiltration, and the latter is runoff. Infiltration restores groundwater to the water table that has been lost from wells. During the infiltration process, the water is purified by cascading amongst rocks and minerals that draw impurities out of the water.

Water that does not infiltrate the earth's crust runs off into streams, rivers, seas, and oceans. Runoff replenishes bodies of water that have lost water due to evaporation. Runoff can occur either above the land or below it. Large amounts of water can run across the land immediately after precipitation. Smaller amounts of water run through the ground and along the water table until they reach a larger body of water.

So thusly does the water complete its cycle throughout the different media of the earth. This process is essential for the survival of life on the earth because it allows water to permeate every accessible region of the crust and atmosphere, thereby allowing life to flourish wherever water exists.

WATER FLEA *(Crustacea, Cladocera).* Minute aquatic crustaceans of compact form, usually transversely compressed and provided with a bivalve carapace. They are superficially like fleas in form.

WATERFOWL *(Aves, Anseriformes).* This large order of birds includes the *ducks, geese, mergansers, swans*, and related species. Ducks are swimming birds of moderately large size with heavy bodies, short legs, webbed feet, and broad flattened beaks with sieve plates at the sides. In common usage, the term includes the closely related teals, sheldrakes, and mergansers. With exception of the mergansers, which have narrow beaks with serrate edges and live chiefly on fish, the ducks eat rice and other plant products, with some insects and other small animals. Ducks are among the leading game birds and many wild species have very palatable flesh. Many species have been domesticated and interbred with the common domestic duck.

The *baldpate* is a North American duck (*Mareca americana*) and is not to be confused with a dove of the same common name found in the West Indies. The baldpate is about 18 inches (45 centimeters) long, with a bill rounded at the tip. The wings are long and the tail is wedge-shaped. The head is mainly black and gray with white on the very top. Green plumage surrounds the eye. Baldpates are swift, but irregular in flying pattern. These birds breed in Canada and winter in Central America. They feed on insects, grain, tender green plants, leeches, and worms. When feeding, the head is usually completely immersed below the surface of the water. The birds nest on the ground and have from 8 to 10 eggs at incubation time. The eggs are white and close to the size of a chicken egg. The European species, known as the *widgeon* (*M. penelope*) is smaller and is sometimes seen along the American coast line.

The *bufflehead, Charitonetta albeola*, is a small North American duck of wide distribution, particularly of inland waters. The bird ranges up to 24 inches (61 centimeters), wing tip to wing tip and is about 10 inches (25 centimeters) long. The color is white and black, crested with rich silky green plumage and white streaks across the top of the head. The bufflehead nests in old stumps, burrows, or holes in trees. The eggs are dark and number from 10 to 12. These birds fly very fast. They range from the Great Lakes north to the Arctic Circle.

The *canvas-back* is a large North American duck, *Nyroca vallisneria*, similar to the redhead, but with a dusky crown and face. Its flesh at the proper season is considered superior to that of other ducks.

Eider ducks are of several species that breed in the far north along rocky coasts. They are noted for their fine down with which they line their nests. This material has a high commercial value and is collected for market and used in pillows and comforters.

The *gadwall* is a North American duck, *Anas strepera*. The *goosander* is a merganser duck of the Northern Hemisphere, *Mergus merganser*. Old squaw or old wife is the name of a small duck, *Clangula hymenalis*, of the latitudes of most of the Northern Hemisphere, migrating into the United States in winter. It is chiefly black and white and the male has a long slender tail. It is also called the long-tailed duck. The *scaup* or *bluebill*, *Aythya* (*Nyroca*) *marila*, is a duck found throughout the Northern Hemisphere and the lesser scaup, *N. affinis*, is common in North America. Both are principally black and light gray or white. The head of the scaup duck is glossed with green and that of the lesser scaup with purple.

The *scoter* is a duck found chiefly along the seacoasts and less often on fresh waters. The American scoter, *Oidemia americana*, is a bird of the northern Atlantic, breeding from Alaska to Labrador. The *white-winged scoter, Melanitta deglandi*, breeds from the northern United States northward and is fairly common on the Pacific Coast. The *surf scoter, M. perspicillata*, also breeds northward into the Arctic regions and is more generally distributed on both coasts and in inland waters. All scoters are dark-colored birds with a few light areas.

The *shoveller* is a widely distributed duck, *Spatula clypeata*, of the Northern Hemisphere. The male has a dark green head and is beautifully marked with blue, white, chestnut, and orange. The female is brownish but for the blue wing patch. The species is named from the greatly broadened beak. Also called the *spoonbill*.

The *teal* is a small duck whose beak has almost parallel sides. The several species are beautifully marked. Teals are found throughout Europe, Asia, and North America. The common European species migrates into Africa and is sometimes found in northern and eastern North America, while other species have a much more limited range. In North America, the *blue-winged teal, Querquedula discors*, is common east of the Rocky Mountains; the *green-winged teal, Nettion carolinense*, throughout the continent; and the *cinnamon teal, Q. cyanoptera*, west of the Mississippi. The *garganey, Anas querquedula*, is the summer teal of Europe.

Pochard is a name applied in the Old World to ducks of several species related to the *scaup ducks*, the *redhead*, and the *canvas-back* of North America. Smew is a European name for a small merganser, *Mergellus albellus*. The name also is applied to widgeons and pochards, and said to be used for the pintail duck, although pintail is by far the more common name.

TABLE 1. WATER HAMMER PRESSURE FOR DIFFERENT PIPE DIAMETERS

Diameter of pipe, mm	<250	300	400	500	600	750	>750
Water hammer pressure, kg/cm^2	8.50	7.75	7.00	6.30	5.75	5.60	4.90

Geese are large swimming birds with webbed feet and thick, strong beaks. They live chiefly on vegetation. Geese are found on all continents. They are strong fliers, and some species migrate from their nesting grounds in the north to the Southern Hemisphere. Among the several North American species, the *Canada goose, Branta canadensis*, is sometimes called *brant*, and a related species is the *black brant, B. nigricans*. Geese are excellent game birds and good food. The domestic goose is also valuable for its smaller feathers and down for filling pillows and cushions.

The *swan* is a large bird related to the geese and of similar form and habits. The swan differs in the length of the neck, which is at least as long as the body. Although the more familiar species are white, some swans are marked with black and in Australia a species with almost entirely black plumage occurs. The *mute swan, Cygnus olor*, is habitually silent. The two North American species, the *whistling, Cygnus columbianus*, and *trumpeter, C. buccinator*, swans, breed far to the north and are not often seen. The whistling swan also bears the name *whooper, C. cygnus*, in Europe. See also **Anseriformes**; and **Poultry**.

WATER HAMMER. Water hammer is a hydraulic phenomenon that has to be considered for the safe design of water-carrying pipes. It is basically a pressure fluctuation that would result in disturbing noises and, more importantly, rupture of pipes and fittings.

Water hammer can be defined as a transitory increase in pressure in a water system when there is a sudden change of direction or velocity of the water. Water hammer may also be known by names like shockwave effect or hydraulic shock.

If the velocity of water flowing in a pipe is suddenly checked, the energy given up by the water will be utilized in compressing the water itself. This pressure energy is transferred to the pipe wall and this leads to the setup of shock waves in the system. These shock waves travel backward (with a speed similar to the speed of sound), until encountering a solid obstacle (the valve), and crash into the obstacle back and forth repeatedly. This repeated crashing produces an undesirable sound and may lead to rupture of valves and pipes.

The concept of water hammer is normally explained by drawing an analogy to the movement of a train. Assume a real train, instead of slowing to a stop, hits into a mountainside. The back of the train continues forward even though the front cannot go anywhere. Similarly, the hammer occurs because an entire train of water is being stopped so fast that the end of the train hits up against the front end and sends shock waves through the pipe.

Effects of Water Hammer

Water hammer cannot be ignored as another hydraulic effort in water conveyance, as it poses undesirable effects during water conveyance. The major effects of water hammer are the following:

1. Water hammer will cause disturbing noises that tend to be highly problematic in houses and industrial areas.
2. Water hammer may account for the malfunctioning of pipe appurtenances like pressure relief valves, mud valves, backflow preventers, or stop valves.
3. Water hammer may also lead to rupture of the pipes and connected fittings.
4. Water hammer may at times lead to minor flow losses.

Causes of Water Hammer

The problem of water hammer can be encountered in varied places like houses, irrigation systems, domestic water supply, and industries. The causes for water hammer (i.e., causes for sudden change in flow velocity/direction) are varied, yet they can be grouped under five major cases:

- Rapid opening or closing of control valves.
- Starting and stopping of pumps.
- Recombination of water after water column separation.
- Rapid exhaustion of all air from the system.
- Power failure in water pumping system.

Computation of Water Hammer

The pressure rise caused by the water hammer should be quantified to understand its impact and to sort out remedial measures. The rise in pressure due to water hammer can be attributed to pipe velocity, pipe diameter, and pressure wave travel in the pipe. The maximum pressure caused by water hammer can be obtained by the expression

$$H_{\max} = \alpha \times V_n / g$$

where H_{max} is the maximum pressure rise due to water hammer, V_n refers to the velocity of flow in the pipe, g refers to the acceleration due to gravity, and a is the velocity of pressure wave travel, which in turn can be obtained by the expression

$$\alpha = 1425/(1 + kd/EC)^{1/2}$$

where k is the bulk modulus of water, d is pipe diameter, C is wall thickness of the pipe in meters, and E is the modulus of elasticity of the pipe material.

The pressure exerted due to water hammer is taken into consideration for the structural design of pipelines for public water supplies. In case of unavailability of data and as a rule of thumb, Table 1 presents the extra pressures taken depending on pipe size.

Control of Water Hammer

As a hydraulic effect, water hammer is undesirable but inevitable. However, there are a lot of techniques to minimize the pressure rise due to the water hammer, which need to be exercised for proper flow profile.

1. The best and simplest technique would be to close or open the valves slowly. Even the first 80% of the valve travel may be executed conveniently, but the last 20% should be done at a snail's pace to avoid problems. The usage of flywheels for this purpose is advisable, and automatically controlled valves with slow closing are desirable.
2. The provision of check valves, surge relief valves, and similar instruments may help in reducing the water hammer. Today, specialized water hammer arrestors are commercially available for this purpose. Apart from these surge-absorbing water hammer arrestors, pressure regulation devices can also be used. An example is a pressure snubber, a device for slowing the rate of change of system flow that will protect from water hammer damage if installed (using a proper size) near the input of a pressure sensor.
3. The pumps are also a matter of concern. Pump startup problems can usually be avoided by increasing the flow slowly to collapse or flush out the voids gently. Also, an uninterrupted power supply for pumps would prevent water hammer. The above arrangements may also contribute to lower horsepower and maximum operating efficiency.
4. Great care should be taken to incorporate the pressure rise due to water hammer during the structural design of pipelines.

There has not been much study about the phenomenon of water hammer and its significance in the design and performance aspects of a water system, but the current scientific forum is coming up with better descriptions.

WATER (Hard). Water containing low percentages of calcium [CAS: 7440-70-2] and magnesium carbonates [CAS: 13717-00-5], bicarbonates, sulfates [CAS: 7487-88-9], or chlorides [CAS: 7786-30-3] as a result of long contact with rocky substrates and soils. Degree of hardness is expressed either as grins per gallon or parts per million (ppm) of calcium carbonate [CAS: 471-34-1] (1 grain of $CaCO_3$ per gal is equivalent to 17.1 ppm). Up to 5 grains is considered soft, more than 30 grains

very hard. Hardness may be temporary (carbonates and bicarbonates) or permanent (sulfates, chlorides). Treatment with zeolites is necessary to soften permanently hard water. Temporary hardness can be reduced by boiling. These impurities are responsible for boiler scale and corrosion of metals on long contact. Hard waters require use of synthetic detergents for satisfactory sudsing.

See also **Water Treatment (Boiler)**; and **Zeolite Group**.

WATER HYACINTH. Water hyacinth (*Eichhornia crassipes*), a perennial, herbaceous monocotyledon member of the pickerelweed family (Pontederiaceae), is native to tropical America. It is usually found as a floating plant with mature specimens having long feathery roots that can be over 2 m (6 ft) in length (Fig. 1). However, in shallow waters, individuals can root themselves into sediment, and individual plants can even be found fully rooted on banksides. Water hyacinth is found in a number of differing morphological growth forms, and the morphology and architecture of leaves, petioles, and clonal groups can be highly plastic. However, two forms dominate. One, typically found in open water or at the edges of plant mats, is characterized by short bulbous and very buoyant petioles containing air-filled aerenchyma, whereas another form occurs in crowded areas, such as in the middle of plant mats, with slender, tall, nonbulbous petioles. The short bulbous form can develop into the tall nonbulbous form if crowding occurs and sufficient nutrients are available. Petioles can therefore grow to over a meter (over 3 ft) in length, although 50 cm (20 inches) is usually more typical. Center and Spencer found that in mature plants, between 6 and 8 leaves or lamina are present on each plant and that an equilibrium establishes between new leaves appearing and old leaves senescing.

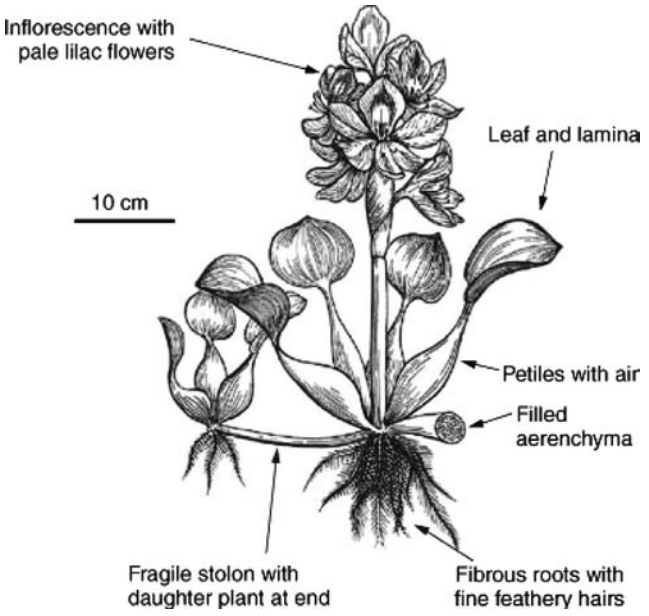

Fig. 1. Water hyacinth (*Eichhornia crassipes*).

Plants can double their biomass in 6 days and although water hyacinth produces seeds, which form part of the waterbodies seed bank, plants generally reproduce through clonal propagation with daughter plants being produced at the ends of fragile runners or stolons. These stolons are easily broken by wind, current, or animal and boat movements, thus allowing the detached clones to disperse and colonize new areas.

In the center of each mature rosette of leaves rises a broad stem, on top of which is an inflorescence that usually bears between 6 and 14 lily-like pale lilac or violet flowers. Each flower consists of 6 petals, the upper one marked with blue and yellow, 6 stamens, and a 3 segmented ovary. The fruit that develops comprises of a simple capsule containing in the region of 400 to 500 seeds. After flowering, the inflorescence bends down into the water and seeds sink to the bottom of the waterbody where they can remain dormant for 20 + years before germinating if the correct conditions prevail. For instance, a waterbody may become temporarily dry, resulting in all the parent plants dying; however, following the replenishment of water to the system, the seeds can germinate, thus providing a new stock of plants.

The fine feathery hairs that surround the main fibrous roots have a purple tinge and capture small particles as well as removing nutrients from the water column. Ideal growth conditions include a high nutrient concentration, especially of nitrogen and phosphorus, with water hyacinth thriving especially well where anthropogenic influences have artificially raised these levels. In addition, tropical temperatures, plenty of sunlight, and a high relative humidity all benefit the growth and expansion of water hyacinth.

With different morphological forms and an ability to adapt the growth form to the prevailing conditions, water hyacinth is able to colonize new areas very quickly. Although mats often develop out from the shoreline of lakes, rivers, and reservoirs, detached floating mats can also exist that are many kilometers (many miles) in diameter and several meters (several feet) thick. However, in its native habitat, the plant is kept in check through both natural pests and, more importantly, annual floods. During these periods, rivers may rise by over 10 meters (over 33 ft), resulting in a torrent of water that sweeps the plants out to sea where they perish because of the effects of salinity. A few individuals remain, however, snagged on the banks and protected in quieter backwaters, which act as the new source of the following years stock. Overall, therefore, water hyacinth only becomes a significant problem when it finds its way into areas outside of its natural range.

The World's Most Problematic Weed

Water hyacinth was seen as a botanical speciality and, because of its beautiful and delicate inflorescence, used to decorate ornamental ponds. Therefore, from its native range, it was spread around the world during the nineteenth century. It was recorded in Egypt in the 1870s, the United States in the 1880s, Australia and southern Asia by the 1890s, China and the Pacific by the early 1900s, South Africa in 1910, East Africa by the 1930s, and West Africa by the 1970s. It is now established throughout tropical and warm temperate regions of the world. Moreover, as demonstrated in the Democratic Republic of Congo, where two plants were seen to produce 1,200 daughter plants over four months, water hyacinth has massive growth potential. In terms of biomass, a m^2 of the weed can increase by up to 500 g each day so within a year, a hectare of plant can increase by over 1,800 tons fresh weight, which, of course, does not include the subsequent growth of the new material. This exceptional growth rate is often partly attributable to the presence of large quantities of available nitrogen and phosphorus, and unfortunately, because anthropogenic eutrophication has affected the great majority of waterbodies throughout the world, the growth of water hyacinth and the problems associated with it have been greatly exacerbated. As such, and further aided by its ability to colonize new habitats and a lack of natural controls outside of its native range, water hyacinth is now commonly described as the world's most problematic aquatic weed.

Invasive species such as water hyacinth have been referred to as a form of biological pollution because they can upset equilibria between native species that have formed slowly over millennia. When an invasive plant such as water hyacinth enters a new habitat it will out-compete and thus displace native vegetation, thereby becoming established. Some of the ways such displacements affect the native biota include a reduction in biodiversity, a decrease in habitat and food, and an overall change to ecological processes.

In the case of water hyacinth, native plants along the fringes of rivers and lakes are eliminated through successional shifts and, generally, a loss of biodiversity occurs. Furthermore, as native flora and fauna have coevolved over long periods of time, replacement of native vegetative systems with ones dominated by water hyacinth typically alters these relationships with accompanying reductions in available habitat and food. For instance, under the dense mats that can form, a reduced light and oxygen climate can lead to a decrease in plankton primary production, resulting ultimately in the death of native fish.

Ecosystem processes may change as a result of the spread of water hyacinth. Native ecosystems have developed under and adapted to particular abiotic factors and processes, such as rates of nutrient cycling, rainfall patterns, and fire regimes. The presence of alien species can alter these processes, which has a knock on effect to the ecosystem as a whole. For instance, where water hyacinth has been introduced, it can disrupt the natural hydrologic cycle by transpiring greater quantities of water, up to three times more, than native vegetation in the same habitat. Water tables and some surface water habitats are thus reduced and native species impacted.

Water hyacinth, with its characteristic thick fringes and floating mats, also has more direct impacts on anthropogenic activities. The weed can impede navigation, even in motorized boats, and transportation costs may increase because of the necessity of taking alternative indirect routes or as a result of motoring through the mats, which, if physically possible, increases fuel consumption. The weed has affected fishermen by fouling their nets and traps, reducing catches, and preventing access to landing sites. In West Africa, the inland waters of Ghana, Burkina Faso, and Togo have been particularly hard hit. Here, not only has the weed slowed down the boats of fishermen, it has also made landing difficult to the point that more of their catch goes off. Fish are often an important source of protein to lakeside communities, and without it, health suffers. Moreover, the mats are breeding grounds for carriers of human and animal disease such as malaria, schistosomiasis, encephalitis, and river blindness. Irrigation schemes have been put under pressure and, indeed, irrigation channels blocked. In many cases, the weed has reduced the supply of clean potable water and caused difficulties in water extraction. Unsurprisingly, its presence has increased disputes between local communities and overall has been responsible for the translocation of some communities away from affected areas when local watering points and lake access have become unavailable. Furthermore, in Lake Victoria, apart from the reduction in national revenue from the reduced export of fish produce, tourism has declined and intermittent closure of the hydroelectric plant in Jinga, because of weed buildup, has caused disruption within Uganda's capital, Kampala.

Unsurprisingly, therefore, the World Bank, together with the United Nations, the International Monetary Fund, and a plethora of other international and national organizations, has pumped hundreds of billions of dollars into tackling the problem of water hyacinth around the world.

Methods of Control

Once established, water hyacinth is extremely difficult, if not impossible, to eliminate, and attempts to do so often adversely impact remnant native vegetation. More achievable, however, is the control of the weed, but the elimination or even control of waterweeds is a costly process both in fiscal and temporal terms. Three basic methods exist to remove water hyacinth: physical, chemical, and biological controls.

Physical control involves employing manual labor and mechanical harvesters to remove the weed. The use of physical barriers, such as floating booms, to corral water hyacinth and prevent its spread as well as aiding ease of physical removal can also be implemented. Often, manual removal at landing stages can be undertaken extensively by locals if they are provided with equipment such as rakes and wheelbarrows. Aquatic vegetation cutters or "Swamp devils" have been used widely throughout the world, and booms are often used in conjunction to reduce weed expansion. These techniques have often worked in that weed can be contained and removed. However, often as a result of the sheer scale of the problem, benefits are typically short lived as a cleared site can be inundated with new weed in a matter of days, either through growth of any remaining weed or immigration of plants from outside of the site. Furthermore, booms can become overburdened from the weight of the weed and machinery can breakdown. Unfortunately, with a lack of expertise, tools, and spare parts, the expensive harvesters have, on occasion, been left to rust on the shore. However, physical control has been used successfully throughout the world to manage water hyacinth, and in Nigeria, such methods are considered relatively effective. Nonetheless, physical control has to be intensive and regular and is thus ultimately expensive. The cost of clearing a hectare (2.5 acres) of weed is estimated to be between US $2,400–30,000. Therefore, for a waterbody of more than a few tens of hectares, physical control is not a feasible long-term control option.

Chemical control is, worldwide, one of the most commonly used methods of macrophyte repression. Chemicals can be applied from the air, water, or land, and some degree of accuracy as to where the herbicide lands can be achieved. Chemicals such as diquat, glyphsophate, amitrole, and the amine and acid formulations of 2,4-D are the most effective and commonly used chemicals against water hyacinth. Application needs to be undertaken by trained individuals using correct dosages and applied at appropriate stages of growth. When they are applied incorrectly, problems can be encountered, not least of which is killing nontargeted plant species such as aquatic macrophytes or agricultural crops. Herbicides themselves typically only cost in the region of US $ 50 ha^{-1} of treated area; however, application costs whether by plane, boat, or hand are in addition to this. Therefore, herbicide use is only viable over small areas; on the larger scale application, it can become prohibitively expensive. However, whatever the operational costs, if weeds grow faster than chemicals can be applied, then the control of water hyacinth is clearly not accomplished. Moreover, if the dead or dying weed is not removed, the rotting biomass can lead to localized deoxygenation, which can, in turn, lead to other detrimental impacts on the waterbody. Furthermore, although plants may appear to have been controlled, the problem may not have been solved if, as in the case of water hyacinth, seeds remain buried in the sediment and propagate some years later or, as is more typical, plants remaining in the marginal vegetation recolonize the waterbody. Repeated applications are therefore required.

The main problem associated with herbicide use, and indeed the reason they are not used as widely as they might be, is the potential effect, real or perceived, of chemicals on humans either directly through ingestion or indirectly through reduced income. Many affected rivers and lakes are major sources of drinking water, and therefore the problem of ingestion is clear. Also, the sites most affected by water hyacinth, and therefore most in need of herbicide application, are typically adjacent to lakeshore communities and farmlands, which increases the risk of destroying nontargeted plants and crops. Furthermore, fear concerning the impact on native biota, not just the loss of nontargeted plants, but also the potential for bioaccumulation of contaminant dioxins through the food chain, is also an area of concern for governments considering their own populations health and the sale of fish to international exporters. Lake Victoria, for instance, supports an extremely valuable export fishery that earns critical foreign exchange for the riparian countries. The European Union, which is a major importer of fish from the lake, made it very clear that widespread application of chemicals could threaten the marketability of the fish. Finally, if biological control is used (see below), the application of herbicides may have impacts on the biological agents. Although experiments have found that diquat, glyphsophate, and 2,4-D do not increase mortality rates of mottled water hyacinth beetle *Neochetina eichhorniae*, they did move away from treated plants to untreated ones. In addition, researchers found that *N. bruchi* mortality was increased by several of the commonly used herbicides.

On the whole, chemical control, if undertaken correctly, can be very effective in the short term, but as with physical control, the use of herbicides is too expensive for repeated use on large expanses of water.

Biological control involves the use of host-specific agents that are naturally occurring enemies of invasive weeds in their native bioregion. The United States Department of Agriculture initiated biological control in Argentina in 1961, and since then, weevils, moths, and fungi have been tested for host specificity. Host-specific agents have now been successfully used to control water hyacinth in a variety of localities around the globe. Indeed, by 1998 a total of 7 agents had been released in 33 countries. Biological control of water hyacinth has therefore become very popular, and two weevils in particular, *N. eichhorniae* and *N. bruchi*, have been used extensively and successfully in North America, Asia, Australia, and Africa.

In the long term, once the weed is under control, a natural flux between agent and weed should exist, thus keeping in balance the density of weed and numbers of weevils present, although, as with all dynamic systems, fluctuations in both populations will occur. Biological control can provide an environmentally sensitive, cost-effective, and permanent solution to the problem of water hyacinth. However, the two drawbacks, assuming that host specificity is guaranteed, is that biological control usually takes between 3 to 5 years for the weevil populations to reach a level from which control can be achieved and, moreover, it does not always work.

Overall, of most use in the control of water hyacinth is an integrated method of control. Integrated control employs all three of the above control methods in an overall management strategy. Each of the three is tailored to suit a specific problem, and the extent to which each is used varies with location. In general, however, mechanical and chemical controls are used initially to bring short-term benefits, whereas the biological approach, taking longer to implement and develop, follows after the first two control strategies. In this regard, maintaining weevil-rearing centers is an essential feature of active management to ensure that weevil populations remain at an adequate level for control.

One other type of control exists that is of key importance but yet is not mentioned as often as the above control methods — the control of nutrient inputs. The levels of available nitrogen and phosphorus have often been

cited as the most important factors in limiting water hyacinth growth. Indeed, a Commonwealth Science Council survey of exotic floating weeds throughout Africa recommended "that action be taken at a national and sub-regional level to reduce nutrient input (particularly from urban and industrial waste) into water bodies, and to develop land-use schemes for long-term utilization and sustainable development of watersheds." However, in 1993, at a symposium on water hyacinth control, only three papers from 13 country and regional reports mentioned the importance of managing nutrient inputs through improved watershed management. In 1998, during a global working group on biological and integrated control of water hyacinth, in a session dedicated to integrated management, only two out of the 13 papers presented identified the importance of nutrients in controlling water hyacinth. A similar scenario was seen in 2000, at the second meeting of the global working group.

It is understandable and necessary that from within affected countries scientists and practitioners of weed control turn to mechanical, chemical, and biological means of short-term control and management. Moreover, in the short term, all biological possibilities should be vigorously explored, as appropriate insects are available and have been used elsewhere often to good effect. Yet the only real long-term solution to the water hyacinth problem is not biological control but rather the control of anthropogenic eutrophication through sustainable management of watersheds and resources. The reliance of developing nations on biological control as a long-term solution rather than sustainable management and development of their treasured resources is of major concern.

WATERJET CUTTING. The power of a pressurized waterjet has been known for decades. For example, pressurized jet has been used in the timber, lumber, and pulpwood industries for many years as a means of debarking, in less than one minute, logs from huge trees. The concept of using an abrasive waterjet for machining metals was first developed in 1974, but only since the mid-1980s has practical equipment become available for use in precision machining. Testing of automated abrasive waterjet cutting systems was undertaken by Gerin Sylvia (University of Rhode Island) in early 1985. Manufacturers of equipment now claim that the process can be used to cut "everything" from simple gray cast iron to 2-inch (50 mm) thick armor plate and boron-reinforced aluminum. See Table 1. The relationship between jet pressure and jet velocity is shown by Table 2.

TABLE 1. REPRESENTATIVE MATERIALS CUT BY ABRASIVE WATERJET (Thickness = 1 inch; 25 mm)

Material	Cutting Speed	
	In. min	Mm/min
17-4PH Stainless steel	2.0	51
HY-80 High-strength steel	2.0	51
6A1-4V Titanium	2.0	51
Ni-Cr Superalloy (UNS NO 7718)	2.0	51
Aluminum	4.0	102
Lead	18.0	457
Glass	18.0	457

Source: Flow Systems Inc.

TABLE 2. PRESSURE VERSUS VELOCITY OF ABRASIVE WATERJET

Pressure		Jet Velocity	
Psi	MPa	Ft/sec	M/sec
60 000	415	2985	910
50 000	345	2726	830
40 000	275	2438	745
30 000	205	2111	645
20 000	140	1724	525

Note: A doubling of system pressure produces only about a 50% increase in jet velocity, thus illustrating how minor pressure fluctuations do not affect cutting ability (velocity) of the jet.

Source: Flow Systems Inc.

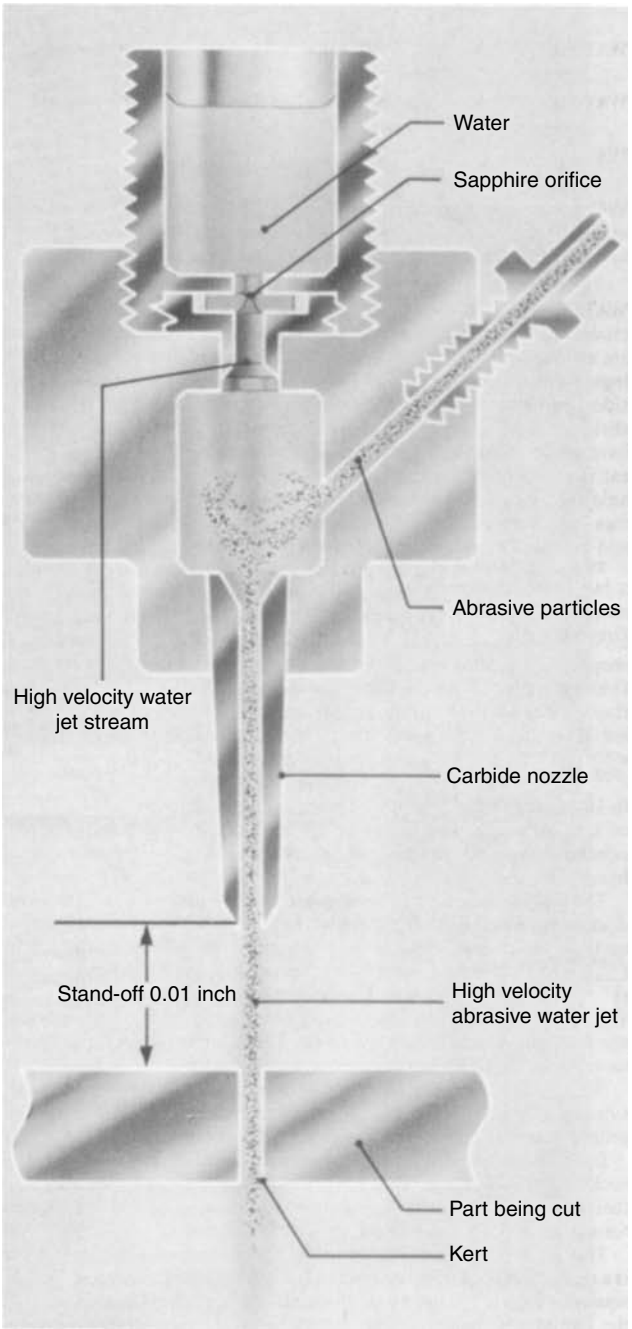

Fig. 1. Cross section of abrasive waterjet cutter, showing how water and abrasive material mix and travel through the nozzle. (*Aerospace Engineering*.)

Abrasive waterjet cutting produces no heat that can degrade metallurgical properties. Because of the smooth edges produced, often no postmachining is required. Generally, the fresh-cut edge has a surface roughness of 150 to 250 microinches (2.5 to 6.3 micrometers). Although there is no surface deformation because of heat, as is common with plasma cutting or grinding, the jet usually cuts at slower travel speeds. However, with reduced or no postcutting operations, net speeds may be increased. Maneuverability is also an excellent feature of jet cutting. Saws, for example, are mainly limited to cutting straight lines or essentially small arces of circular cuts, whereas the jet can be guided to cut curves, holes, and complex shapes. In addition to metals and glass, jet cutting can be used to cut through large sections of concrete.

Abrasives used are fine rather than coarse. It has been found that the harder abrasives, such as garnet, cut more effectively and up to 30% faster than foundry sand. However, where practical, sand is often favored because of its much lower cost.

As pointed out by Brahney (*Aerospace Engineering*), particularly in connection with aerospace structures, it is becoming increasingly apparent that traditional machining methods, such as routing and abrasive wheels, will not be acceptable. Although some individual methods can provide satisfactory results for specific tasks, they are not always an effective solution to the accuracy and flexibility demanded by complex cutting and trimming operations. For this reason, engineers have studied the feasibility of combining the special capabilities, including enhanced repeatability, afforded by computer automation with the power and precision offered by abrasive waterjet cutting technology.

Aerospace engineers have found that the waterjet process is capable of cutting aluminum up to 6 inches (152 mm) thick and composites up to 4 inches (102 mm) thick in a single pass.

A cross section of an abrasive waterjet cutter is given in Fig. 1.

WATER LILIES *(Nymphaeaceae)*. The water lilies form a small family of water or marsh plants. The leaves may be submerged or floating or carried well above the surface of the water on stiff petioles, as in the Lotus. The flowers are usually large and solitary. The principal genera are *Cabomba, Nuphar, Nymphaea*, and *Nelumbo*.

Cabomba is a genus of tropical American water lilies having two types of leaves; some are submerged and much-divided, into linear segments, while others are entire and floating with the petiole centrally attached. The small flowers are borne on long peduncles, and have their parts in threes. These plants are frequently used in aquariums, both for ornament and to oxygenate the water.

Nuphar is a genus of yellow-flowered plants occurring in the Northern Hemisphere. *Nuphar advena* is the common yellow water lily or spatterdock of the marshes.

Nymphaea contains the showy-flowered water lilies so frequently grown in artificial ponds. Northern hardy forms are white- or sometimes pink-flowered and fragrant. Many tropical species have red, yellow, blue, or pink flowers of great beauty. These flowers float on the surface of the water, as do the large cleft leaves. The fruit is a berry containing many seeds, each enveloped in a spongy aril. The fruit ripens under water, the mature seeds floating upward from the fruit and drifting about, by means of the air bubbles contained in the aril. Eventually each seed sinks to the bottom.

Nelumbo is a genus that contains but two species, *N. lutea*, a native of the southern half of North America, and *N. Nucifera*, of Asia and the East Indian Islands. The American species is pale yellow-flowered, the flowers and also the large peltate leaves standing well above the surface of the water. The Asiatic species is the Sacred Lotus, which has showy fragrant pink flowers of great beauty. The fruit of the lotus is a curious obconical receptacle in the top of which are embedded the many carpels. At maturity the receptacle is very light and dry, so that when broken from its stalk it floats on the water, carrying the seeds about until it breaks apart. The seeds of the lotus are used as food by many peoples, especially in Asia.

Victoria regia, the giant water lily of the Amazon, is related to *Nymphaea*. It is a plant of tremendous size, the floating leaf with its upturned rim often having a diameter of six feet or more. The flowers are likewise very large. The seeds are used as food in the Amazon valley, where the plant is native. See also **Hydrophytes**.

WATER LOSS (Plants). See **Guttation**.

WATER MASS. A body of water with a common formation history, for example, convection caused by surface cooling, having its origin in a particular region of the ocean. Water masses are identified by their temperature, salinity, and other properties such as nutrients or oxygen content. They have exclusive occupation of an oceanic region only in their formation region; elsewhere they share the ocean with other water masses with which they mix. Just as air masses in the atmosphere, water masses are physical entities with a measurable volume.

Common water masses in the World Ocean are: Antarctic Bottom Water (AABW), North Atlantic Deep Water (NADW), Circumpolar Deep Water (CDW), Antarctic Intermediate Water (AAIW), Arctic Intermediate Water (AIW), the Central Waters of various ocean basins, and various Surface Waters.

WATER MEASURER *(Insecta, Hemiptera)*. A long slender bug that creeps slowly on the surface of water. Also called the marsh treaders.

These are not the common insects that skate rapidly on the water, although they are closely related. The water measurers make up the family *Hydrometridae*, and the other insects are water striders of the family *Gerridae*.

WATER MOCCASIN. See **Snakes**.

WATER PENNY *(Insecta, Coleoptera)*. A small flattened oval insect found chiefly on the underside of rocks in running water. Water pennies are the larvae of beetles of the family *Psephenidae*. They resemble crustaceans and were originally described as such.

WATER PHEASANT. See **Waders, Shorebirds, and Gulls**.

WATER PLANTS. See **Hydrophytes**.

WATER POLLINATION. See **Pollination**.

WATER POLLUTION. Means for treating polluted waters are described in a prior entry on **Water**. This article is devoted to the current state of water pollution in the United States and some European countries, sources of pollution, and ways and means for preventing water pollution. This article also relates directly to articles on **Wastes and Pollution**; and a later article on **Water Resources**.

Water Pollution in the United States[1]

For an abridged analysis of the water pollution problem in the United States, a concerted look is taken at (1) the rivers and (2) groundwater.

[1] It is interesting to note how interrelated the topics of water, air, and solids (soil) pollution are. Acid rain, for example, commences as an air pollutant and ends up as a soil and water pollutant. See also **Pollution (Air)**. Thus, water pollution may be direct or indirect. Because they have a mass, air pollutants ultimately fall to Earth's surface and thus pollute the oceans, bodies of freshwater, and the land.

Water Quality in the Rivers. River water serves as an excellent overall index of the pollution problem, because ultimately, most water, even consumed groundwater and a vast majority of the lakes, ponds, etc., in the long run ends up in a river (or series of rivers), and thence flows to the oceans. The majority of rivers are accessible with relative ease and thus add to the convenience of obtaining water samples for analysis.

Probably the most complete study of river water quality was completed by the U.S. Geological Survey, released in early 1987 and periodically updated. The initial survey was coordinated by Smith and Alexander (USGS) and Wolman (The Johns Hopkins University), including water quality records from two nationwide sampling networks. The network included over 300 locations on the major rivers of the United States. Twenty-four water quality parameters are measured. Originally, the two networks were comprised of: (1) the National Stream Quality Accounting Network (NASQUAN) and (2) the National Water Quality Surveillance System (NWQSS). Locations of stations are shown on the map in Fig. 1. The measured water-quality indicators include:

pH (hydrogen ion concentration)	Trace Elements
Alkalinity ($CaCO_3$)	Arsenic
Sulfate (SO_4)	Cadmium
Nitrate (total as N) (TN)	Chromium
Phosphorus (total as P) (TP)	Lead
Calcium	Iron
Magnesium	Manganese
Sodium	Mercury
Potassium	Selenium
Chloride	Zinc
Suspended sediment (SS)	
Fecal coliform bacteria	
Fecal Streptococcal bacteria	
Dissolved oxygen	
Dissolved-oxygen deficit (DOD)	

Particularly noteworthy are widespread decreases in fecal bacteria and lead concentrations and widespread increases in nitrate, chloride, arsenic,

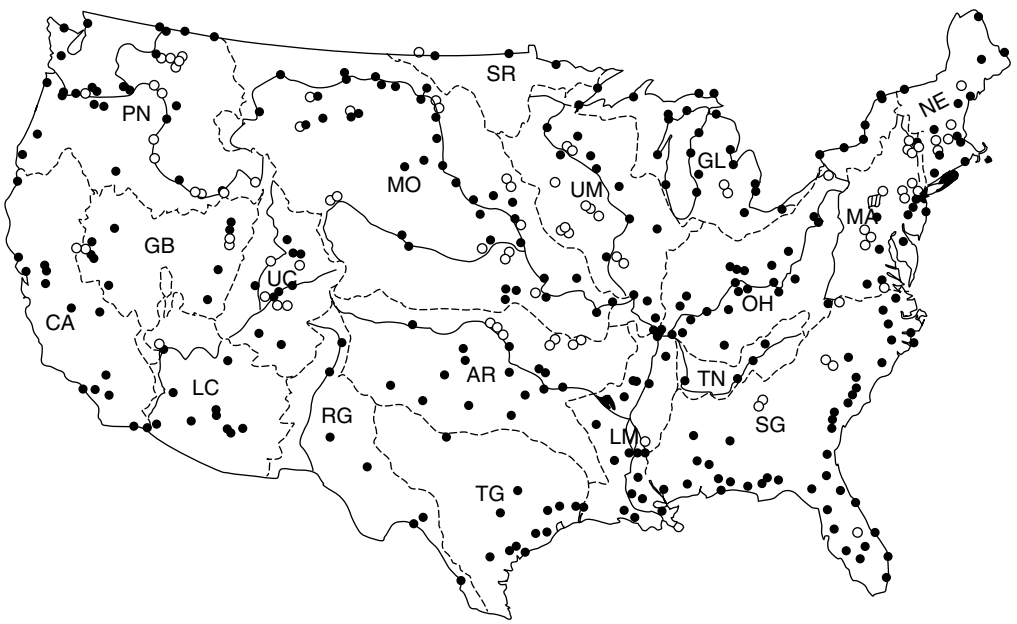

Fig. 1. Analysis of major river waters based upon a sampling network comprised of over 300 stations and involving two systems: (1) The National Stream Quality Accounting Network (NASQAN), indicated by solid black dots in map; and (2) the National Water Quality Surveillance System (NWQSS), indicated by open black circles on map. Shown in outline are regional drainage basins. Abbreviations used for these basins are:

NE New England	UM Upper Mississippi	RG Rio Grande
MA Mid-Atlantic	LM Lower Mississippi	LC Lower Colorado
SG Southeast-Gulf	TG Texas-Gulf	UC Upper Colorado
TN Tennessee	AR Arkansas-Red	GB Great Basin
OH Ohio	MO Missouri	CA California
GL Great Lakes	SR Souris-Red-Rainy	PN Pacific Northwest

The largest rivers are shown as solid black lines. The NASQAN stations are located and associated with these rivers and their tributaries; the NWQSS stations are located along smaller rivers and usually near agricultural areas and some urban communities. (*U.S. Geological Survey*.)

and cadmium concentrations. Recorded increases in municipal waste treatment, use of salt on highways, and nitrogen fertilizer application, along with decreases in leaded gasoline consumption and regionally variable trends in coal production and combustion during the period, appear to be reflected in water-quality changes. In addition to data from the network of sampling stations, the researchers depended upon considerable ancillary data in their interpretation of the sampling station trend results.

Because of the passage of restrictive legislation, mainly over the past decade, improvements in river water quality can and should be expected. As discussed later, indirect pollution of landfills as they reach underground aquifers is an even more important concern and is less visible and hence less easy to police and control.

Since the passage of the Clean Water Act by the U.S. Congress, numerous improvements have been evidenced and thus tend to reinforce confidence that in many aspects the environment can be improved.

Trends in River Water Pollution

Biological Oxygen Demand (BOD). The Clean Water Act was passed by the U.S. Congress in 1972. In the decade that followed, municipal loads of BOD decreased an estimated 46% and industrial BOD loads decreased at least 71% nationwide. These reductions are impressive, especially in light of an increase in population (up 11% during the period) and an increase in the gross national product (GNP, adjusted for inflation) of 25%. Federal funding for upgrading municipal facilities peaked in 1980 and amounted to $35 billion for the decade.

Dissolved Oxygen Deficit (DOD). The sampling station report indicated a net decrease in DOD (thus an improvement in dissolved oxygen conditions). DOD declines were reported in the New England, Mid-Atlantic, Ohio, and Mississippi regional basins; increases were most frequently found in the Southeast. These data appear to confirm the success of point-source control efforts. Decreases in DOD were found most often (beyond expectations) where point sources dominated; increases where nonpoint sources prevailed. The chronology of the station data also indicates that gains from industrial water treatment preceded those from modernization of municipal facilities.

Fecal Bacteria (coliform, FC; streptococcal, FS). During the study period, decreases in FC and FS were widespread. Major decreases were particularly evident in parts of the Gulf Coast, central Mississippi, and Columbia basins; significant decreases were also noted in the Arkansas-Red basin and along the Atlantic Ocean. During the study period, major efforts were made to control both municipal and agricultural sources of fecal bacteria.

Suspended Sediment (SS). These impurities, originating from nonpoint sources (notably agricultural) are probably the most damaging nonpoint sources of water pollution. E.H. Clark estimates the cost of the hydrologic impacts of soil erosion and related nutrients on aquatic ecosystems may increase. Fertilizer application rates increased by 68% during most of the testing period described here. The long-term history of fertilizer in the United States has been one of almost continuous increases in nitrogen and phosphorus application rates. As reported by Smith, et al., the extent to which changes in agricultural practice are reflected in trends of SS, phosphorus, and nitrogen concentrations in the nation's rivers has largely been a matter of conjecture because of the lack of systematic long-term studies.

Certain forms of land use, such as logging, traditionally have been associated with high rates of soil erosion. Thus, the study indicated large increases in SS in the Columbia (logging) and in the Arkansas-Red and Mississippi basins (agriculture) during the test period. Significant amounts of SS were also found along the Texas Gulf Coast, northern Florida, and scattered locations in northern Ohio, New England, and northern Minnesota. Declining rates of SS were indicated in the Missouri River basin and have been clearly traced to the effects of reservoir construction throughout that basin during the 1950s and 1960s.

Total Phosphorus (TP). Mainly as the result of controls over point sources of pollution, decreasing trends in TP were found in the Great Lakes and Upper Mississippi regions. Significant correlations in TP increases were found in connection with nonpoint sources (mainly agriculture) in several regions.

Total Nitrate (TN). Increases in TN were found to be widespread. Although also found to be significant in the Pacific Northwest and along the California coast, the great majority of increases in TN were found east of the 100th meridian (southward from North Dakota to southern Texas). Increases of TN were strongly associated with agricultural activity including fertilized acreage (as a percentage of basin area), livestock population density, and feedlot activity. Atmospheric deposition, in addition to agricultural runoff, was found to be a major source of nitrate in surface waters, particularly in the forested basins of the East and northern Midwest. Separate studies of NOx emissions showed a general pattern of increasing rates, notably in the Ohio, Mid-Atlantic, Great Lakes, and Upper Mississippi basins. The river water quality study correlated well with the emission studies.

It is interesting to note that the differences in nitrogen and phosphorus trend patterns appear to be the result of three factors: (1) atmospheric deposition seems to play a large role in the high frequency of nitrate trends; (2) the low frequency of, and strong association patterns between phosphorus and SS trends suggests that increases in TP resulting from rises in agricultural activity have been moderated or delayed by temporary storage of sediment-ground TP in stream channels; and (3) during the study, point-source control efforts were focused much more intensely on TP than on TN because phosphorus was considered more limiting to eutrophication in freshwater ecosystems. The greatest consequence of the differences in TN and TP were seen in changes in the delivery of nutrients to coastal areas. Nitrate loads to East Coast estuaries, the Great Lakes, and the Gulf of Mexico have increased markedly, while phosphorus loads to coastal areas have changed little or have declined. Exceptions are the Gulf Coast and the Pacific Northwest basins, in which instances phosphorus loads to estuaries have increased in association with substantial increases in sediment loads. Researchers have stressed that increased delivery of nitrate to estuaries is of major concern because of the tendency for nitrogen to be limiting to eutrophication in many estuarine environments. See Table 1.

TABLE 1. CHANGES AND TREND PATTERNS OF DELIVERY OF NUTRIENTS TO COASTAL AREAS OF THE UNITED STATES

Region	Change in Load	
	Total Nitrate (%)	Total Phosphorus (%)
Northeast Atlantic Coast	32	−20
Long Island Sound/New York Bight	26	−1
Chesapeake Bay	29	−0.5
Southeast Atlantic Coast	20	12
Albemarle/Pamlico Sound	28	0
Gulf Coast	46	55
Great Lakes	36	−7

Source: Smith/Alexander/Wolman 1987 reference listed.

Salinity. Increasing trends in chloride, sulfate, and sodium were found in a large majority of the rivers tested. An average increase of 30% in salinity was found. Researchers attribute this increase to the following factors. (1) Increases in population in the basins surveyed — human wastes are a major source of chloride in populated basins. (2) Use of salt on highways increased by a factor of 12 between 1950 and 1980 and is considered a major contributor to total stream salinity. (The rates of highway salt use were particularly significant in the Ohio, Tennessee, lower Missouri, and Arkansas-Red basins.) (3) In the Missouri, Arkansas, and Tennessee basins, salinity increases were accurately correlated with changes in surface coal production during the testing period. By contrast, salinity decreased in the Upper Colorado Basin, an area historically plagued with salt problems. Decreases are attributed to control efforts and the effects of reservoir filling during the early 1970s.

Trace Elements. Moore and Ramamoorthy reported that trends in toxic element concentrations in surface waters have remained largely unknown despite rapidly increasing knowledge of the potential sources of toxic substances in aquatic systems. The study reported on analyses of several trace elements, including arsenic, cadmium, chromium, lead, iron, manganese, mercury, selenium, and zinc. Researchers found increases in dissolved arsenic and cadmium, particularly in those basins in the industrial

Midwest. Atmospheric deposition is considered more significant than terrestrial sources of trace element contamination. Heit et al. confirmed this conclusion as based upon the results of lake sediment analyses in regions with high deposition of fossil-fuel combustion products. At many network sampling stations, dissolved lead concentrations showed a decrease, but despite significant declines in gasoline lead consumption, some sampling stations showed no decline. Lead concentrations were found particularly heavy in the Texas Gulf Coast region.

In deference to the excellence of the sampling study, researchers point out that additional sampling in selected smaller basins is needed to improve the ability to determine the effects of changes in point-source pollution. Although the effects of improved sewage treatment on dissolved oxygen levels appear to be more localized than previously thought, it is possible that the ecological and social benefits of water-quality improvements have been large in proportion to their spatial extent. As pointed out by W.M. Leo, et al., individual case studies have demonstrated local effects of point-source pollution controls, but they do not provide an adequate national sample on which to base an assessment of the benefit of pollution abatement programs. Smith/Alexander/Wolman, in their report, suggest that in designing water-quality monitoring programs for the future, we should recognize the growing number of both point- and nonpoint-source issues that our economic and political systems must address.

Groundwater Quality and Contamination

Groundwater as used by humans consists of subsurface water, which occurs in fully saturated soils and geological formations. Nearly half the population of the United States uses groundwater from wells or springs as a primary source of drinking water. An estimated 75% of major cities depend upon groundwater for most of their supply. Total fresh groundwater withdrawals (1980) were estimated at 88.5 billion gallons per day, of which 65% was used for agricultural irrigation. See also the article on **Groundwater**. Numerous regulatory acts have been passed by the U.S. Congress in recent years to protect groundwater from pollution. These various acts are listed in article on **Wastes and Pollution**.

As early as the 1980s, the U.S. Environmental Protection Agency (EPA) proposed a national groundwater strategy — with the emphasis of targeting on prevention as contrasted with taking remedial action in treating known contaminated sites. Transport of groundwater is very slow. Flow rates are governed by hydraulic gradients and aquifer permeability, thus flows may range from a few centimeters to a meter or so per day. Contaminants usually mix with the water at a low rate. Sometimes natural ingredients tend to retard the actions of contaminants; in other cases the concentrations of contaminants in groundwater may exceed those found in surface water. Groundwater contamination occurs out of view and the effects of pollution may not be noted for weeks or months (even years in sparsely settled communities) after the initial cause(s). A wide variety of substances are involved in groundwater contamination. These include inorganic ions (chloride, nitrate, heavy metals), complex synthetic organic chemicals, and pathogens (viruses and bacteria). Thus, rarely does one find the same combination of variables when attacking a groundwater contamination problem.

The extent of groundwater is statistically very impressive: (1) of the water in the hydrologic cycle, 4% is groundwater, exceeded only by the seas and oceans; (2) groundwater volume at any given time exceeds that of the combined fresh water in lakes, streams, and rivers, of which an estimated 30% of the volume is furnished by groundwater; (3) during dry spells, groundwater furnishes a large majority of the low water flow of streams.

The manner in which waste disposal practices may interact with and contaminate the groundwater system is illustrated schematically in Fig. 2.

A study of groundwater contamination in ten selected states, sponsored by the Environmental Assessment Council of the Academy of Natural Sciences (Philadelphia) provides an excellent view of the sources and kinds of contamination that have been found in known, reported incidents of contamination. See Table 2.

One of the most serious cases of groundwater pollution occurred above the Great Miami Aquifier, which is a 2-mile (3.2-km) wide and 80-mile (129-km) long water basin that essentially follows the Great Miami River in southern Ohio and a section of which is located directly under the city of Hamilton. This aquifer is considered to be one of the Midwest's most productive sources of groundwater, making up about one-third of Ohio's groundwater. At points, the aquifer rises to within 20 feet (6 m) of ground level. A small, private firm established a waste-disposal operation in the 1970s at a time when regulations were minimal. Cleaning up the severely polluting operation commenced in May 1983 and was one of the first projects selected by the EPA to clean up after passage of the Superfund Act in late 1980. Cleanup contractors found 8600 drums, 30 storage tanks, and two open-top tanks on an approximately 10-acre (40,470−square-meter) area. Containers were found holding and leaking some 300,000 gallons (1,135,000 liters) of toxic wastes, including pesticides, rodenticides, waste oils, plastics and resins, acids, arsenic, and cyanide sludges. Among the chemicals found were DDT and PCBs. It was estimated in 1990 that environmental correction actions will require an additional 10 years at a multimillion dollar cost. Professionals in the cleanup field have estimated the existence of about 400 additional sites of serious groundwater pollution of the extent and nature of the site just described.

Remediation of Poisoned Aquifers. Means for correcting polluted underground water systems are limited and costly. To the knowledgeable would-be polluter, the costs and time involved serve as incentives for preventing such damage in the first place.

Containment. Once subterranean pollution has been detected for the first time, not only must the source(s) be located, but the extent of damage must be determined. This often involves the meticulous analysis of core samples and thorough geologic and hydrologic mapping of the poisoned volume of earth and groundwater affected. Effective permanent remedial actions require an extensive and reliable data base. In some cases it may be found that, by way of constructing underground barriers, the polluted underground sections can be isolated and an aquifer rerouted. In such rerouting, it may be found that gravity flow underground may be insufficient, thus requiring pumps to assure flow through what, in essence, is a new "artery" for groundwater flow.

Where containment (isolation) procedures are not practical or fully adequate, extraction of pollutants may be required.

Extraction. In this process, sometimes referred to as the "pump and treat" method, polluted water is pumped to the surface, after which it is treated to remove toxic materials. Then the treated water is returned to the aquifer. Depending upon the extent of pollution, a large water-treating facility may be required adjacent the cleanup site, even though the facility may be required only for a comparatively short time of a few to several months.

Bioremediation. This process is gaining acceptance among site cleanup professionals. Wastes that have been pumped out of the aquifer are transferred to specially constructed tanks, to which fungi, bacteria, and other microbes are added, along with hydrogen peroxide, which furnishes oxygen. Also added are small amounts of nitrogen fertilizer, which acts as a nutrient for the microbes. Under these ideal conditions, the microorganisms secrete enzymes that transform immense quantities of substances such as benzene and trichloroethylene into harmless salts. A delicate balance must be maintained in providing just enough oxygen and nutrients, thus avoiding repollution of the wastes.

For cleaning up sites less extensive than the one just described, and thus requiring aboveground treating facilities for less time, portable plants are receiving consideration. New techniques also are being evaluated. In one system, a *wet oxidation* process converts waste sludge into clean water and sterile ash. Organic pollutants also are being subjected to a laser oxidation process that breaks molecular bonds in a photochemical reaction chamber. Low-frequency soundwaves and electric charges also are being tested to free pollutants from soils. In this process, after a positively charged anode is introduced to the ground, positively charged water and contaminants migrate toward a negatively charged withdrawal well, which acts as a cathode.

Above- and Underground Storage of Products and Wastes

For practical economic reasons, some potentially polluting products must be stored for indeterminate periods above ground. Chemical, petroleum, and petrochemicals are examples of the need for temporary holding. In the blending of gasolines, for example, refineries pump different grades of fuel to a "gasoline pool," out of which quantities can be drawn and blended to achieve the desired specifications for a given gasoline. In producing commercial chemicals where batch or semibatch processing is used, a supply for several weeks or months may be produced within a

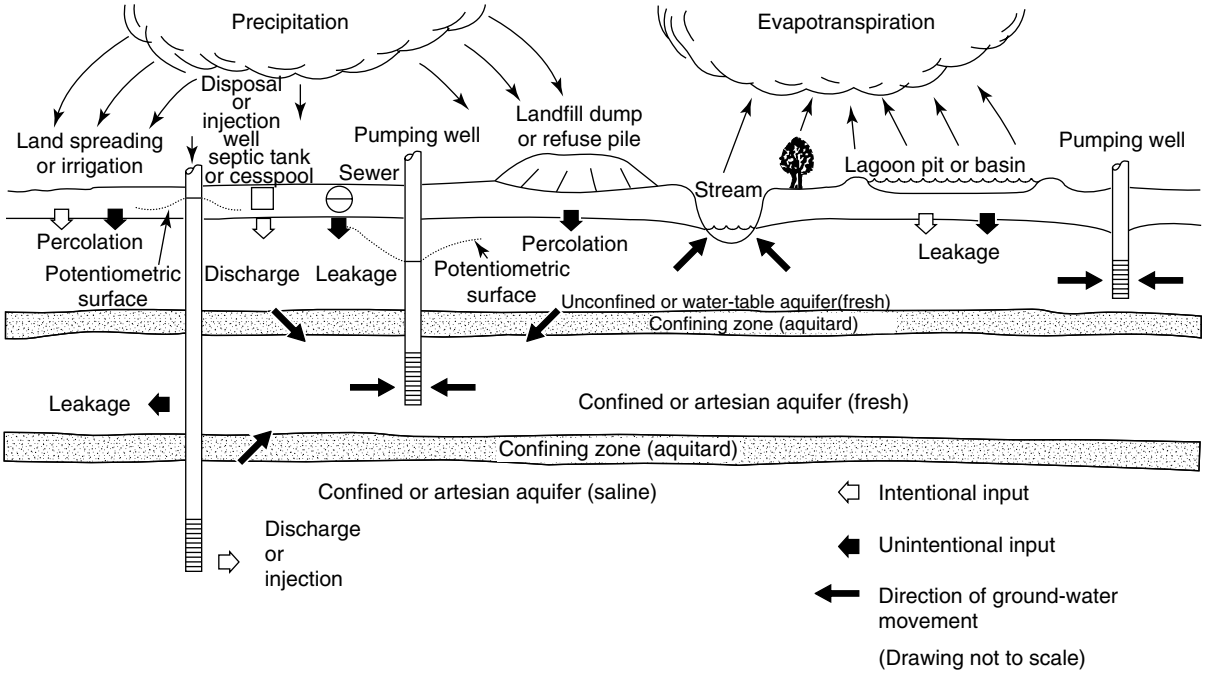

Fig. 2. Processes by which wastes can reach and contaminate groundwater systems. (*U.S. Environmental Protection Agency*.)

TABLE 2. REPORTED INCIDENTS OF GROUNDWATER CONTAMINATION IN TEN SELECTED STATES (Academy of Natural Sciences, Philadelphia)

State	Groundwater Consumed (Million Gallons/Day)	Source of Contamination
Arizona	4800	Industrial wastes; landfill leachate; human and animal wastes
California	13,400–19,000	Saltwater intrusion; nitrates from agriculture; brines and other industrial and military wastes
Connecticut	116	Industrial wastes, petroleum products, human and animal wastes
Florida	3000	Chlorides from saltwater intrusion and agricultural return flow; industrial wastes; human and animal wastes
Idaho	5600	Human and animal wastes; industrial wastes; radioactive wastes
Illinois	1000	Human and animal wastes; landfill leachate; industrial wastes
Nebraska	5900	Irrigation and agriculture; human and animal wastes; industrial wastes
New Jersey	790	Industrial wastes; petroleum products; human and animal wastes
New Mexico	1500	Oil field brines; human and animal wastes; mine wastes
South Carolina	200	Petroleum products; industrial wastes; human and animal wastes

Note: Probably the most newsworthy, publicized incidents have stemmed from public and industrial dumping sites, covered in this summary under "landfill leachate." A class of pesticides most commonly found in groundwater is nematocides. They are particularly difficult because manufacturers design them to be both persistent and toxic. DBCP (1,2-dibromo-3-chloropropane) is a representative nematocide.

short time frame and then stored in inventory to fill orders over a period much longer than that required to make the product. Thus, numerous products that are considered toxic must be inventoried. Frequently, at the manufacturing level, aboveground tanks are preferred. In terms of gasoline, at the consuming level, safety regulations and sheer convenience require that fuels be dispensed from underground tanks. Unfortunately, over the years, tank leaks have become an important cause of land pollution and ultimately the poisoning of aquifers.

Other toxic products that require some form of storage include solvents, chemical raw materials (fluid) and wastes that are "waiting" for final disposal/destruction.

Pollutant Pathways When Leaked Follow Different Pathways Underground. Relatively recently, cleanup specialists have made the surprising discovery that organic substances generally differ from inorganic substances when they are leaked underground. See Fig. 3. This information is helpful for preventing future leaks and for remedying situations where pollution already has occurred.

Means for Preventing Tank Leakage. In addition to the "common sense" approaches, such as selecting corrosion, weather, and moisture-resistant materials of construction, providing excellent foundations, and leak-detection instrumentation, there are additional preventive measures that can be taken. Cathodic protection, for example, is described in an article on **Corrosion**.

Secondary containment of underground storage tanks is another means. EPA regulations now require secondary containment systems for hazardous substance underground storage. Many industrial firms now are turning to flexible membrane systems, which offer a number of advantages over their rigid counterparts. EPA regulations for new tank construction permit four options:

1. Fiberglass-reinforced plastic.
2. Steel with cathodic protection, using either dielectric coating, field installation by a corrosion expert, or impressed current system.
3. Metal without cathodic protection if site is determined to be noncorrosive.
4. Steel-fiberglass–reinforced plastic composite.

Options for existing tanks include:

1. Interior lining.
2. Cathodic protection if internal inspection is conducted and tank is less than 10 years old and is monitored monthly.

Landvaults. Approval of aboveground permanent landvaults sometimes can be obtained. They have a number of advantages:

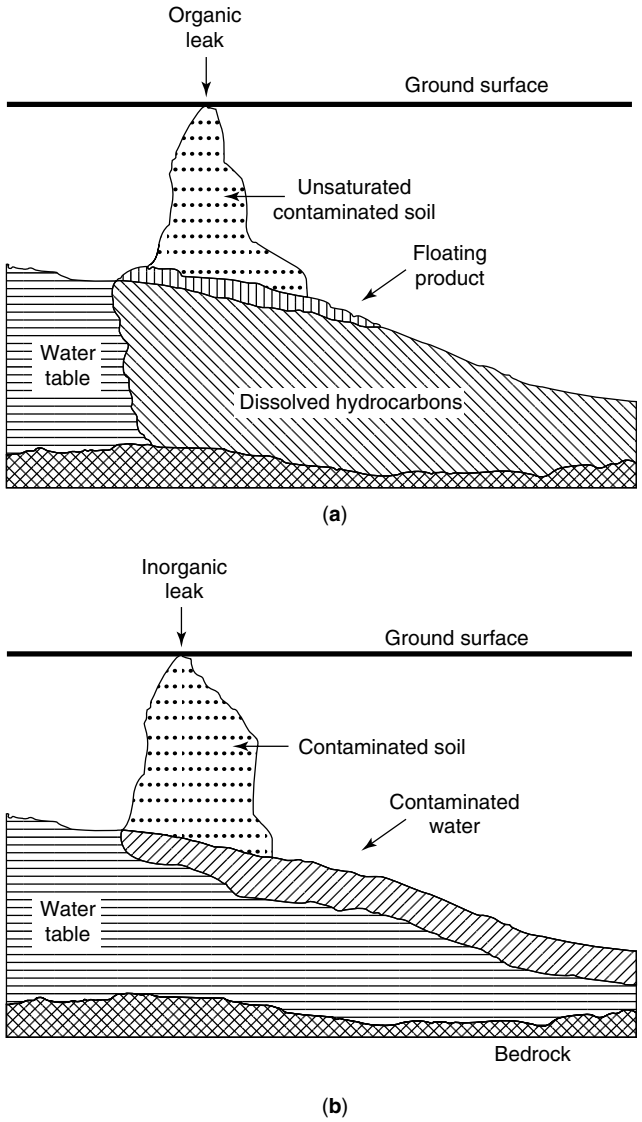

Fig. 3. Schematic diagrams illustrate how organic and inorganic fluids differ in how they permeate ground and water table: (**a**) Organic substances contaminate the soil to the surface of the groundwater table. If contaminant is lighter than water and only slightly soluble, such as a petroleum product, a substantial layer of product may be found floating on the groundwater surface. The groundwater will contain varying concentrations of dissolved contaminants, depending upon solubility. (**b**) Inorganic compounds, such as acidic wastes containing metals, may be attenuated in their flow. Soils tend to attenuate movement of positively charged ions (cationic) metals at various rates, depending on the cation exchange capacity of the soil. Clays have a high cation exchange capacity. Thus, extensive contamination of soils by metals is infrequent. In contrast, acids can increase movement through the soil.

1. A double or triple composite liner system provides maximum protection.
2. They permit future retrieval of wastes for improved treatment when such a process may be developed, and, inasmuch as the vault is fully sealed, the underground geology need only be strong, stable, and free of any tectonic history.

Pollution of the Seas and Oceans

Over the centuries, populations living along the tens of thousands of miles of coastline of the oceans and seas worldwide have dumped their refuse into these sinks of saline water. This was done with little if any reluctance or concern prior to the early 1900s. Ocean waters, without desalination, could not serve as drinking or irrigation water, and, inasmuch as these bodies of water are so tremendous as compared with the amounts of waste that may be added to them, there was no real sense of guilt when polluting them. Only within the last few decades has a public awareness of pollution of all types, including the oceans, developed. Modern means for exploring Earth's hydrosphere, from the surface to great depths, are relatively recent achievements. The American explorer, Charles Beebe, did not accomplish his remarkable descent to ocean depths until 1934, when he reached a depth of 3028 feet (923 m). Progress in the ocean sciences is described in several articles devoted to the ocean. See also **Ocean**.

The effects of polluted waters on the proliferation and edibility of fishes and other forms of ocean life have been researched extensively in recent years, and this knowledge has created a vital incentive for reducing pollution. Just a few years ago lightweight refuse that rises to the ocean's surface and littered beaches created an environmental crisis and another incentive for ceasing ocean dumping of sewage and solid wastes into the oceans.

The U.S. Congress passed the Ocean Dumping Act in 1972. To continue with such dumping, permits were required and the polluter had to demonstrate to the Environmental Protection Agency that the materials to be dumped would not "unreasonably degrade or endanger human health or the marine environment." Radiological, chemical, and biological warfare agents and high-level radioactive wastes were fully banned. The dumping of dredged materials from navigable waters was put under the regulation of the U.S. Army Corps of Engineers. Dredged material is comprised of a mixture of sand, silt, and clay, but can include rock, gravel, organic matter, and contaminants derived from a wide range of agricultural, urban, and industrial sources. As reported by R.M. Engler (U.S. Army Corps of Engineers), "Contaminated or otherwise unacceptable dredged material accounts for only a small fraction of the total — less than 10 percent in the U.S. and globally." Clean dredged waste has a number of positive uses, including the enhancement of wetlands and aquatic and wildlife habitats, beach nourishment, offshore mound and island construction, agriculture mariculture uses, and as a construction aggregate. All requests for the ocean dumping of dredged materials had to be accompanied by a list of suggested alternative actions.

As will be noted in the article on **Wastes and Pollution**, much emphasis is given to reducing pollution by creating less waste. "No Waste," of course, is an impractical target, but "Much Less Waste" can be achieved globally within the next several years, even considering major population increases. But, even then, from an economical and practical viewpoint, some scientists do not believe that the oceans can escape, in the long term, playing a major role as a "waste sink." As of the mid-1990s, both scientific and lay opinions were strongly polarized. The oceans can accommodate huge annual volumes of nonhazardous, nonfloatable wastes. Much scientific research and engineering remains to be done in removing toxic materials prior to dumping and thus protect ocean life forms and the people who eat seafood. Detoxification is mandated now prior to land dumping. Also, much more knowledge of ocean characteristics is required in the way of selecting dumping sites.

Oceanologists and waste-handling professionals presently are attempting to answer the question, "How can society use the oceans for waste disposal without harming the marine environment or fisheries resources?" Much research remains, and numerous other questions remain unanswered.

The Boston Harbor Project

For nearly a century, scores of villages (later to become cities) developed around the city of Boston, Massachusetts. The Boston Harbor and associated rivers (Charles, Mystic, and Neponset) traditionally have been used for the disposal of sewage wastes. In 1904, Boston established a centralized area sewage disposal system, which because of population expansion, has multiplied in capacity manyfold. The cities that cluster around Boston found it easier and less costly to hook into the Boston central sewage system than to build their own treating and disposal facilities. The result over the past 20 years or so has been no surprise, and Boston Harbor became known as one of the most polluted in the world. Reconstruction of the Boston sewage system commenced during the same time frame as increased state and federal regulations governing sewage disposal. Although construction of a 9.5-mile (25-km) tunnel to carry sewage wastes out of the immediate Boston harbor area to Massachusetts Bay was nearing completion as of 1994, this project serves as an interesting example of how a major environmental project can become entangled in legislation and regulatory red tape and the involvement of citizen groups in environmental issues. An excellent background description is contained in the Spring 1993 issue of *Oceanus* magazine.

The waste-transporting tunnel was bored through bedrock that supports the seafloor of Boston Harbor and Massachusetts Bay. With exception of the tunnel bored under the English Channel (see also **Tunnel Engineering**), it was the major tunneling project to take place during the 1980s and 1990s. Toward the end of the tunnel, a series of 55 vertical effluent discharge pipes release the sewage into the bay.

Further Quantification of Ocean Data Needed

Factors[2] that remain to be studied concerning the oceans in terms of waste disposal include:

Physical — Diffusion, advection, sedimentation.

Chemical — Volatilization, neutralization, precipitation, flocculation, adsorption, desorption, dissolution, oxidation.

Benthic — Geochemical, biological.

Over the past several decades, oceanographers have found that the oceans and seas are not as uniform as once contemplated, ranging with regard to their latitudinal and longitudinal locations and also with depth. This suggests, then, that various areas of the ocean may be more suited to accept anthropogenic debris than others. For example, temperature profiles, depths, thermal gradients, and numerous other physical, biochemical, and life-sustaining qualities are known to exist.

An early appreciation of natural oceanic detritus is given by biologist Rachel Carson, who in 1950 observed in her book, *The Sea Around Us*, "When I think of the floor of the deep sea, the single overwhelming fact that possesses my imagination is the accumulation of sediments. I see always the steady, unremitting, downward drift of materials from above, flake upon flake .... For the sediments are the materials of the most stupendous 'snowfall' the earth has ever seen." Fine particles are sinking into the global oceans every microsecond of the day and night. Such particles may include "shreds and motes and globs of stuff" — dead and decayed remains of plants and animals, meteorites and other cosmic dust, old lobster molts, volcanic fallout, radioactive fallout, the pollen from flowers, grains of sand from the deserts — in summary, just about everything that is airborne contributes to oceanic detritus. The rate of passage of suspended material from the ocean's surface to the bottom of the sea varies widely, but some scientists estimate that for some particles it may take thousands of years to reach the ultimate deep-sea graveyard. It is only in recent years that some oceanologists have studied this phenomenon seriously. Some detritus never may reach the sea floor because it is consumed by various forms of ocean life as food. A. Aldredge and M. Silver (University of California) observe, "Marine snow particles are typically smaller than a pinhead. However, in Monterey Bay off California (and probably elsewhere), the particles may be 4 inches (10 cm) across. These particles are usually aggregates of many smaller particles that stick together, often with mucus .... The largest type of marine snow is the *giant house*, which can be 6 feet (1.8 meter) across. Each house is a blob of mucus that has been secreted by a zooplankter. Some investigators refer to them as "floating islands .... While a single zooplankter inhabits its balloon of mucus, there may be hundreds of copepods on its exterior, apparently grazing on the nourishing tidbits of *marine snow* .... We find typically that *marine snow* hosts organisms in very high concentrations .... There are certain groups of organisms that seem to be found only on these .... Among the unusual characters are rare species of copepod, certain protozoans and a unique assemblage of bacteria .... *Marine snow* is a major means by which material reaches the ocean floor, a major vehicle for the transport of organic matter down to the ocean's interior .... As these particles sink through the water, they change continuously, as do the communities living on them."

Scientists have observed that *marine snow* can be a nuisance. Because in some cases gas may be produced, particles rise and create a scum, and this can be dried by the sun to produce a surface of sufficient strength to permit seagulls to walk upon it. Such scum extends for many thousands of acres (hectares) in the Adriatic Sea, where it has become a menace to fishermen and the tourist trade. Such scums were reported as early as the 1700s.

Natural Pollution of the Oceans. Frequently overlooked is what may be termed "natural" pollution, which, when coupled with artificial (anthropogenic) pollution, contributes to the sum total of all pollutants found in fresh and ocean waters worldwide. Deep fissures in the ocean floor, fumaroles, and seamounts (underwater volcanoes) release megatons of sulfur-laden and other noxious gases into ocean water; other discontinuities in the ocean basins release vast quantities of crude oil and other hydrocarbons. Surface volcanoes are major contributors to atmospheric pollution, much of which ultimately affects Earth's hydrosphere. The present dissolved solids content of the oceans represents natural water pollution that has taken place ever since the land masses rose above sea level — through a constant erosion of soil.

Oil and Hydrocarbon Pollution of the Oceans

Petroleum is not a substance foreign to the marine environment. Natural seeps have been discharging petroleum hydrocarbons into the marine environment for millions of years, in amounts substantially greater than those resulting, for example, from present offshore production activities. About 200 submarine oil seeps have been identified worldwide. There is little doubt that many more exist. Petroleum has also continuously entered the seas as a result of erosion of uplifted sedimentary rocks containing trace amounts of petroleum hydrocarbons. There is also evidence of organisms living in the ocean that biologically produce hydrocarbons, ranging from gases (methane, ethane) through liquids, to solid paraffin waxes of high molecular weight.

These substances enter the marine environment from a variety of sources, both through natural phenomena and anthropogenic activities. In 1985, the National Academy of Sciences (NAS) published an assessment of petroleum pollution of the world's oceans and estimated that between 1.7 and 8.8 million metric tons per annum (mta) of oil enter the oceans. Within this range, 3.2 mta is regarded as the best single estimate — equivalent to about 0.1% of the total oil produced annually worldwide (about 3 billion metric tons).

Table 3 compares these estimates with those published by NAS in 1972. All categories except spills show about a 50% decrease. According to the NAS, part of the reduction in most categories can be attributed to refinements in estimating techniques. Other reductions, however, are attributed to efforts to reduce oil pollution, such as the international program to reduce tanker operational discharges. Because annual Figures for marine accidental spills vary significantly, an average over a number of years was used for both the 1975 and 1985 reports. The increase shown for such spills in the 1985 study reflects the influence of major incidents — such as the loss of the 220,000 dead-weight-ton tankers *Amoco Vadiz*, which occurred in the period (1975 through 1980) — used to calculate its annual average. The Alaskan oil spill (1989) is discussed later.

TABLE 3. PETROLEUM INPUTS TO THE OCEANS FROM DIFFERENT SOURCES

Source	1975 Study[1] (Million Metric Tons Annually)	1985 Study[2] (Million Metric Tons Annually)
Municipal and Industrial Wastewater		
Discharges and Runoffs	2.5	1.0
Refinery Wastewater Discharges	0.2	0.1
Offshore Oil Production	0.08	0.05
Marine Transportation		
Tanker Operations	1.3	0.7
Accidental Spills	0.2	0.4
Other Maritime Activities	0.6	0.4
Natural Seeps and Erosion	0.6	0.25
Atmospheric Fallout	0.6	0.3
	6.1	3.2

[1]Petroleum in the Marine Environment, National Academy of Sciences, 1975.
[2]Oil in the Sea: Inputs, Fates, and Effects, National Academy of Sciences, 1985.

Most surface and near-surface open ocean waters contain petroleum hydrocarbons in the range of about 1 to 10 parts per billion (ppb), according to the NAS 1985 study. In deeper open ocean waters, the concentrations are 1 ppb or less. (One ppb is equal to about one drop of oil in 100,000 quarts of water.) Coastal waters, particularly those near populated and industrialized areas where the presence of oil is most likely, show higher

[2] As suggested by I.W. Duedall (Florida Institute of Technology).

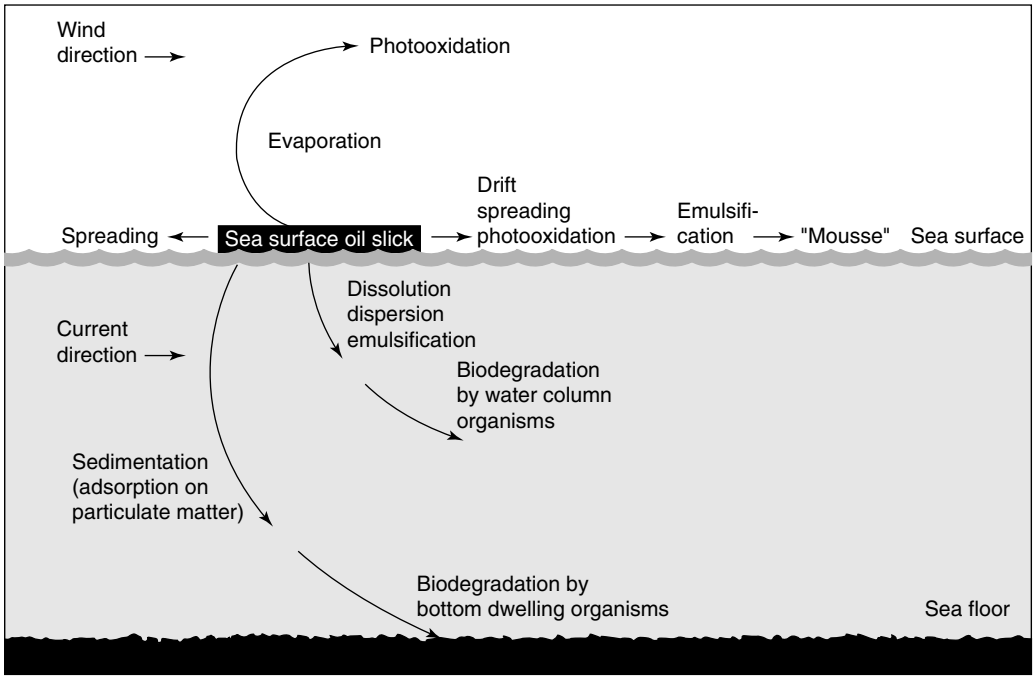

Fig. 4. Processes that act upon an oil slick.

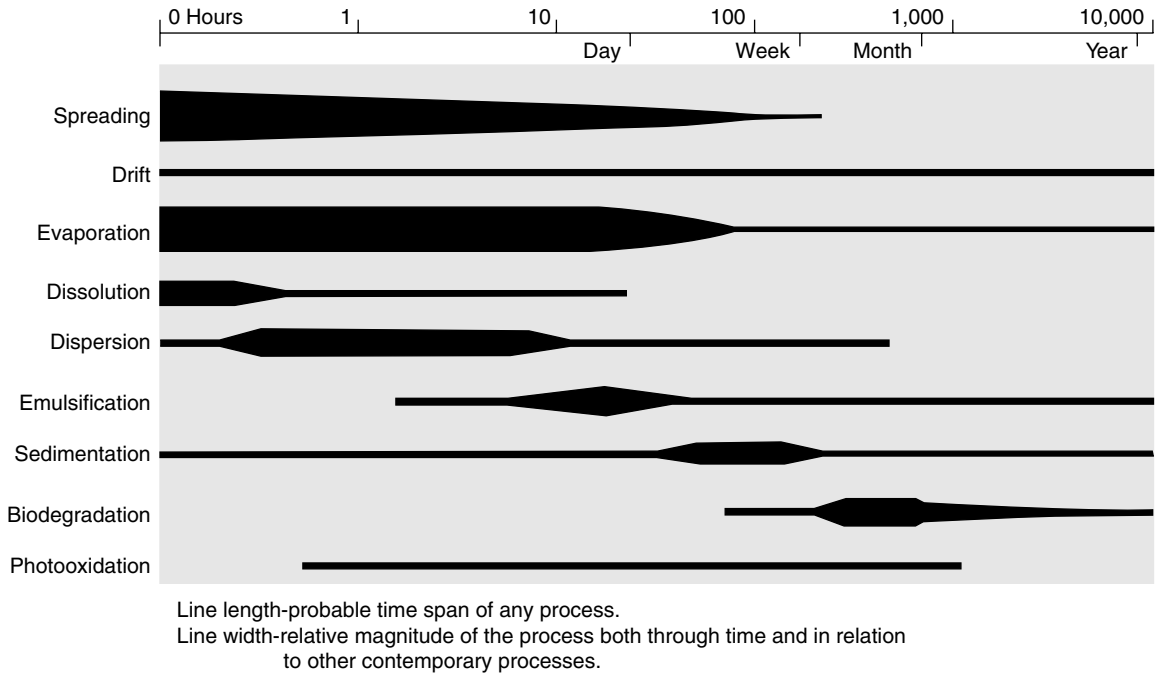

Fig. 5. Time span and relative magnitude of processes acting on spilled oil.

levels (up to 100 ppb). Laboratory experiments conducted to determine the toxicity of crude oils or petroleum products indicate that concentrations from 10 to 100 times greater than those of coastal waters are required before measurable effects on marine organisms can be detected.

The process whereby an oil slick from a sudden spill is ultimately disposed has been the subject of intense research. Figure 4 depicts the processes occurring in the water, the overlying atmosphere, and the underlying bottom sediments. Figure 5 relates the time following discharge of oil into the sea to the various processes of movement and degradation. These processes include:

Drift. The movement of the center of a mass of oil on the surface of the ocean, drift, is caused by the combined action of wind, surface currents, waves, and tides. With larger amounts of oil, such as occur with accidental spills, the oil drift is largely independent of spill volume, spreading, or weathering. Since the "thick" portion of the slick drifts faster than the "thin" portion, a heavy oil accumulation forms the leading edge of an advancing slick. The drift process is always active — from the moment oil is released into the sea until the oil disappears from the surface. It is difficult to predict precisely all the complex interactions of oceanographic and meteorological factors that influence drift of an individual oil slick. However, field and laboratory observations of oil slick drift are surprisingly consistent.

Evaporation. The primary weathering process involved in the natural removal of oil from the sea is evaporation. It is particularly dominant soon after oil is released. Evaporation involves the transfer of hydrocarbon components from the liquid oil phase to the vapor phase. Estimates from major spills as well as experimental data indicate that evaporation may be responsible for the loss of up to 50% of a surface oil slick's volume

during its life. Evaporation rates of oil at sea are determined by wind velocity, water and air temperatures, sea roughness, and oil composition. Some of the light, low-boiling hydrocarbons, such as benzene, toluene, and xylenes, which are rapidly lost through evaporation, are the most toxic. Thus, their removal decreases toxicity to marine life of the oil remaining on the surface.

Photooxidation. Much of the oil that evaporates is photo-oxidized in the atmosphere, but in the absence of good analytical data the contribution of this process cannot be estimated. It is reasonable to assume that some of the oil returns to the seas as atmospheric fallout.

Dissolution. This is another early process acting on spilled oil. Dissolution involves the transfer of oil compounds from a floating slick, or from dispersed oil droplets, into solution in the water phase. Lower-molecular-weight compounds tend to be the most soluble. It is unlikely, however, that dissolution significantly affects slick weathering as only a very small fraction of the oil dissolves. Evaporation proceeds much more rapidly than dissolution.

Dispersion. Oil also enters the water in forms larger than dissolved molecules. In natural dispersion, small droplets of oil (ranging in diameter from very small fractions of a millimeter to a few millimeters) are incorporated into the water in the form of a dilute oil-in-water suspension. Natural dispersion reaches a maximum rate in only a few hours (4 to 10) following a spill, but continues for some time. Oil dispersion is influenced by oil composition (e.g., wax and asphaltene content), density, viscosity, oil-water interfacial tension, and water turbulence. Crude oils and many petroleum products contain trace amounts of nitrogen, sulfur, and oxygen-bearing organic compounds, which can act as natural surfactants. These surfactants reduce the oil-water interfacial tension, allowing the oil to break up and to disperse into droplets more readily. Chemical dispersants may be applied to an oil slick to supplement the natural surfactants, thereby enhancing the dispersion process. The primary purpose for removing oil from the surface through dispersion is to enhance the degradation process. The increase in the surface area of dispersed oil droplets resulting from surfactant action accelerates the degradation of oil. Accelerating the dispersion process through the use of chemical dispersants also reduces the threat of floating oil stranding on a shoreline, where it can damage biota and property.

Emulsification. This is a water-in-oil process in which water is incorporated into the floating oil. Such emulsions, which may contain from 20 to 80% water, are often very viscous and referred to as "mousse." Mousse formation is highly dependent on oil composition. High levels of asphalt-type compounds, as well as waxes, appear to promote the formation of these emulsions. Ocean turbulence also accelerates mousse formation, although a fully developed, stable emulsion may be formed from some oils under relatively quiescent open-water conditions. Early treatment of spilled oil with chemical dispersants is an excellent way to prevent emulsification.

Sedimentation. Some organisms may ingest dispersed oil droplets in the water column and subsequently deposit them as fecal pellets. In some instances, this has been estimated to be a significant form of sedimentation.

Biodegradation. This is an important process for removing petroleum hydrocarbons from the marine environment. All surface waters, fresh or marine, contain natural populations of bacteria, yeast, and fungi capable of metabolizing and chemically degrading hydrocarbons through their normal life processes. These organisms are also primarily responsible for degrading most of the biologically produced hydrocarbons in the ocean. The rate and extent of biodegradation depend on the abundance and variety of existing microorganisms, their predators, available oxygen and nutrients, temperature, and oil composition. Hydrocarbons, dissolved or dispersed in water, are the most easily degraded. Degradation of hydrocarbons contained in bottom sediments also occurs if oxygen is present. Emulsified oil (mousse) is slow to degrade because water is trapped within the emulsion and the nutrients and oxygen essential to biodegradation are kept out.

Invention of Oil-Eating Bacterium. It is interesting to note that the concept of genetically altering bacteria to transform crude oil into cattle feed was proposed by A.M. Chakrabarty (General Electric Co.) in the late 1960s. A patent was not granted until 1980 after considerable litigation. The concept is considered by many as the cornerstone of the biotech industry. Chakrabarty as of the 1990s continues in this field. Although applications in other areas of the petroleum industry may find applications for such bacteria, the primary interest in recent years has been in connection with oil tanker spill cleanups.

After the Alaskan oil spill of March 1989, approximately 70 miles (113 km) of beaches around Prince William Sound were sprayed with a fertilizer (*Inipol*) that had been invented by a French petroleum company (*Elf Aquataine*). The effort was made to stimulate the growth of naturally occurring bacteria (i.e., microorganisms that eat petroleum). This was the first large-scale test of bacteria for cleaning up an oil spill. Improvement was noted within a couple of weeks after the spraying. Research continues with the material to determine its effectiveness on shoreline rocks and pebbles. Early findings indicated that oil caught beneath the surface of rocks was consumed in 6 to 7 weeks. Researcher C. Oppenheimer (University of Texas) also developed microbial strains for producing fatty acids from oil, the product of which is more soluble in water. These compounds serve as food for plankton and other organisms.

Oil Tanker Spills

Usually the most publicized and one of the most dramatic examples of ocean water (and adjacent shoreline) pollution involves oil tanker or barge accidents. Most often, the saline waters of the oceans and seas are polluted, although there are instances where such accidents have occurred in fresh and brackish waters.

Oil spills present many different variations in the manner in which they develop and react to cleanup efforts. The Alaskan spill that occurred on March 24, 1989, in Prince William Sound was the most extensively researched to date. The cost of cleaning up the spill also exceeded all other tanker spill expenses to date. A study reported by the U.S. Forest Service estimates the final fate of the 10 million gallons as follows: evaporated, 35%; recovered, 17%; burned, 8%; biodegraded, 5%; and dispersed, 5%. The total in the form of oil slicks on the Sound amounted to about 10% of the original spill and that on the shoreline about 18%. For many weeks after the spill, a fleet of specially equipped vessels mopped up about 120,000 gallons of crude oil per day. Other tanker spills have carried crude oil of somewhat different composition. The state of the sea, temperature, winds, and presence or absence of sunshine are among other variables that make each spill unique.

Tanker Design. One ship designer has observed that modern tankers are uniquely fragile and unwieldy vessels. The goal of tanker design is "to get as much cargo as you can into as little steel as possible and still have economical propulsion." Thus, the larger the ship, the easier to meet these specifications. Ultra-large crude carriers (ULCCs) required a distance of 3 miles (4.8 km) and about 20 minutes to stop from a top speed of 15 to 16 knots. Oil tankers have steadily increased in capacity and length over the last few decades. See Fig. 6.

Because of several major tanker incidents over the last few years and highlighted by the Alaskan spill, much design thought has gone into the "double-hull" concept. Indeed, this is not a new concept because two "skins" are used on the nearly 60,000 merchant vessels afloat — with the important *exception* of oil tankers. Double hulls have been standard on liquefied natural gas (LNG) ships for many years, and the design has been credited with preventing disasters at sea. The double-hull design enabled one LNG ship to sail many miles at its highest speed to the nearest port even though the outer hull had been torn open under several of the cargo tanks. None of the highly volatile cargo escaped.

The oil industry has objected to two hulls for the following reasons:

1. If oil leaked from the inner to the outer shell, the space in between could generate a vapor and thus be an explosion hazard.
2. When the outer hull was breached by an accident, water would fill the void, causing the ship to lose buoyancy and possibly go aground.

Even with these objections, there are some 530 oil tankers with double hulls, and these have been accident-free thus far.

Other improvements in tanker design have included more precise navigation systems that are customized to the vessel and the coarse of travel that it usually follows. In a single video readout are shown the ship's location and course with respect to shoreline, bottom contours, buoys, markers, and other ships. With another system, which includes radar reflectors located along the shoreline, the ship location can be determined within less than about 6 feet (1.8 meters). Another concept embraces use

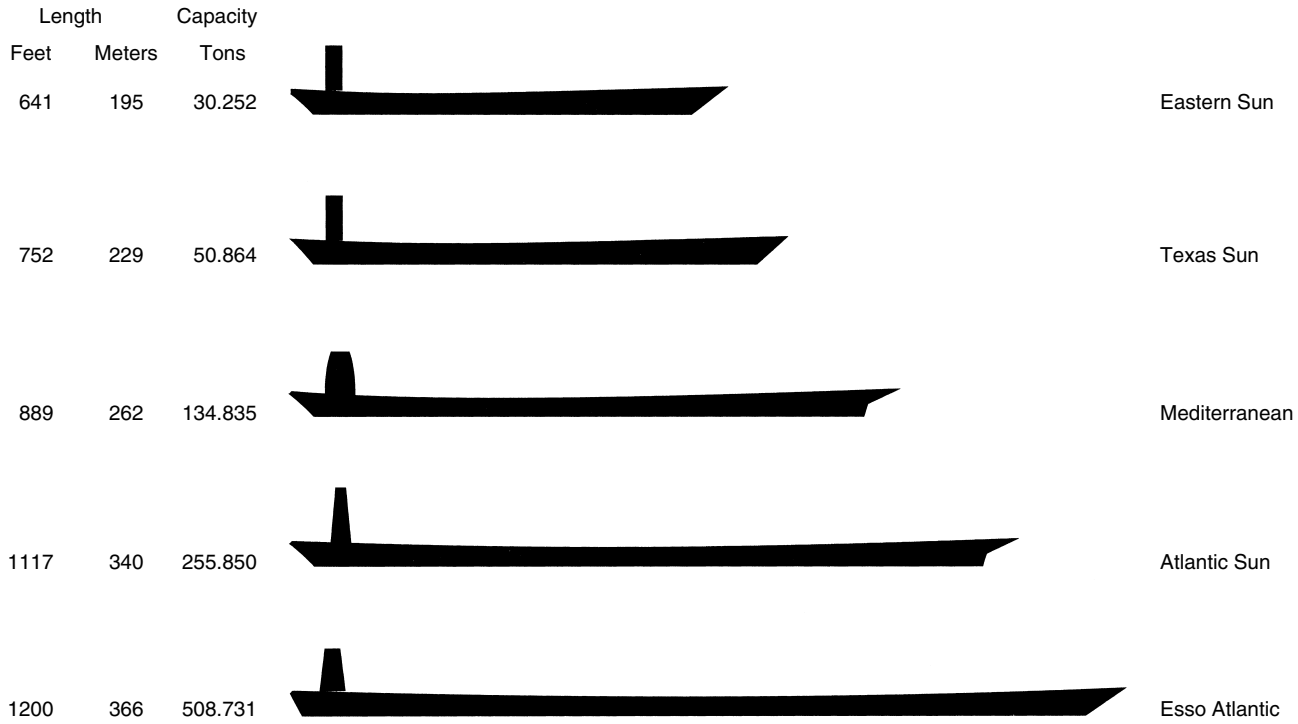

Fig. 6. Trends in oil tanker design characteristics. (*After A. Dane*.)

of a funnel that can be lowered from the ship immediately when a spill occurs and sucks the spilled oil back into the ship. A design of this kind has been under test in the Gulf of Mexico.

Radioactive Waste Dumping. Numerous proposed solutions for dumping radioactive wastes, including ocean burial, are described in the article on **Nuclear Power**.

WATER RESOURCES. As pointed out by various authorities, major problems pertaining to water, in addition to pollution, include: (1) the heavy consumption, which began some years ago to limit the growth of various cities and of agriculture, particularly in the southwestern United States; (2) evaporation losses from reservoirs and storage ponds, particularly important in the arid western and west central sections of the United States, the control of which may be found to be more economic than that of developing new water sources; (3) lowering water Tables, again of major concern to the southwest and Pacific coastal regions of the United States, but also becoming a major factor near larger cities, and to some middle-Atlantic areas of the United States, a situation which is exerting considerable influence on the choice of new irrigation areas; (4) long-distance water transmission systems, which in the future may not be confined to the western United States; (5) waste water return to the oceans, which can become the largest and least expensive potential secondary water source and a very attractive source for many industrial uses; (6) salt water encroachment, which already is destroying some water sources and land; (7) watershed trash vegetation, the eradication of which can increase water yield, particularly in the southwestern United States; and (8) storage of seasonal and flood flows, which has been practiced for many years in most areas that are away from good lake or groundwater supplies, but which will require extension as the water problem becomes more severe in the less-arid areas. See also **Dam**.

The water supply problems of the United States image those of many other areas of the world. As is evident from Fig. 1, the eastern one-third of the United States, excepting a few areas and several of the major cities, does not generally run a seasonal water deficiency. Somewhat over one-third of the western United States, however, is characterized by no available surplus, and other areas by summer deficiency and winter surpluses.

Water resources must be evaluated in the long term because unusually wet or dry winters (such as 1980–1981), while of near-crisis proportions, do not represent the average of a decade or more. What is important is to watch trends that appear to be consistent.

Widespread flooding in the midwestern United States during the summer of 1993 is regarded by some experts as a 1 in 100 year experience. Every century experiences a few weather phenomena that statistically contribute to the minimums and maximums of data, but do not necessarily predict any permanent changes in the weather picture for a given region. Final analyses of data from the 1993 flooding will not be completed for another year or two.

The environmental problem of finding additional sources of clean water have some parallels with the problem of finding new ways for disposing of wastes. These are indeed limited. Again, the subject of *waste reduction* enters into the picture. Whereas, fundamentally, pollution equates with cutting back on the production of wastes, water shortages equate markedly with reducing the waste of water. This, too, presents a variety of sociological preferences and concerns. Persons who live in communities where water shortages approach near-crisis proportions are fully aware of how inconvenient it is to cut back on water consumption. Over the years, a few imaginative suggestions have been made. Weather alteration in an effort to produce rain essentially has been abandoned by technologists. Dam building, in addition to creating hydroelectric power, also contributes to smoothing out the water supply for many regions. In recent years, however, a substantial citizen's movement against creating dams has arisen.

Although nearing the fantasy level, icebergs have not been ruled out technically as "portable and potable" sources of excellent water.

While desalination now serves a number of the arid regions of the world (see also **Desalination**) and the costs of desalination have been reduced because of improved processes, the economics of processing discourage the use of desalination in the less arid regions of the world. However, if the world's population continues to expand geometrically, the price per gallon or liter of drinking water, for example, may rise beyond belief.

Water from Icebergs. The concept of obtaining fresh water from icebergs dates back many years. One of the earlier proponents was Isaacs (Scripps Institute of Oceanography) who described the concept in the 1940s. The concept has been characterized by a cycling of interest over the years, but with little follow-through among world scientists and planners. In 1977, the first conference on iceberg utilization of major proportions was held at Iowa State University, with over 200 scientists, consultants, and representatives of private firms from 18 nations present to consider the technical, economic, environmental, and legal problems that may be involved in transporting and exploiting icebergs. In discussions over the last several years, most attention has been given to icebergs from the Antarctic rather than the Arctic region, principally those icebergs that break away from the Ross Ice Shelf.

Melted water from an iceberg is extremely pure, with only traces of rock fragments and with almost complete absence of trapped organic matter. Contamination has been estimated at one part per billion and thus far superior to other fresh water unless it is distilled. The Iowa State conference was financed in part by the National Science Foundation and Saudi Arabia. In contemplating the possible use of icebergs as a future source of fresh water, it is interesting to note that although there are about 1.4 billion cubic kilometers of water on Earth, only about 9 million cubic kilometers (six-tenths of one per cent) of the total is both liquid and fresh. The useful

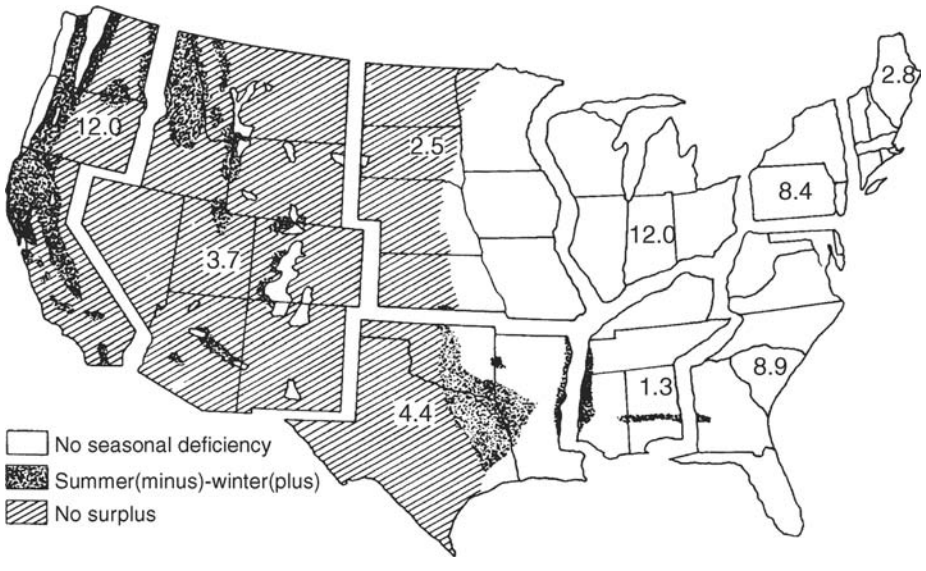

Fig. 1. Water supply versus population increases. Figures indicate expected increases (millions of people) by the year 2000. (*U.S. Department of the Interior*).

supply tends to be about 10–20% of the total precipitation per year, or about 10,000–20,000 cubic kilometers.

The ice sheet in the Antarctic accumulates an input of precipitation equivalent to about 2000 cubic kilometers of water per year. About half of this total forms into tabular (flat) icebergs, each equivalent to about 200 cubic kilometers of water. The slabs are from 200 to 250 meters thick and up to about 0.5 kilometer wide. Greenland icebergs, in contrast, are more irregular in shape and size. Antarctic icebergs would have to be transported about 4,000 miles (6,436 kilometers) to the southwestern coast of Australia; about 9,500 miles (15,286 kilometers) to southern California; and about 12,000 miles (19,308 kilometers) to the Middle East. Several studies have been made as regards towing icebergs and the consensus is that the technology for this already exists. Towing of some icebergs already has been done in connection with oil drilling activities, where tugs are used to deflect Greenland-originated icebergs from the path of drillships and platforms. Also, many attempts have been made to destroy (break up) icebergs through the use of explosives to prevent the icebergs from drifting into major sea lanes. These experiments have largely been unsuccessful because one kilogram of explosive will break up only about 4 cubic meters of ice. Even though ice possesses a low strength and density, it reacts to blasting much like ordinary rock.

During the 1990s, the use of icebergs as a source of fresh water remained a topic of considerable conjecture. Topics discussed at the Iowa State Conference included: (1) use of earth resources satellites to find the most suitable icebergs for this purpose; (2) study of various transportation modes, such as tugs for pulling, semi-submersibles and submarines for pushing, and propellers mounted on icebergs to make them self-transportable; (3) ways to minimize melting during transport, e.g., stretching plastic sheets over the iceberg or spraying its surface with urethane foam; (4) investigation of legal problems relating to ownership of Antarctic ice; (5) the numerous environmental effects which such actions might provoke; (6) possible use of icebergs as energy sources, through harnessing of thermal and salinity gradients. See also **Ocean Resources (Energy)**. If the concept takes hold, it would seem that the first tests would be conducted in the Southern Hemisphere.

For further details, see "The Iceberg Cometh," by W.F. Weeks and Malcolm Mellor, *Technol. Rev* . (*MIT*), pp. 66–75 (August/September, 1979), and *Science*, **198**, 274–276 (1977).

WATER SCORPION *(Insecta, Hemiptera)*. Moderately large water bugs of oval or slender and elongate form, with a long breathing tube at the end of the body. The front legs are adapted for catching small prey.

WATERSHED. The area that supplies water to a stream and its tributaries by direct runoff and by ground water runoff is the drainage area or watershed for the stream (Fig. 1). The yield of the watershed is the direct runoff plus the ground water runoff for a given period of time. That part of yield used for industrial or domestic purposes is called the draft. When the draft approaches the yield, the latter may be adjusted by the construction of an impounding reservoir.

Water Quality

All factors and activities within a watershed directly or indirectly affect the water quality of river systems. Although local climate, geology, soil type, and vegetation play an important role in determining of the water quality conditions within a watershed, one of the most important factors affecting water quality is land use. Runoff from different land use types, such as agricultural, industrial, urban, or even barren or deforested land may contribute a number of pollutants to a waterbody. Some of these pollutants include excessively applied fertilizers or pesticides, animal

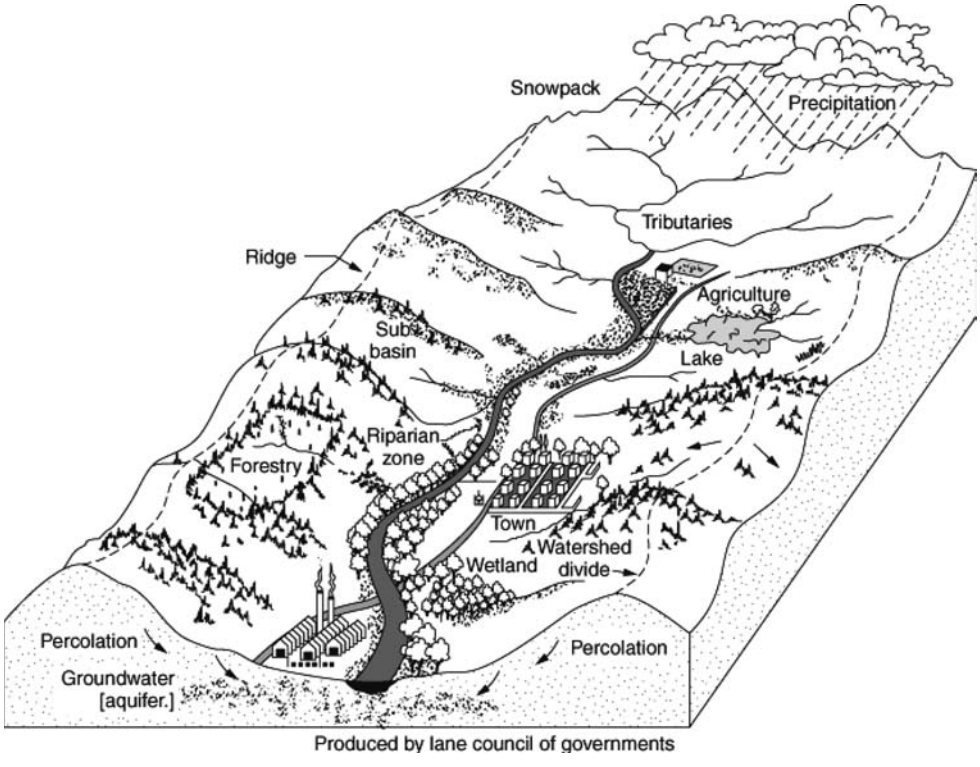

Fig. 1. Sample drawing of a watershed. (*Lane Council of Governments, Eugene, Oregon*).

waste, toxic chemicals, sewage from broken sewer lines or septic tanks, oil, and sediment.

Best management practices on all types of land use help reduce the amount of pollution entering waterways. Preserving, restoring, or creating wetlands, which "filter out" many pollutants is another way to help ensure clean water and a clean environment within a watershed.

Flood Potential

Flooding is also influenced by factors such as the percentage of impervious cover within the watershed boundary. In addition, concrete drainage control ditches and canals have been built over the years to help control flooding. When a channel is lined with concrete, natural aquatic habitats are disturbed or destroyed, and pollutants can more easily enter a waterway due to the lack of vegetation to control and filter runoff.

Recently, engineers have used more "environmentally friendly" types of flood control. Some these include constructed wetlands and detention ponds. In these cases, habitat is not destroyed, but created, and pollutants are kept from entering waterways.

Although a person or entity may not be located near a waterbody, the results of various actions eventually flow downhill or through stormwater infrastructure to creeks and streams.

WATERSPOUT. A funnel-shaped weather disturbance which exists over a body of water, a waterspout is often referred to as a tornado on water (Fig. 1). This is accurate for one type of waterspout, the aptly named tornadic waterspout. It is somewhat inaccurate with regard to the much more common type of waterspout, the fair weather waterspout.

Fig. 1. Picture of waterspout taken in 1969 from an aircraft off the Florida Keys, a location arguably the hottest spot for waterspouts in the world with hundreds forming each year. (*Dr. Joseph Golden, NOAA*).

Tornadic waterspouts are tornadoes over water. These are stronger, larger, and faster than fair weather waterspouts. However, they do tend to form over land as true tornadoes before moving over water. Fair weather waterspouts form differently from tornadoes. Rather than developing downward, they begin at the surface, building up toward the sky.

For waterspouts to form, a series of things must occur. First, a small portion of air over the surface of water must become heated. As this warm air begins to rise, the cool air around it starts to form a small vortex of rotating air. This vortex of swirling air is carried upward by rising water vapor; waterspouts usually form over warm water because there is more water vapor present. Upon rising to an overhead cloud mass, the vortex forms a funnel cloud. At this point, a fair weather waterspout begins its five-stage life cycle.

The first stage of fair weather waterspout development involves the formation of a light spot on the surface of the water, which is surrounded by a darker area. The second stage is the formation of a spiral pattern on the surface around the dark spot. This spiral is colored lightly in some places and darkly in others. The third stage is when the funnel winds begin to pick up speed. The waterspout becomes more visible as sea spray is picked up from below.

This water swirls around the dark spot, known as a cascade. Like a hurricane, it appears to center around an eye. The fourth, or mature, stage is when the funnel reaches all the way from the cloud to the ocean (Fig. 1). This is the most powerful stage of the waterspout. Winds can be 60 mph or more. You can usually see through the funnel — it is really a thin cloud of tiny water droplets. The funnel cloud can be hundreds or even thousands of feet high. During this stage, small waves are being kicked up and the spout leaves a bubbly wake behind as it moves across the ocean. These tiny bubbles could be carbon dioxide and other gases that are dissolved in the water that are caused to effervesce by the low air pressure in the spout's center, like a bottle of soda that's just opened. Almost all the destruction caused by a waterspout occurs during this stage. The fifth and final stage is the decay of the waterspout. Often, rain begins to fall from the top of the waterspout. As these vortices require warm air to sustain themselves, the resulting downdraft of cool air speeds the process of dissipation of the waterspout. The entire life span of a fair weather waterspout is not often longer than 15 minutes.

Fair weather waterspouts can cause some damage, but it is always over water; they are rarely a threat upon reaching land. Tornadic waterspouts, however, are much more destructive. Their winds can exceed 150 miles per hour, they can last a half-hour or longer, and they are much more likely to appear during severe weather disturbances, such as tropical storms, tropical depressions, and hurricanes. These waterspouts can sink smaller ships and can cause extensive damage to sails and masts on larger ships. However, most waterspouts merely result in large amounts of rain.

See also **Fronts and Storms**; and **Tornado**.

Location of Waterspouts

The Florida Keys "are the greatest, natural vortex lab in the world," says Joseph Golden, a senior National Oceanic and Atmospheric Administration scientist. "Waterspouts probably occur more frequently in the Florida Keys than anywhere in the world." Waterspouts hit the Florida Keys because the weather and geography supply two necessary ingredients.

First, the islands and the shallow water along them help heat the air. During the summer, waterspout season, the air is extremely humid with temperatures in the mid-80s into the low 90s. The heat causes the air to rise. As it rises, the air's humidity condenses into the tiny water droplets that make up clouds. As water vapor condenses, it releases more heat that makes the air rise even faster. Rising air currents are needed for waterspout formation.

The second ingredient in the Keys seems to be the regular east or northeast "trade winds" that blow right down the islands. These winds help line up the clouds. Lines of clouds encourage waterspouts. Exactly how is one of the questions researchers are trying to answer. Clouds that spawn waterspouts in the Keys are generally from around to 18,000 to 22,000 feet high. Golden says, waterspouts are likely to form when the clouds are growing upwards.

In the Keys, waterspouts are most likely to form between 4 and 7 p.m. with a secondary maximum from 11 a.m. to 1 p.m. A few waterspouts form around sunrise.

Waters around the Keys, especially from Marathon past Key West on westward to the Dry Tortugas, probably see 400 or 500 waterspouts a year. The US National Weather Service will often issue special marine warnings when waterspouts are likely or have been sighted over coastal waters, or tornado warnings when waterspouts can move onshore. Since they are so common, most go unreported unless they cause damage.

After the Florida Keys, the next most active U.S. waterspout area is the southeast Florida Coast from around Stuart south to Homestead. Tampa Bay has the greatest number of damaging waterspouts, probably because the shores of the Bay are so built up.

Places around the Gulf of Mexico along with the Atlantic Coast northward to Chesapeake Bay are also likely to see waterspouts. Waterspouts have been reported on the West Coast from Tatoosh Island, Wash., south

to San Diego, but they tend to be weak and short lived. Waterspouts also skip across the Great Lakes and Utah's Great Salt Lake from time to time.

WATER STRIDER *(Insecta, Hemiptera)*. A moderately large bug whose two posterior pairs of legs are modified for locomotion on the surface film of water. The claws are set back from the tip of the leg and the hairs of the dense covering are turned under so that the tip of the leg rests on their curved surfaces. These bugs are common on streams and ponds. The members of one genus, *Halobates*, are the only truly marine insects. They are found in tropical waters, often far from land, and their eggs have been found attached to floating feathers.

WATER TEMPERATURE. See **Atmosphere-Ocean Interface**.

WATER TREATMENT. See **Ion-Exchange Resins**; and **Water**.

WATER VAPOR. Water substance in vapor form; one of the most important of all constituents of the atmosphere. Its amount varies widely in space and time due to the great variety of both "sources" of evaporation and "sinks" of condensation that provide active motivation to the hydrologic cycle. Approximately half of all of the atmospheric water vapor is found below 2-km altitude, and only a minute fraction of the total occurs above the tropopause. Water vapor is important not only as the raw material for cloud and rain and snow, but also as a vehicle for the transport of energy (latent heat) and as a regulator of planetary temperatures through absorption and emission of radiation, most significantly in the thermal infrared (the greenhouse effect). The amount of water vapor present in a given air sample may be measured in a number of different ways, involving such concepts as absolute humidity, mixing ratio, dewpoint, relative humidity, specific humidity, and vapor pressure.

WATSON, JAMES DEWEY (1928–). James Watson is an American scientist who, with Francis Crick, discovered the double helical structure of DNA and went on to establish the Human Genome Project in the USA.

James Watson was born on 6 April 1928 in Chicago, Illinois. His house was filled by books, and his father inspired him with a love of both learning and bird watching. Although a radio quiz kid contestant, Watson claims not to have been a childhood genius. His early entry to the University of Chicago (at age 15) was due to the University's enlightened policy and the encouragement of his mother. Watson studied zoology at Chicago and was awarded a BS in 1947. During his undergraduate work, he read and was greatly impressed by Erwin Schrödinger's *What Is Life*? with its discussion of the physical nature of the gene. Nevertheless, after graduation, he went to Indiana University still interested in ornithology. Hermann Muller was in the Department of Zoology and Watson took both his course on genetics and that of Salvador Luria on viruses. He realized that Muller's *Drosophila* was unlikely to yield new insights and that the cutting edge of genetics was in the analysis of microorganisms. He began his thesis research on X-ray inactivation of bacteriophage with Luria. See also **Muller, Hermann Joseph (1890–1967)**.

Luria, Max Delbrück and Alfred Hershey were using bacteriophage to study genetics and, although all three were at other institutions, phage research became inextricably linked with Cold Spring Harbor where Delbrück and Luria had established the Phage Course in 1945. It was this course that trained many of the future leaders of molecular genetics. In 1948, Luria brought his two graduate students — Watson and Renato Dulbecco — to Cold Spring Harbor for a summer of phage experiments. See also **Bacteriophage**; **Dulbecco, Renato (1914–Present)**; and **Hershey, Alfred Day (1908–1997)**.

Watson completed his PhD in 1950 and, although his thesis research had not led to new insights into the nature of the gene, he was determined to pursue research on its chemical basis. Inspired by his contacts with European scientists like Luria and Delbrück, Watson decided to carry out research in Europe and Luria arranged for him to take up a National Research Fellowship in Herman Kalckar's laboratory in Copenhagen. However, he discovered that his and Kalckar's interests were not the same, and he was fortunate to find that Kalckar's friend Ole Maaloe was interested in phage replication. Watson worked on phage but had to move when Maaloe went to the California Institute of Technology (Caltech). In the spring of 1951, Watson had met Maurice Wilkins, from Kings College London, at a meeting in Naples. Wilkins had shown him an X-ray diffraction picture of DNA that suggested that DNA must have a regular structure that might be determined. Watson was convinced that knowing the structure of DNA was the key to understanding the gene and that he had to go to the European centre for X-ray crystallography–the Cavendish Laboratory in Cambridge, England. See also **Wilkins, Maurice Hugh Frederick (1916–2004)**.

He arrived there in September 1951, and began a collaboration with Francis Crick. Using information from Rosalind Franklin, together with other data on the chemical composition and properties of DNA and model building, he and Crick eventually arrived at the double helical structure of DNA. Published in *Nature* on 25 April 1953, it established Watson as an intellectual leader in a new discipline of molecular genetics. DNA did not completely occupy Watson's energies and he also carried out an X-ray study of the structure of *Tobacco mosaic virus*. See also **Crick, Francis Harry Compton (1916–2004)**.

Between 1953 and 1955, Watson was Senior Research Fellow at Caltech. Here he began studies aimed at understanding the role of ribonucleic acid, again by determining first its structure. Unfortunately, the X-ray diffraction patterns of RNA were not distinct and Watson and Alex Rich had to admit defeat. Watson did not find Caltech a congenial environment and spent 1955 back at the Cavendish Laboratory. During that year, he and Francis Crick wrote an important paper on the structure of small viruses. In 1956, Watson became an assistant professor of biology at Harvard University, becoming a professor in 1961. He was noted at this time for his strenuous efforts to introduce molecular studies into the Harvard department and curriculum. See also **Genetics and Gene Science (Classical)**.

Watson continued his research on RNA but used molecular biology techniques rather than X-ray crystallography to try to understand its role. With Alfred Tissieres, he published an important paper on the ribosome and later one of the two papers that reported the discovery of messenger RNA. Watson's insistence in not putting his name on the papers of his graduate students gives a false impression of the extent of his research interests at this time. His students included R. W. Risebrough, J. Steitz, N. Hopkins, R. Burgess and M. Capecchi. As a consequence of teaching at Harvard, Watson wrote a famous textbook, *The Molecular Biology of the Gene*, which set a new style and standard in biology textbooks. (Subsequently, he was a coauthor of two other textbooks, *The Molecular Biology of the Cell* and *Recombinant DNA: A Short Course*.) It was while at Harvard that Watson wrote an account of the discovery of the structure of DNA–*The Double Helix*. This controversial account (Harvard University's President Nathan Pusey barred the Harvard Press from publishing it) instantly became an international bestseller, was translated into over 20 languages and has remained in print ever since it was published in 1968.

Watson had been the Harvard University representative on the Board of Trustees of Cold Spring Harbor Laboratory on Long Island, New York, and in 1968, he became director of the Laboratory, while retaining his Harvard position. In 1972, he moved to Cold Spring Harbor to work full-time as director. Watson steered the Laboratory into the field of tumor virology and other research on cancer, as well as plant molecular biology, cell biology, and neuroscience. He expanded the program of meetings and courses held at the Laboratory and the activities of Cold Spring Harbor Laboratory Press.

In 1974, Watson was one of the signatories of the "Berg" letter, written to the journal *Science*, warning of possible dangers of recombinant DNA technology. This letter led to the Asilomar Conference where scientists decided that voluntary restrictions on certain types of experiment were appropriate. Watson argued strongly against such restrictions fearing that the government would impose regulations, as indeed it did. The restrictions were later relaxed and there is no evidence that recombinant DNA techniques have caused any hazard to scientists or the public. He and John Tooze published a history of the recombinant DNA controversy, *The DNA Story*.

Between 1988 and 1992, Watson was responsible for directing the NIH Human Genome Project, while maintaining his activities as director of Cold Spring Harbor. It was through his efforts that the scientific community came to embrace the Project and that it received the necessary funding from Congress. Watson, worried about the societal applications of human molecular genetics, established the Ethical, Legal and Social Issues program (ELSI), allocating it about 5% of the Project's budget. Watson

resigned in 1992 after a disagreement with Dr Bernadine Healey, director of the NIH, over patenting of DNA sequences. See also **Human Genome Project (The)**.

Watson returned full-time to Cold Spring Harbor Laboratory, where he became its first President in 1994. He continues to promote the Human Genome Project and its applications; his fear being that overemphasis on possible abuses will delay the beneficial use of genetic knowledge. In 2000, he published a collection of his essays dealing with this and other controversial topics in genetics.

Watson has received many honors, including the Eli Lilly Award in Biochemistry (1960), the Albert Lasker Prize (1960), the Nobel Prize for Physiology or Medicine (1962), the John J. Carty Gold Medal of the National Academy of Sciences (1971), the Presidential Medal of Freedom (1977), the Copley Medal of the British Royal Society (1993), the Charles A. Dana Distinguished Achievement Award in Health (1994), the National Medal of Science (1997) and the Liberty Medal (2000). He was elected a member of the National Academy of Sciences (1962) and the Academy of Sciences, Russia (1989), and a Foreign Member of the Royal Society (1981). He is an Honorary Fellow of Clare College, Cambridge University (1968).

WATTLE TREE. See **Acacia Trees**

WAVE ACTION. See **Ocean**.

WAVE ANALYZER. See **Spectrum Analysis**.

WAVE BREAKING. A complex phenomenon in which the surface of the wave folds or rolls over and intersects itself. In the process it may mix (entrain) air into the water and generate turbulence. The causes of wave breaking are various, for example, through the wave steepening as it approaches a beach, through an interaction with other waves in deep water, or through the input of energy from the wind causing the wave to steepen and become unstable.

WAVE CYCLONE. See **Fronts and Storms**.

WAVE ENERGY. See **Ocean Resources (Energy)**; and **Tidal Energy**.

WAVE EQUATION. A partial differential equation of classical mathematical physics. In vector form it is

$$c^2\nabla^2\phi = \partial^2\phi/\partial t^2$$

where ϕ is a quantity characterizing the propagated disturbance, c is the velocity of the wave, and t is the time. It applies also in the electromagnetic theory of light and in the theories of electric waves, elastic vibrations, and sound. In solving it by the method of separation of variables, assume $\phi(x, y, z, t) = F(x, y, z)T(t)$. The result is $T(t) = e^{\pm ikct}$ and $\nabla^2 F + k^2 F = 0$, where k is an arbitrary constant. In most cases, some other curvilinear coordinate system (u, v, w) is more suitable than (x, y, z). If the partial differential equation again separates there will be three ordinary differential equations in $f_1(u)$, $f_2(v)$, $f_3(w)$ and the solution of the wave equation becomes $\phi = f_1(u)f_2(v)f_3(w)T(t)$. In cylindrical coordinates, Bessel functions occur in this solution; in spherical polar coordinates, Bessel and associated Legendre functions.

In quantum mechanics, the Schrödinger wave equation for a single particle of mass m and potential energy $V(\mathbf{r}, t)$ is

$$\frac{h^2}{2m}\nabla^2 u = Vu - ih\frac{\partial u}{\partial t}$$

where $h = h/2\pi$ and h is Planck's constant. See also **Schrödinger Equation**.

WAVE (Estuary). See **Estuary**; and **Tidal Energy**.

WAVE (Gravitational). See **Gravitation**.

WAVEGUIDE. A structure with the capability of confining and supporting the energy of an electromagnetic wave to a specific relatively narrow and controllable path. Waveguides are altered to suit the needs of the medium communicated, such as microwave guides, coaxial cables, and optical fiber guides.

WAVE INTERFERENCE. The phenomenon that results when waves of the same or nearly the same frequency are superposed; characterized by a spatial or temporal distribution of amplitude of some specified characteristic differing from that of the individual superposed waves. Also called *interference*.

WAVELENGTH. Of a periodic wave in an isotropic medium, the perpendicular distance between two surfaces of equal phase in which the displacements have a difference in phase of one complete period. Otherwise phrased, the wavelength is the "space period" of a wave, i.e., the least translation distance that leaves the wave invariant.

In a harmonic wave, the wavelength is the distance between any two points at which the phase at the same instant differs by 2π, specifically if the wave is a plane harmonic wave in the x-direction with angular frequency ω, so that the disturbance has the form

$$\sin(\omega t - kx)$$

the wavelength is

$$\lambda = 2\pi/k = 2\pi V/\omega$$

where V is the wave velocity.

WAVELET COMPRESSION. See **Data Compression**.

WAVELLITE. The mineral wavellite is a hydrous phosphate of aluminum, formula $Al_3(PO_4)_2(OH)_3 \cdot 5H_2O$. It is orthorhombic but crystals are of rare occurrence as it is ordinarily found in crusts or radial aggregates, sometimes fibrous. Its hardness is 3.25–4; specific gravity, 2.36; may be of various colors, gray, blue, green, yellow, black, or colorless. It has a vitreous luster, and is translucent. This mineral is of secondary origin, probably formed by waters bearing phosphoric acid which have acted on aluminum minerals. Wavellite is found in Saxony, Bavaria, Devonshire, from where it was originally described; and in the United States in Chester and Cumberland Counties, Pennsylvania; and Montgomery and Garland Counties, Arkansas. It was named after its discoverer, Dr. Wavel.

WAVE (Meteorology). 1. Generally, any pattern with some roughly identifiable periodicity in time and/or space. This applies, in meteorology, to atmospheric waves in the horizontal flow pattern (e.g., Rossby wave, long wave, short wave, cyclone wave, barotropic disturbance). See also **Barotropic Disturbance**; **Cyclone Wave**; **Inertia Wave**; **Long Wave**; and **Short Wave**.

2. At the surface of the ocean, a disturbance generated by wind action with dynamics governed by the influence of gravity and/or surface tension. See also **Atmosphere-Ocean Interface**; **Ocean**; and **Ocean Waves**.

3. Popularly used as a synonym for "surge" or "influx," as in tidal wave (storm surge), heat wave, cold wave. See also **Cold Wave**; **Heat Wave**; **Storm Surge**; and **Tsunami**.

WAVE MOTION (Sound). See **Acoustics**.

WAVE NORMAL. The curves of a family normal to the equiphase surface of a wave are called wave normals. The equiphase surfaces are those satisfying $\Phi(x, y, z) = \text{constant}$ for the wave $A(x, y, z)^{ej[\omega t - \Phi(x,y,z)]}$. Wave normal may also be defined as a unit vector normal to an equiphase surface, with its positive direction taken on the same side of the surface as the direction of propagation. In isotropic media, the wave normal is in the direction of propagation.

WAVE NUMBER. The reciprocal of the wavelength in a harmonic wave. Some authors use $2\pi/\lambda$ instead of $1/\lambda$ in this sense. In this case, it is often symbolized by k and called the wave parameter.

WAVE (Ocean). See **Atmosphere-Ocean Interface**; and **Ocean**.

WAVE PERIOD. In a harmonic wave, the time between attainment of successive maximum disturbances at the same place. The reciprocal of the frequency.

WAVE PHASE. The argument in the wave function. Thus in the general arbitrary progressive wave function $f(x - Vt)$ the phase is $x - Vt$. For a harmonic plane wave in which the disturbance has the form $\sin(\omega - kx)$, the phase is $\omega t - kx$. Here ω is the angular frequency $= 2\pi f$, where f is the actual frequency, $k = 2\pi/\lambda$, where λ is the wavelength.

WAVE POLE (or Wave Staff). A device for measuring sea-surface waves. It consists of a weighted pole below which a disk is suspended at a depth sufficiently deep for the wave motion associated with deep-water waves to be negligible. The pole will then remain nearly as if anchored to the bottom, and wave height and period can be ascertained by observing or recording the length of the pole that extends above the surface.

WAVE PROPAGATION (Huygens' Principle). A well-known method of analysis applied to problems of wave propagation. It recognizes that each point of an advancing wave front is in fact the center of a fresh disturbance, and the source of a new train of waves; and that the advancing wave as a whole may be regarded as the resultant of the secondary waves arising from points in the medium already traversed. This view of wave propagation facilitates the study of various phenomena, such as diffraction. For example, if two rooms are connected by an open doorway, and sounds are produced in a remote corner of one room, a person in any part of the other will hear the sounds as proceeding from the doorway, which is indeed the case. So far as the second room is concerned, the vibrating air in the doorway is the source, and from it sound waves enlarge in all directions through the second room. The same is true of light reaching a slit or passing the edge of an obstacle, though this is not quite so easily observed because of the short wavelength. The interference of light from variously distant areas of the moving wave front accounts for the maxima and minima observable as diffraction fringes.

WAVES AND WAVE MECHANICS. A wave is a disturbance propagated in a medium in such a manner that at any point in the medium, the displacement is a function of the time, while at any instant the displacement at a point is a function of the position of the point. Any physical quantity having the same relationship to some independent variable (usually time) that a propagated disturbance has, at a particular instant, with respect to space, may be called a wave. In this definition, displacement is used as a general term, indicating not only mechanical displacement, but also electric displacement, etc. In short, a wave is a time-varying quantity that is also a function of position; for example, any time-varying voltage or current in a network is often called a wave. Other examples of waves are: (a) a wave on the surface of a liquid, in which the disturbance is the displacement of any particle in the surface from its equilibrium position; (b) an acoustic wave, in which the disturbance is the change in pressure from its equilibrium value at any point in a material medium (fluid or solid); (c) an electromagnetic wave, in which the disturbance is the change in the electric and magnitude field intensities from their equilibrium values in space.

Wave Mechanics. This is a term and field that essentially grew out of the quantum theory. Wave mechanics in the modern sense is an integral part of quantum mechanics. The fact that radiant energy (light, X-rays, etc.) is certainly emitted by atoms or molecules and is as certainly done up in parcels, called quanta, the magnitude of each of which is definitely associated with a vibration or wave frequency of some kind (see also **Planck Law**), leads one to inquire what there is about an atom or the electrons in it that has to do with vibrations or waves. The now classic Davisson-Germer experiment gave most conclusive evidence that electrons actually do have wave characteristics even when flying freely through space (or at least when they strike and rebound from something like a crystal), and that, again, the energy of their motion is expressible in terms of a wave or vibration frequency. Even whole atoms are reflected by crystals as if they were waves, as shown by the experiments of Ellett, Olson, and Zahl.

Such facts have given rise to the idea that perhaps all physical processes are, in the last analysis, wave processes, with frequencies or wavelengths appropriate to the quanta into which the energy divides itself. Instead of being particles which revolve in orbits like planets, the electrons in the atom, according to this conception, become wave trains reverberating like sound in a closed room, and setting up stationary interference patterns corresponding to the stationary quantum states. It is of such boldly revolutionary concepts that the new wave mechanics is built. The mathematical formulation of the theory has been developed largely by de Broglie and by Schrödinger.

As pointed out in the entry on **Relativity and Relativity Theory**, Einstein played an invaluable role in establishing concepts that later led to the development of quantum mechanics. Rather than duplicate information here, the reader is referred, in particular, to three entries in this encyclopedia — **Gravitation; Quantum Mechanics**; and the aforementioned entry on relativity.

Wave Motion. The motion of waves can be said to be the most common and the most important type of motion that we know. It is through wave motion that sounds come to our ears, light to our eyes, and electromagnetic waves to our radios and television sets; tidal waves and earthquakes, among other phenomena, are also characterized by wave motion. Wave motion can be defined as that mechanism by which energy is transported from a source to a distant receiver without the transfer of matter between the two points.

Waves can be classified according to the manner of their production, namely, a vibrating material object, or in the case of electromagnetic waves, sources such as electrical oscillations in an aerial. The wind blowing across water causes surface waves; a piezoelectric quartz crystal vibrating under an applied electric field can generate underwater motion. Waves can also be classified according to the medium in which they travel. The most useful classification, however, involves the direction of motion of the particles of a medium (or of an electric or magnetic field in the case of electromagnetic waves) relative to the direction in which the energy of the wave is itself propagated. Such a classification is useful because wave motions falling into the same class according to the selected criterion will have other similar properties.

Wave motion can be most easily understood if one considers first, as an example, wave motion of a horizontal, stretched string and then, by analogy, other types of wave motion. If one end of such a string is moved up and down, a rhythmic disturbance travels along the string. Each particle of the string moves up and down, while at the same time, the wave motion moves along the length of the string. It is the state of the particles that advances, the medium as a whole returning to its initial condition after the disturbance has passed. Such a wave motion, one in which the vibratory motion of the medium is at right angles, or essentially at right angles, to the direction of propagation, is called *transverse*. Surface waves on liquids are transverse; so also are electromagnetic waves (X-rays, visible light, radio waves, etc.), but here, since electromagnetic waves can travel in a vacuum, we must think of the electric and magnetic fields associated with such waves as changing in intensity in a direction at right angles to the direction of propagation.

Another type of wave motion, termed *longitudinal* or *compressional*, can occur only in material media. In this type of motion, the particles of the medium move forward and backward along the direction of propagation

of the wave. Compressional waves are exemplified by sound waves in air, in which a volume in the path of the wave is alternately compressed and rarefied. These variations in pressure are very small. Even for the loudest sounds that an ear can tolerate, the pressure variations are of the order of 280 dynes per square centimeter (above and below atmospheric pressure of about 1 million dyes per square centimeter).

Yet another type of wave motion is the *torsional wave*, which can take place only in solids. Less frequently seen, this type can be demonstrated by a long helical spring supported on a flat surface. As one end of the spring is given a quick, momentary twist about the axis of the spring, a pulse travels down the spring.

Whatever the type of wave, certain useful definitions can be set forth and general statements made. *Phase* describes the relative position and direction of movement of a particle in its periodic motion as it participates in a wave motion, or the relative intensity at a point of the electric field accompanying electromagnetic waves. *Frequency* is the number of complete vibrations performed per unit of time by a particle (or field) through which a wave passes. *Period* is the time required for one complete vibration of a particle participating in wave motion. *Wavelength* is the distance between any two points that are in phase on successive waves or pulses. The *velocity* of a wave is the product of the frequency and the wavelength. All waves except electromagnetic waves require a medium for propagation.

Wave motions may vary in the energy they transport per unit of time. This property depends upon the amplitude. The *amplitude* of a wave in a string, to take again an example, is the maximum displacement experienced by the particles of the string as they move from their equilibrium positions. The *intensity* of the wave is the power (energy per second) passing through a square centimeter perpendicular to the wave front, and it is related to the square of the amplitude. In the case of sound, intensity is related to loudness.

Two or more waves crossing one another's paths will not cause any change in the direction, frequency, or intensity of any of them. The displacement effects of two or more waves of the same kind passing through a medium are additive at any point. And, at any moment, the displacement at a point is the vector sum of the separate displacements caused by the separate waves. Two transverse wave motions passing at right angles through a point in a medium cause a particle at that point to perform a path called a *Lissajous figure* (see also **Frequency Measurement**), whose form depends upon the amplitudes and frequencies of the two waves and upon their phase relationship.

Standing (stationary) waves are produced by combining two similar wave trains moving in opposite directions. Not themselves waves, they are patterns of vibration that simulate waves standing still. An example is exhibited by a string, one end of which is fastened rigidly and the other vibrated transversely at a constant frequency. Waves traveling down the string from the source meet waves reflected from the fixed end. If the tension in the string is adjusted properly, the string can be made to display *nodes*, points where the string does not move transversely because at those points the two waves cancel the effects of one another. Between the regularly spaced nodes are found the *antinodes* or loops, where the two waves reinforce one another.

Wave motion is also characterized by the phenomena of absorption, reflection, refraction, interference, diffraction, beats, resonance, and polarization. (Longitudinal waves do not exhibit polarization.)

Complex waves can be analyzed into sets of simple waves according to the principles of Fourier analysis, where by "simple waves" are meant waves whose variations of displacement with time can be represented by sine curves.

Compressional waves require about 5 seconds to travel a mile in air, 1 second to travel a mile in water, and $\frac{1}{3}$ second to travel a mile in iron. To travel a kilometer a compressional wave takes 3.1 seconds in air, 0.6 second in water, and 0.2 second in iron. Although varying in speed from material to material, low-frequency compressional waves travel with the same speed in a particular medium, i.e., they do not exhibit dispersion. Small variations in speed sometimes found at high frequencies are due to relaxation phenomena.

Compressional waves in a fluid have a speed v that depends only on the density ρ and the adiabatic bulk modulus β of the medium according to the relation

$$v = \sqrt{\beta/\rho}$$

In solids, the speed of compressional waves is given by the relation

$$v = \sqrt{Y/\rho}$$

where Y is Young's Modulus. Thus, it may be seen that a study of the propagation of waves in a medium gives important information about the medium.

Transverse waves on the surfaces of liquid do *not* travel with a fixed speed that is dependent only upon the properties of the liquid. Their speed depends upon their wavelength and amplitude, the depth of the liquid, and whether the surface is confined, as in a canal. Surface tension waves on the surface of water have wavelengths less than 1.7 centimeters, while gravity waves on the surface of water have wavelengths greater than 1.7 centimeters. Ripples on water often move only 30 centimeters per second. They have higher velocity as their wavelength becomes smaller. In contrast, for example, ocean waves measuring 244 meters (800 feet) from crest to crest have been found to travel 20 meters per second (45 miles per hour).

Transverse waves in strings (or wires) travel with a speed that depends only on the tension in the string T and the mass per unit length of the string m, according to the formula

$$v = \sqrt{T/m}$$

Electromagnetic waves of all frequencies travel with the same speed in a vacuum (2.9979×10^{10} centimeters/second). In a particular medium, however, different frequencies (colors in the case of visible light) travel with different speeds. The speeds at particular frequencies also vary with the media.

The observed wavelength of a wave motion, whether it be longitudinal or transverse, depends on whether the source and the receiver are moving relative to one another, a phenomenon known as the Doppler effect. In the case of electromagnetic waves, the Doppler effect depends only on the relative velocity. In the case of a compressional wave, as for instance, sound, the magnitude of the effect depends not only on the relative velocity of the source and receiver, but also the effect depends upon whether the receiver or the source is in motion with respect to the transmitting medium. In both cases, the wavelength of the wave is increased if the source and receiver move away from one another and the wavelength is decreased if they move toward one another.

In some uses of wave motion, care must be taken to differentiate between "phase" and "group" velocity. The group velocity of a wave is the velocity usually observed, and the energy in a wave is transmitted with the group velocity. For example, measurements of the speed of light wherein the time for "chopped" pulses to travel a known distance is determined, result in values of the group velocity. On the other hand, if one carefully observes the expanding group of ripples when a stone is dropped into water, the group travels with one velocity, the group velocity, while a particular wave crest will advance through the group to the outer leading edge and exhibit the phase velocity. The difference in the two velocities depends on the wavelength in the material medium and on the dispersion, i.e., on the change in phase velocity with wavelength. In a vacuum, such an interstellar space, the two velocities are the same for light, whatever the color.

WAVE (Supersonic). See **Supersonic Aerodynamics**.

WAVE TRAIN. The series of waves produced by a "vibrating" body is called a train of waves.

WAVE VECTOR. A vector, usually represented as **k**, which, at each position in space, points in the direction of propagation of the wave under consideration. The magnitude assigned to the wave vector associated with a wave of wavelength λ is not unique, but with present usage it is almost certain to be either unity, $1/\lambda$, or $2\pi/\lambda$. The magnitude of the wave vector is called the wave number when $|k| = 1/\lambda$ and sometimes when $|k| = 2\pi/\lambda$.

WAVE VELOCITY (or Phase Velocity). A plane wave has a velocity uniquely defined as the reciprocal of the phase slowness. The wave velocity is thus the velocity with which the displacement profile of a sinusoidal progressive wave travels. In three dimensions, the reciprocal of the magnitude of the (vector) phase slowness is the speed of the wave along a wave normal, and is often called phase velocity.

WAVE VELOCITY SURFACE. An elliptical surface used to indicate the difference in the velocity of the ordinary and the extraordinary ray of radiation in different directions in a double-refracting crystal.

WAXES. The English term *wax* is derived from the Anglo-Saxon *weax*, which was the name applied to the natural material gleaned from the honeycomb of the bee. In modern times the term *wax* has taken on a broader significance, as it is generally applied to all waxlike solids, natural or synthetic, and to liquids when they are composed of monohydric alcohol esters. Unlike the ordinary oils of animal and vegetable origin and the animal tallows, the waxes, with a few exceptions, are free from glycerides, which are common constituents of oils and fats. Bayberry wax is a vegetable tallow which happens to have all the physical characteristics of a wax, and has always been classed as such.

Animal and Vegetable Waxes

The most important insect wax from an economic viewpoint is *beeswax*, secreted by the hive-bee. Wax scales are secreted by eight wax glands on the underside of the abdomen of the worker bee. These wax wafers are used by the bee in building its honeycomb. From $1\frac{1}{2}$ to 3 pounds of wax can be obtained from the combs when they are scraped. The crude wax must be rendered and refined before it can be sold as "yellow beeswax." When this is bleached, it is known as "white beeswax."

The chemical components of beeswax are alkyl esters of monocarboxylic acids (71–72%), cholesteryl esters (0.6–0.8%), coloring matter (0.3%), lactone (0.6%), free alcohols ($1–1\frac{1}{2}$%), free wax acids (13.5–14.5%), hydrocarbons (10.5–11.5%), moisture and mineral impurities (0.9–2%). Myricyl palmitate ($C_{46}H_{92}O_2$) is the principal constituent of the simple alkyl esters (49–53%); the simple esters include alkyl esters of unsaturated fatty acids. The complex esters include hydroxylated esters the chief component of which is believed to be ceryl hydroxypalmitate, $C_{42}H_{84}O_3$. The principal free wax acid component is cerotic acid ($C_{26}H_{52}O_2$). The principal hydrocarbon is hentriacontane ($C_{31}H_{64}$).

The uses of beeswax are many, including church candles, electrotypers and pattern makers wax, cosmetic creams, adhesive tape, munition shells, modelling of flowers, shoe paste constituent, etc. The United States consumes about 8 million pounds of beeswax annually, more than half of which it imports from foreign countries.

Although there are many other kinds of insect waxes, only two are of economic importance namely, shellac wax and Chinese insect wax. Shellac wax is derived from the lac insect, a parasite that feeds on the sap of the lac tree indigenous to India. The commercial wax is not ordinarily the native Indian lac wax, but is a by-product recovered from the dewaxing of shellac spar varnishes. Lac wax melts at 72–80 °C, whereas commercial shellac wax melts at 80–84.5 °C. Its high melting point and dielectric properties favor its use in the electrical industry for insulation. Chinese insect wax is the product of the scale insect.

The land animal waxes are either solid or liquid. *Woolwax*, derived from the wool of the sheep, is of great economic value. It is better known as anhydrous lanolin, and is of a stiff, soft, solid consistency. The only representative of liquid animal wax is "mutton bird oil" obtainable from the stomach of the mutton bird.

The unsaponifiables of woolwax, known as "woolwax alcohols," are in considerable demand by cosmetic and pharmaceutical industries. Woolwax has a great affinity for water, of which it will absorb 25 to 30%. Refined woolwax is kneaded with water to produce a water-white, colorless ointment, known as hydrous lanolin or "lanolin USP." Anhydrous lanolin is widely used in cosmetic creams, since it is readily absorbed by the skin. It is also used in leather dressings and shoe pastes, as a superfatting agent for toilet soap, as a protective coating for metals, etc. United States consumption of wool wax is about 1.5 million lb/year.

The waxes obtained from plants occur in the leaves, stems, barks, fruit, flowers, and roots. The leaves of palm trees furnish wax of great economic importance. Particularly is this true of the product furnished by harvesting the leaves of the carnauba palm. The wax is removed from the leaves by sundrying, trenching, threshing and beating; the powdered wax is melted in a clay or iron pot over a fire, strained, cast into blocks, and broken into chunks for shipment from Brazil. *Carnauba wax* dissolves well in hot turpentine and/or naphtha, from which solvents it gels or cooling; it has a good solvent retention power. Its hardness, luster, and favorable behavior with solvents make it a highly valued ingredient in shoe pastes, floor polishes, carbon paper, etc. A small amount of carnauba, such as 2.5%, when added to paraffin will raise the melting point of the latter enormously (e.g., from 130 to 170 °F; 54 to 77 °C), making it a very useful ingredient in the production of inexpensive high-melting blended waxes. United States consumption is provided by imports from Brazil which amount to over 11 million lb/year.

The chemical composition of carnauba wax comprises 84–85% of alkyl esters of higher fatty acids. Of these esters only 8–9% (wax basis) are simple esters of normal acids. The other esters are acid esters 8–9%, diesters 19–21%, and esters of hydroxylated acids 50–53% (was basis) of which about one-third are unsaturated. It is the hydroxylated saturated esters that give carnauba its extreme hardness, whereas the esters of the hydroxylated unsaturated fatty acids produce the outstanding luster to polishes.

Ouricury, carandá, and raffia are commercial palm leaf waxes of lesser importance. Ouricury wax has a very high content of esters of hydroxylated carboxylic acids and is used as a substitute for carnauba in carbon papers, etc. Carandá and raffia waxes have a very low contents of these acids and make unsatisfactory substitutes for carnauba.

The most important wax obtainable from the stems of plants is *candelilla*, obtained in Mexico and the southwestern United States. To recover the wax the plant stalks are pulled up by the roots and boiled in acidulated water. On cooling, the congealed wax is removed from the surface of the water in the tank. The crude wax is given an additional refinement before it si placed on the market. Candelilla wax is brownish in color, and melts at 66–78 °C. Most vegetable waxes are essentially alkyl esters of aliphatic acids; candelilla, on the other hand, contains 51 to 59% of hydrocarbons and less than 30% of esters. The chief hydrocarbon is hentriacontane ($C_{31}H_{64}$), common to other vegetable waxes. The hydrocarbons melt at 68 °C, and the esters at 88–90 °C. Candelilla is often used in conjunction with carnauba in leather dressings, floor waxes, etc. It is also used in sound records, electrical insulators, candle compositions, etc. Imports average about 1600 tons per year.

Because of the enormous tonnage of sugar cane processed in Cuba and elsewhere, it is possible to recover an appreciable tonnage of *sugarcane wax* as a by-product. The crude wax contains about one-third each of wax, resin, and oil, and hence needs considerable refinement by selective solvents before it can become of value for industrial use. The refined sugarcane wax is dull yellow in color, melts at 79–81 °C and is hard and brittle. It has a durometer hardness of 85–96. It is chemically composed of 78–82% of wax esters, 14% free wax acids, 6–7% free alcohols, and 3–5% hydrocarbons. A proportion of the esters are sterols — sitosterol and stigmasterol — combined with palmitic acid, which are responsible for the good emulsification properties of the wax itself in the preparation of polishes and the like. The proportions of sterols in the refined wax is far less than in the crude wax.

Of waxes obtained from fruits, *japanwax* is the only one of great economic importance, particularly to the Asiatic countries. The wax occurs as a greenish coating on the kernels of the fruit of a small sumac-like tree. Japanwax is actually a vegetable tallow, since it is comprised of 90–91% of glycerides. Peculiarly the glycerides include 3–6.5% (wax basis) of alkyl esters of dicarboxylic acids as well as monocarboxylic acids. The chief dicarboxylic acid is known as japanic acid $[(CH_2)_{19}(COOH)_2]$ which is present with lower as well as higher homologs. The dicarboxylic acids

have 19 to 23 carbon atoms, whereas the monocarboxylic acids of the simple glycerides present have 16 to 20 carbons.

The textile industries in the past have been large users of japanwax since it is a source of emulsifying softening agents. Other industries using japanwax include those engaged in the manufacture of rubber, soap, polishes, pomades, leather dressings, cordage, etc. Japanwax is a relatively soft but firm wax, which melts at 48.5–54.5 °C. About 3000 tons are normally produced per year in China, and twice that amount in Japan.

Other fruit waxes include *bayberry wax* , used in making Christmas candles since the days of the Pilgrams. The wax of rice bran is coming into commercial use, but waxes of the cranberry, apple, grapefruit, etc. are only of academic interest.

Waxes from grasses include bamboo leaf wax, esparto wax, and hemp fiber wax. Esparto wax is a hard, tough wax with a melting point of 73–78 °C, and is the most important grass wax. Most of the esparto wax produced is consumed in the British Isles. It is chiefly useful as a substitute for carnauba. Waxes obtained from roots of various species of plants are minute in quantity and of no economic importance.

Mineral Waxes

The fossil waxes are associated with fossil remains which have not been bituminized, that is, converted to hydrocarbons by geological change. A fossil wax, chemically speaking, is composed largely of saponifiables, such as wax acids and esters. Fossil waxes of nearly pure ester composition are occasionally found in fragments of prehistoric plant life, still in a state of preservation as to the original wax constituents. Not far removed from fossil wax of the pure ester composition is *montan wax*, a natural mineral wax which is essentially an ester wax that has undergone partial bituminization. Montan wax is commercially extracted from the nonasphaltic insoluble pyrobitumen with which it is associated, by means of selective solvents such as alcohol and benzene, or by means of benzene alone. Crude montan wax is black and contains about 30% of resins, which is reduced to 10% or less upon refinement. The chemical components of montan wax (deresinified) are alkyl esters of fatty acids (40%), alkyl esters of hydroxy fatty acids (18%), free wax acids (18%), free monohydric alcohols (3%), resins (<12%), and ketones (<10%). There are a number of industrial uses of montan wax: electrical insulation, leather finishes, polishes, carbon papers, shoe pastes, brewer's pitch, etc. The crude wax is also used as a basic material in the manufacture of many synthetic waxes where its montanic acid content is utilized in making derivatives.

The principal source of the montan wax consumed in the United States is imports in annual amounts of some 3.4 million lb from Germany and Czechoslovakia, where it is derived from lignites and brown coals. Also, one California company extracts it from lignite.

Peat wax has somewhat the same composition as montan wax. It has only been produced on a limited scale in Ireland, where it is processed from the native peat. It has asphaltic constituents that tend to make it incompletely miscible with paraffin waxes.

The earth waxes are naturally occurring mineral waxes consisting of hydrocarbons with some oxygenated resinous bodies which can be eliminated by ordinary refining procedures. The earth wax of great economic importance is *ozocerite*, which originally was called ceresin wax. Important sources are the Carpathian mountains in Europe and to a far lesser extent Utah. Chemically speaking, ozocerite has hydrocarbons of a type different from those found in paraffin wax, giving it unique physical properties. The melting point of pure Galician ozocerite is 73 °C. It is less soluble in organic solvents than paraffin. When added to paraffin wax in amounts of 15% or thereabouts, it will reduce the paraffin crystals to micro size and improve the tensile strength. Crude imported ozocerite has a dielectric constant of 2.37–2.43, the refined 2.03, and domestic (Utahwax) 2.63. Ozocerite is used in the electrical industry, paste polishes, cosmetics, wax flowers, crayons, etc. Of all the waxes it has the greatest affinity for oil.

Petroleum Waxes

Petroleum is the largest single source of hydrocarbon waxes. The largest single use of petroleum waxes is in paper coatings which require about 53% of the total. The second largest use is in candles. The third greatest use in electrical equipment. In contrast, in the early 1950's the largest single use for petroleum waxes was in the manufacture of paper containers for dairy products, and the second was in waxed wrappers for bread. Both outlets are now dominated by plastics.

Crude petroleums differ greatly in both the nature of their hydrocarbons (paraffinic, aromatic, naphthenic, etc.), as well as in their available content of wax. Wax distillates are obtainable with the batch-type, continuous-type, and pipe-still processes, but not from the cracking process. There are, broadly speaking, three principal types of wax encountered in crude oil, namely *paraffin wax, slop wax*, and *petrolatum*. The ordinary procedure in producing slack wax is to pump the paraffin distillate at a temperature of 80–100 °F (26.7–38 °C) to the paraffin sheds (wax plant), where it is allowed to repose in tanks to promote settling at a temperature between 0 and 32 °F (−17.8–0 °C). It is then pumped through a bank of cooling units (wax chillers) to hydraulic presses, which squeeze out the wax from the chilled distillate. The product is a soft solid known as *slack wax*. Slack wax finds uses in the industries, but most of it is sweated, pressed, and further refined to produce the various grades of fully refined paraffin wax of commerce. Some of the slack may be "pudged" to the extent that it still contains several percent of oil; it is then called *scale wax*. Most of the scale waxes produced have a melting point (drop) of 126–130 °F (52–54 °C) (ASTM) and are used in waterproofing thread in the fabrication of cotton duck and canvas, waxing kraft papers, builders' papers, cement bag stock, roofers' felt, car liners, and match splints. Scale wax of very low oil content and higher melting point is used in the manufacture of crayons.

Paraffin wax contains 14 hydrocarbons ranging from $C_{18}H_{38}$ to $C_{32}H_{66}$, solidifying between 27.0 and 68.9 °C (80.5 and 156.0 °F; 26.9–68.8 °C). *Petrolatum wax*, which is a microcrystalline wax, has hydrocarbons ranging from $C_{34}H_{70}$ to $C_{43}H_{88}$, inclusive. Its solidifying range is 71.0–83.8 °C (159.7–182.7 °F). *Slop wax* (by-product from the heavy distillate in the coking process) has 13 hydrocarbons ranging from C_{26} to C_{43}, solidifying between 55.7 and 83.3 °C (132.2 and 182.0 °F). *Rod wax* (collected from the sucker rods in the field) has 8 hydrocarbons ranging from C_{35} to C_{41}, solidifying at 73.9 to 82.5 °C (165.0–180.5 °F).

Fully refined paraffin wax as regularly offered in the market is graded according to its melting point. There are also special refined grades offered by some refining companies, such as the so-called hard block fully refined paraffins with melting points of 138–140 °F (58.8–60 °C), and 143–145 °F (61.6–62.7 °C). The tensile strength of a paraffin wax is greatly influenced by the oil content. Ordinarily a well-refined paraffin of 130 °F (54 °C) melting point will have a tensile strength of about 250 psi (1.7 MPa). The addition of 1 or 2% of an oil-absorbent wax of microcrystalline structure will increase the tensile strength to 350 psi (2.4 MPa).

Microcrystalline Waxes

Microcrystalline petroleum waxes are characterized not only by microcrystalline structure but by very high average molecular weight, manifested by a much higher viscosity than that of paraffin wax. The chlorophyll present in plants is considered to be a microcrystalline wax.

Microcrystalline waxes are obtained as by-products from (a) the dewaxing of "lube oil raffinates," (b) the deoiling of petrolatum produced from deasphaltic residual oil, or (c) the deasphalting and deoiling of settlings of tanks holding crude oil in the oil field. These types of microcrystalline waxes are sometimes referred to as "motor-oil wax," "residual oil microcrystalline wax," and "tank-bottom microcrystalline wax," respectively. They have also been referred to as "micro wax," "petrolatum wax," and "petroleum ceresin," respectively.

The *micro waxes* are graded with 145–150 °F (63–66 °C) and 160–165 °F (71–74 °C) ASTM melting points, and are refined by selective solvent extraction from the crude wax, a "mobile slurry." A yield of 25–27% of refined wax of the lower melting point is claimed from S.A.E. 20 motor-oil distillate. These waxes are paraffin-like. *Petrolatum waxes* are of a 145–175 °F (63–80 °C) melting point range. The *petroleum ceresins* which are refined from deposits taken from tanks near the wells, called lease tanks, or in the refinery storage, have melting points which range between 165 and 195 °F (74–91 °C). In the solvent dewaxing processes the solvents for effectively separating the microcrystalline waxes vary with the refinery methods and the character of the feed stock.

A microcrystalline wax derived from petroleum may be defined as a solid hydrocarbon mixture, of average molecular weight range of 490 to 800, considerably higher than that of paraffin wax, which is 350 to

420. The viscosity (SUS at 210 °F; 99 °C) of a microcrystalline wax is within the range of 45 to 120 seconds. The lower limit corresponds to 5.75 and the upper limit to 25.1 centistokes at 210 °F (99 °C). The penetration value (ASTM) is of wide variation, namely 3 to 33, although sticky oily laminating waxes are encountered with as high a penetration as 60. Microcrystalline waxes have an occluded oil content which is not easily set free as it is in paraffin waxes. Therefore, a microcrystalline wax which has an oil content of 1 to 4% is virtually a dry wax. A microcrystalline wax which shows a penetration 20 to 30, which is desirable for many needs, will have an oil content of 5.5 to 10.5%.

When a microcrystalline wax is added to melted paraffin it acts like a solute with paraffin as the solvent; the melting point of the blend is greatly elevated, and the crystallization of the paraffin is depressed. The behavior is that of a two-phase system until about 15% of the microcrystalline wax has been added. With the addition of 15 percent of the petrolatum wax (M.P. 188 °F; 86.6 °C) the melting point of the paraffin is elevated from 130 to 160 °F (54 to 71 °C). For many industrial uses microcrystalline wax is admixed with paraffin wax.

The uses of microcrystalline waxes include adhesives, barrel lining, beater size for paper stocks, beer can lining, carbon papers, cheese coatings, cosmetic creams, drinking cups, electrical insulation, floor wax, fruit coating, glass fabric impregnation, heat sealing compounds, laminants for paper, ordnance packing, paper milk bottles, shoe and leather treatments, vegetable coatings, wax emulsions, wax figures and toys, and other miscellaneous purposes.

Synthetic Waxes

These include the following types:

1. Long-chain polymers of ethylene with OH or other stop-length groupings at end of chain. An example is polyethylene wax of about 2000 molecular weight.
2. Long-chain polymers of ethylene oxide combined with a dihydric alcohol, namely polyoxyethylene glycol, ("Carbo-wax").
3. Chlorinated naphthalenes, ("Halowaxes").
4. Waxy polyol ether-esters, as for example, polyoxyethylene sorbitol.
5. Synthetic hydrocarbon waxes prepared by the water-gas synthesis in which carbon monoxide (CO) is reduced by hydrogen (H_2) under pressure, at a predescribed temperature, by means of a catalytic agent. (Fischer-Tropsch waxes "F-T 200" and "F-T 300").
6. Wax-like ketones, straight-chain and cyclic: (a) Symmetrical ketones produced by the catalytic treatment of the higher fatty acids. (b) Unsymmetrical ketones produced by the Friedel-Crafts' condensation of fatty acids and the like with cyclic hydrocarbons. Examples of the straight-chain ketones are laurone, palmitone, and stearone, and of the cyclic ketones are phenoxyphenyl heptadecyl ketone.
7. Amide derivatives of fatty acids. The length of the chain may be increased by heating the fatty acid, e.g., stearic acid, with an amino alcohol.
8. Imide (*N*) condensation products that are wax-like are those of the condensation reaction of one mole of phthalic anhydride with one mole of a primary aliphatic amine to produce a phthalimide. Phthalimide waxes are used in polishes and carbon paper.
9. Polyoxyethylene fatty acid esters are produced by the reaction of polyethylene glycols with fatty acids. The commercial products are waxy solids which include "Carbowax 4000 (Mono) Stearate." Some of the products act as plasticizers and lubricants for plastics. The polyethylene glycols are soluble in water.
10. Miscellaneous synthetic waxes (unclassified).

In addition to the above waxes there is a group of synthetic wax-like emulsifiable materials extensively employed in the industries. They are the polyhydric alcohol fatty acid esters, such as ethylene glycol monostearate, glyceryl monostearate, glycerol distearate, and a number of others.

ALBIN H. WARTH, Cape May, NJ

WAX MOTH *(Insecta, Lepidoptera)*. A small moth whose larva lives in the combs of bee hives, spinning silken tunnels as it burrows through them. Although it eats the wax of which the combs are built and will attack the pure wax in stored comb foundation, careful studies have shown that it does not thrive on a pure wax diet. The other materials in old combs are a necessary source of nitrogen, without which the caterpillar may live but cannot grow and develop normally.

The moth does not become a serious pest in strong colonies of bees but it is sometimes a cause of serious damage in weak colonies and stored combs.

WAX MYRTLE. See **Bayberry Shrubs and Trees**.

WAXWING *(Aves, Paseriformes)*. A bird of the Northern Hemisphere, smoothly gray and brown, with limited yellow shading and black marks, and red tips of horny material on some of the wing feathers. The name waxwing refers to these tips. The head bears a sharp crest. One species, the cedar waxwing, or cedar bird, *Bombycilla cedrorum*, is peculiar to the United States. The Bohemian waxwing, *B. garrula*, nests in northern latitudes in Europe and North America and is occasional through the northern half of the states. A third species, the Japanese waxwing, *B. japonica*, breeds in eastern Asia.

WAYFARING TREE. See **Elder Trees and Viburnums**.

WEAKFISH. See **Croakers**.

WEAK INTERACTION. See **Particles (Subatomic)**.

WEASEL. See **Mustelines**.

WEATHERING. The processes by which the atmospheric agencies, commonly associated with the weather, mechanically disintegrate or chemically decompose the rocks at or near the Earth's surface. Mechanical weathering includes the effects produced by changes of temperature, the action of frost, etc. Chemical weathering includes the solvent action of water, the union of atmospheric oxygen with rock materials — oxidation, union with atmospheric carbon dioxide — carbonation, and the chemical combination of substances with water — hydration.

WEATHER MODIFICATION. In general, any effort to alter artificially the natural phenomena of the atmosphere. Also called *weather control.* The term usually refers to cloud seeding activities, but can also include constructing windbreaks, dissipating fog by the forceful addition of heat or water spray, or preventing frost formation on crops by cloud spray, heating, or mixing processes. Inadvertent weather modification refers to accidental weather effects resulting from the release of greenhouse gases, aerosols, and dust, or changes in albedo or surface properties of the earth associated with urban, industrial, or agricultural activity. See also **Cloud Seeding**.

AMS

WEATHER SATELLITES. The world's first meteorological satellite, a polar-orbiting satellite, was launched from Cape Canaveral on 1 April 1960. Named TIROS for Television Infrared Observation Satellite, it demonstrated the advantage of mapping Earth's cloud cover from satellite altitudes. TIROS showed clouds banded and clustered in unexpected ways. Sightings from the surface had not prepared meteorologists for the interpretation of the cloud patterns that the view from an orbiting satellite would show.

The spacecraft, the sensors, the communication links, the data, and the data uses of weather satellites today bear little resemblance to what they were at the time of that pioneering effort. In the decades that have elapsed, satellite weight has grown from about 100 kg (220 lbs) to nearly a metric ton; vidicon cameras have given way to scanning radiometers; hand-drawn analyses of the data have been replaced by computer-generated products; what was analog has become digital; and capabilities have expanded to include atmospheric profiling, ocean sensing, and collecting and relaying environmental data recorded by remote reporting platforms. In addition, weather satellites now measure the space environment in which they operate. Just as their technology and uses have evolved, so have weather satellites proliferated internationally. Meteorological spacecraft in polar orbit and geostationary orbits are operated by the United States, the European Space Agency, Japan, India, Russia, and the People's Republic of China.

Today, U.S. environmental satellites are operated by NOAA's National Environmental Satellite, Data, and Information Service (NESDIS) in Suitland, Maryland. NOAA's operational environmental satellite system is composed of two types of satellites: geostationary operational environmental satellites (GOES) for national, regional, short-range warning and "nowcasting," and polar-orbiting environmental satellites (POES) for global, long-term forecasting, and environmental monitoring. The GOES and POES satellites also carry search-and-rescue instruments to relay signals from aviators and mariners in distress. Both types of satellites are necessary for a complete global weather monitoring system. In addition, NOAA operates polar-orbiting satellites in the Defense Meteorological Satellite Program (DMSP). NESDIS also manages the processing and distribution of the environmental data and images that the satellites produce each day. Figure 1 shows a current GOES spacecraft, and Fig. 2 illustrates a POES space vehicle.

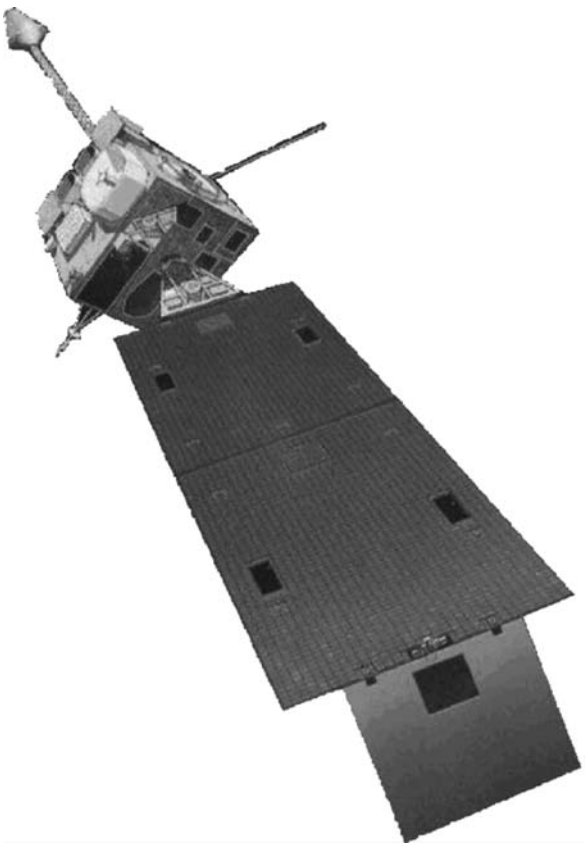

Fig. 1. A geosynchronous operational environmental satellite (GOES). The function of this spacecraft is to make panoramic pictures of the world's weather patterns from an altitude of 22,500 miles. (*NASA*).

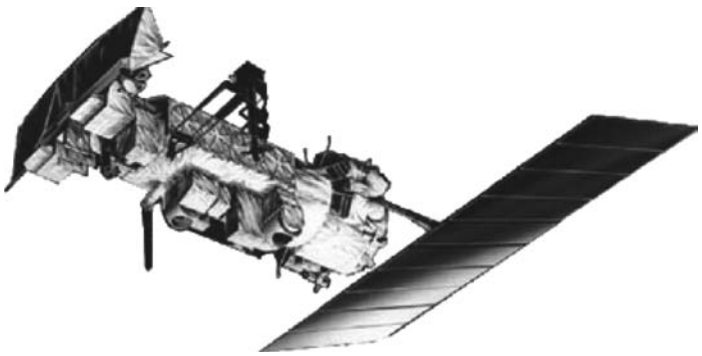

Fig. 2. A polar-orbiting operational environmental satellite (POES). This spacecraft is a stable platform for high-resolution cameras and other sensors. (*NASA*)

See also **Weather Technology**.

NASA's Goddard Space Flight Center (GSFC). http://goespoes.gsfc.nasa.gov/index.html in Greenbelt, Maryland, is responsible for the procurement, development, launch services, and verification testing of the spacecraft, instruments, and unique ground equipment. Following deployment of the spacecraft from the launch vehicle, GSFC is responsible for the mission-operation phase leading to injection of the satellite into either low-altitude polar or geostationary equatorial orbit and for the initial in-orbit satellite checkout and evaluation.

Early History of the Weather Satellite Program

Today's advanced technology and the images of clouds shown daily on television weather forecasts may make it difficult to remember the days when there were no weather satellites. Yet the need for weather observations from space was obvious. Oceans cover about 70% of Earth, and weather observations were sparse over these areas. Observations were limited even over the continents, except over North America and Europe.

The concept and design of weather satellites were developed during the 1950s. Even earlier, in the late 1940s, pictures of Earth taken from high-altitude V-2 rockets launched at White Sands, New Mexico, showed the meteorological potential through viewing cloud systems synoptically. These initial images demonstrated the need for satellites.

The earliest discussion of weather observations from "spaceships" was by Greenfield and Kellogg in a classified RAND report of 1951, later published in 1960. The full potential of a satellite was recognized by Dr. Harry Wexler, chief scientist of the U.S. Weather Bureau (in the Department of Commerce, now part of NOAA). He presented his ideas at a symposium held at the Hayden Planetarium in New York City in 1954. Wexler showed a simulated sketch of cloud cover over North America viewed from a satellite as if it were positioned 4000 miles over Texas. At the same symposium, Professor S. Fred Singer, then at the University of Maryland, presented his concept of a small, instrumented minimum orbiting unmanned satellite of Earth (MOUSE) to obtain a variety of atmospheric, geophysical, and astrophysical data, such as cosmic rays and ultraviolet radiation from the sun. Later, he developed these ideas in greater detail and published them in a review article in 1956. Singer scanned Wexler's high–resolution cloud picture with an array of photocells on a simulated spinning satellite and showed a meteorologically adequate reproduction of cloud patterns. He also discussed measuring albedo (reflection of visible solar radiation) and infrared (IR) emissions from the surface and atmosphere to determine long-term climate changes. The monograph also presented an analysis of an instrument to measure remotely the vertical distribution of ozone in the stratosphere.

By 1958, the United States began to launch a series of instrumented satellites through a newly established agency, the National Aeronautics and Space Administration (NASA). It consolidated programs from many centers of the Department of Defense. In particular, it took over weather satellite design and testing from the U.S. Army Signal Corps. The program was headed by Dr. William Stroud and was transferred to the newly established Goddard Space Flight Center (GSFC) of NASA. The weather satellite, labeled TIROS, incorporated some of the design concepts of the MOUSE. It had a near-polar orbit to cover almost the entire globe; it was spin-stabilized, but it used television cameras rather than the scanning photodetectors of the simpler MOUSE.

In March 1958, the Chief of the USWB, Dr. F.W. Reichelderfer, established a special unit under Wexler, Director of Meteorological Research. He named Dr. Sigmund Fritz as the head of the Meteorological Satellite Section. Six months later, in September 1958, Wexler sent a memo to the USWB units noting the formation of NASA and stating that the Weather Bureau would be designated as its meteorological agent to provide meteorological instrumentation, data reduction, and analysis of observations. The memo also described in detail the types of data that were expected from the satellites and the research and development work needed. Almost 2 years before the launch of the first weather satellite, he identified the following types of data that would become available within the near future:

1. cloud cover
2. heat budget of the earth
3. nocturnal cloud cover using infrared

4. "temperature" as inferred from CO_2 emission in the infrared (IR)
5. ozone distribution
6. spectrum of solar radiation

The first TIROS launch demonstrated the operational value of cloud pictures, primarily for tracking hurricanes. It led directly to a Congressional authorization to set up an operational program in the U.S. Weather Bureau. NASA continued to hold the responsibility for research on satellites and instrumentation, and the Meteorological Satellite Section (MSS) of the USWB dealt with meteorological applications. As the agency responsible for operational applications, the USWB was to set the operational requirements that NASA had to satisfy in designing, launching, and operating the satellites.

The early TIROS carried two vidicon cameras — a wide-angle and a narrow-angle one. The image of the earth and clouds was formed on the vidicon tube (which is about 1 inch in diameter) and persisted for several seconds. During this period, the image was scanned and transmitted to the ground stations to receive and reconstruct the image. As soon as one image was transmitted, the next sequence was started, and thus a large segment of the globe was covered. The satellite also carried a tape recorder to store the pictures when out of range of a ground data-acquisition station. The early satellites (TIROS-1 to -8 and TIROS-10) were shaped like a hatbox and were allowed to spin along their vertical axis to keep them stable. Because of the nature of the polar orbit and the way the cameras were mounted on the spinning satellite, only limited coverage of the globe was possible.

There were two primary ground stations to command and receive the satellite data. They were located at Ft. Monmouth, New Jersey, and Kaena Point, Hawaii. At the ground stations, pictures were displayed on kinescopes for immediate viewing and photographing. In the early stages of this program, NASA had the responsibility for planning; placing the satellite into orbit; and tracking, acquiring, processing, and analyzing the data. Assistance was provided by industry and other governmental agencies. Meteorologists in the USWB/MSS were responsible for analyzing and interpreting cloud-cover data.

When TIROS-1 was launched, it was assumed that the attitude of the satellite in space relative to the fixed stars would stay the same throughout its lifetime. Analysis of the pictures showed that this was not true and extensive corrections had to be made while analyzing the pictures. The causes for this deviation were (*1*) the interaction between the magnetic field of the satellite and that of Earth; and (*2*) the decrease of gravitational force with height, which causes an object in space to tend to align itself vertically. As soon as these factors were known, they were incorporated in future satellite data processing.

To observe both day and nighttime cloud cover, radiometers were installed on the next satellite, TIROS-2, and the follow-on satellites (TIROS-3, -4, -5 and -7). All of these radiometer measurements were stored in the tape recorder on board the satellite and were transmitted to the ground station after each orbit. Using the experience gained from these early measurements, various changes were made to the follow-on instruments, which will be discussed later.

The inclusion of infrared radiometers on TIROS added extra capabilities. For example, the measurements in the 8 to 12-μm channels provided an estimate of the cloud top temperatures, and thus one could infer the cloud top heights. One of the early studies by Rao and Winston showed the cloud-top temperatures and cloud heights determined over the United States using the TIROS-2 radiation data. The researchers compared the results with synoptic and aircraft data and found good agreement.

Another interesting study showed the temporal and spatial variations of the outgoing long-wave radiation derived from the TIROS-2 radiometer (7 to 33-μm channel) to estimate the total outgoing long-wave radiation at the top of the atmosphere. The observed latitudinal distribution agreed well with available theoretical studies.

These early satellites also mapped ice cover over the Gulf of St. Lawrence and the Great Lakes areas. These pictures were found very useful for navigation by observing the leads in the ice cover. Another important application was monitoring the extent of snow cover during winter and the melting of snow during spring. The snow cover information was very useful for hydrological forecasting.

TRIOS-Nimbus Problems (PRE-1964)

Administrative History of NESDIS. In 1960, the Meteorological Satellite Section, established in 1958 in the USWB, became the Meteorological Satellite Laboratory (MSL), and in 1962, the Meteorological Satellite Activities (MSA) with S. Fred Singer as the first Director and David S. Johnson as the Deputy Director. In the following year, it became the National Weather Satellite Center. When Singer departed in 1964, Johnson became Director. Upon the formation of the National Oceanic and Atmospheric Administration in 1972 and the accompanying reorganization, the organization was renamed the National Environmental Satellite Service (NESS). After Johnson's retirement in 1982, it became the National Environmental Data and Information Service (NESDIS). Dr. John McElroy was the Assistant Administrator until 1986. Dr. William Bishop served as Acting Assistant Administrator until Tom Pyke became the Assistant Administrator of NESDIS. He continued until 1992. After Pyke, Robert Winokur held the position until 1999, when Greg Withee became the Assistant Administrator of NESDIS.

In June 1962, the Chief of the USWB appointed Dr. S. Fred Singer as Director of the Meteorological Satellite Activities. In a memo to his staff (Annex 5 of Rao, P.K. Ref.), he described the policies and the organization of the unit and noted in detail the "operational" responsibility for weather satellites bestowed on the USWB by the U.S. Congress in PL 87-332. Eighteen months after the launch of the first satellite TIROS-1, a fully operational entity was in existence.

As part of its responsibility, NASA developed the concept of the Nimbus research satellite. It was much larger, more complicated, and certainly more expensive than the simple TIROS. It was stabilized in three axes and was designed as a platform for a variety of instruments to view Earth by remote sensing. In addition to carrying out an atmospheric research program, Nimbus was also designed to provide a test bed for advanced instruments and systems, later to be transferred to the operational program.

Nimbus was primarily designed by Dr. Rudolph Stampfl and his associates at NASA's Goddard Space Flight Center (GSFC) in 1959. The objectives of the design were (*1*) a near-polar orbit to permit observation of the entire Earth (from pole to pole), (*2*) Earth-stabilization so that the cameras and other sensors could always point toward Earth, (*3*) a retrograde (east to west) orbit inclined about 80° to the equator so that the satellite crosses the equator at local noon (northbound) and local midnight (southbound) in every orbit, (*4*) an altitude of 1000 km (600 nautical miles) to avoid Earth's radiation belt and to provide enough overlapping coverage at the equator, and (*5*) modular construction to allow easy exchange of sensors and communication modules. Originally, the plan was for GSFC to integrate and test the spacecraft. However, in 1961, several separate contracts were awarded for the various subsystems, and General Electric's Missile and Space Vehicle Department handled the final integration. Nimbus was a totally new system and was more complicated than the TIROS. The program was in trouble right from the beginning, and deadlines could not be met in completing the systems for integration and testing.

The second TIROS satellite was launched on 23 November 1960. Its ability to locate and track weather fronts, hurricanes and other tropical storms proved to be a boon for meteorology. In addition to the USWB and its clients, the Department of Defense stated its interest in operational satellite data in no uncertain terms in Congressional hearings.

The evolution of the weather satellite program in the Department of Commerce is well described by P.K. Rao. He relates an interesting episode that took place in the early 1960s when the TIROS satellites were being considered for operational use. Some senior people in NASA wanted to consider it a research program and opposed immediate operational use of TIROS data. NASA refused the USWB use of the TIROS data for operational weather analysis for several weeks after the launch of TIROS. The two main groups that wanted the satellite data to be operational were the USWB and DOD Weather Services.

In October 1960, to settle some of the differences (research vs. operations) with regard to TIROS satellite operations, an interagency group consisting of NASA, USWB, DOD, and FAA established the Panel on Operational Meteorological Satellites (POMS) under the auspices of the National Coordinating Committee for Aviation Meteorology (NACCAM). The Chief of the USWB chaired NACCAM. The first chairman of POMS was Edgar Cortright of NASA; Dr. Morris Tepper of NASA served as

secretary. This group developed the report "Plan for a National Operational Meteorological Satellite System (NOMSS)," completed in April 1961, and submitted to Congress.

POMS gave operational responsibility for weather satellites to the USWB, which then became the position of the Kennedy administration. Under this plan, Nimbus was to be the ultimate operational weather satellite but would also serve as a platform for developing instruments and technology. NOMSS was approved by President Kennedy as his fourth national goal; the first was to put a man on the Moon. On 25 May 1961, in President Kennedy's address to the Congress on "Urgent National Needs", he requested funding for these activities (approximately $53 million dollars) to be given to the USWB.

NOMMS said that the operational meteorological satellite system should

- satisfy the meteorological requirements of all users;
- phase into operation at the earliest date;
- capitalize on the continuing research and development program; and
- serve the United States first, but where possible, also serve international needs.

Already then, Stroud and his NASA colleagues foresaw problems as Nimbus was pushed into an operational role while still basically a research satellite. Because of the delay in Nimbus, new instruments could not be tested in time to incorporate them into operational weather satellites. NASA felt that Nimbus should be fully tested before declaring any instruments ready for operation.

Funds were appropriated for the USWB, which gave it fiscal control of the operational program, but NASA wanted to give responsibility to the USWB only when the system became operational. Nimbus, however, was a long way from becoming operational. As a result of the supplemental appropriation for the USWB of $48 million for fiscal year 1962, the Nimbus Operational System (NOS) agreement was signed; USWB gave up of most of its responsibility to NASA although it had the funds appropriated for it.

As Richard Chapman recounts in his history of the administrative, political, and technological problems of developing a U.S. weather satellite, the USWB was then in a weak position. It had no permanent director for its satellite activities and insufficient competence in the technical areas (outside of meteorology) to match those of the large NASA group at the GSFC. Change came in the spring of 1962, when the Commerce Department selected J. Herbert Hollomon for the position of assistant secretary for research and technology and in June 1962, when atmospheric and space physicist S. Fred Singer, then a professor at the University of Maryland, was appointed director of the weather bureau's satellite efforts.

On taking the position of director, Singer renamed the organization the National Weather Satellite Center (NWSC) and convened a group to correlate the requirements of operational users, including those of the DOD. The group was particularly concerned about the delays in the Nimbus program, that its capabilities had been scaled down, and that its lifetime and period of performance were short. Eventually, the delay lasted 2 years because of a variety of problems that GSFC as the integration contractor could not handle efficiently. At that time, Singer, as Director of the NWSC, decided to provide funds to build a few more TIROS satellites to maintain continuity of operations, rather than continue to fund NASA to develop Nimbus.

Gradually, a shift took place away from the NASA–USWB interagency agreement and NOMSS. Hollomon and Singer became particularly concerned about the accountability of USWB funds committed to NASA. What could the Department of Commerce and WB show the Congressional oversight committee in the way of accomplishments with its appropriated "no-year" funds? First, Singer decided that additional interim TIROS satellites were needed to fill the gap while waiting for Nimbus to become operational. Then, analyses by NWSC demonstrated that an advanced TIROS could handle some of the Nimbus functions, including APT, the all-important direct readout feature of cloud data that the DOD wanted. The main problem with Nimbus, aside from the delay, was its complexity and therefore the question of reliability for operational purposes. NASA itself only foresaw a lifetime of less than 6 months, whereas NWSC, concerned about cost, was looking for satellites that would operate for 3 to 5 years.

In the meantime, while the Nimbus cost had doubled, the USWB had reached the conclusion that an interim improved TIROS would be adequate and that something better than Nimbus was required for the long term. The NWSC studies showed that the cost of the operational program could be cut in half.

During the summer of 1963, a technical battle ensued between GSFC/ NASA and the NWSC/ Department of Commerce, that covered many technical areas relevant to the operational weather satellite system, including optimum orbit, readout stations, instruments, and radiation protection.

The main NASA Command and Data Acquisition (CDA) station was near Fairbanks, Alaska. The turning point came when NWSC initiated its own technical studies and demonstrated that, in the proper orbit, the simpler satellite would require only one readout station (in Alaska) and that a Canadian station was not required. Ultimately, Singer did not accept the NASA analyses and Secretary Hollomon formally withdrew support for the Canadian readout station, which was to be financed with money appropriated for the USWB. He argued that Nimbus had become too costly compared to an improved TIROS satellite. If NASA would not supply the spacecraft, then the DOD was willing to step in and manage the program.

This proved to be the final deciding factor. The TIROS operational satellite (TOS) was developed under NASA direction. It had many of the features of the Nimbus satellite and some of its instruments. However, it was simpler and cheaper. Instead of an active system of attitude control, it was a spin-stabilized wheel in a sun-synchronous, near-polar orbit. Most important, the budget of the operational program had been cut by nearly half, and Nimbus had lost its operational mission.

Nimbus 1 was finally launched from the Pacific Missile Range on 28 August 1964 on a Thor-Agena rocket but failed after 26 days. However, later and improved Nimbus satellites provided a test bed for instruments and technology that eventually found their way into the operational mission. The first Nimbus carried the advanced vidicon camera subsystem (AVCS) to provide global coverage. It also carried the automatic picture transmission (APT) subsystem to provide pictures of local cloud patterns directly to suitably equipped weather stations as the satellite passed over them. The AVCS and APT cameras provided images only during the daylight portion of the orbit. Nimbus also carried an improved version of a radiometer called the high-resolution infrared radiometer (HRIR) to observe in the 8- to 12-μm window region, and in the region of 3.4 to 4.2 μm (a clear window). The Nimbus also carried a radiometer, similar to the TIROS radiometer. This was called the medium-resolution infrared radiometer (MRIR) and again the window channel was changed to 10–11 μm so that the absorption due to ozone and water vapor could be eliminated (a much cleaner window region of the IR spectrum).

Between 1964 and 1979, NASA launched seven Nimbus satellites and tested prototype operational sensors for use in future NOAA polar-orbiting satellites.

See also **Nimbus Satellite Program**.

Satellite Development — Early 1960 to Present

The early satellites TIROS-1 to -8 and TIROS-10 were shaped like a hatbox and were allowed to spin along their vertical axis to keep them stable. Because of the nature of the polar orbit (50°N–50°S) and the way the cameras were mounted on the spinning satellite, only limited coverage of the globe was possible. To obtain day and night coverage of the entire globe, radiometers were installed to observe in both the visible and infrared spectral regions. The rapid improvements in the spatial and spectral resolution of the radiometers made it possible to eliminate the onboard cameras. Both day- and nighttime images could be constructed from the radiometer measurements.

The first change in the weather satellite design occurred in 1965 in TIROS-9. The hat shape was changed to a cartwheel and the cameras were mounted along the radius 180° apart. The cameras could look straight down every time the satellite turned on its axis (at approximately 12 rpm). The spacecraft could view the entire Earth in a 24-hour period as it rolled along its orbit. The launch of the TIROS-9 series increased the daily coverage capability of the satellite substantially. This was also the beginning of the TIROS operational system (TOS) satellites.

The First TIROS Operational System (TOS) Satellites. The first operational weather satellite system of the world started when the

Environmental Sciences Services Administration (now NOAA) satellites, were launched ESSA-1, on 3 February 1966 and ESSA-2 on February 28, 1966. (The satellites reflect the name of the agency. The system consists of a pair of ESSA satellites in a sun-synchronous orbit; each is configured for a specific mission.) The advanced vidicon camera system (AVCS) obtained global imagery, which transmitted to the Command and Data Acquisition (CDA) stations at Wallops Island, Virginia, and at Fairbanks, Alaska. The CDA stations relayed the data to the National Environmental Satellite Service (NESS) in Suitland, Maryland, for processing and distribution to forecasting centers in the United States and other nations. The odd-numbered satellites (ESSA-1, -3, -5, -7, and -9) that had redundant AVCS systems were the global readout satellites. Even-numbered satellites (ESSA-2, -4, -6, and -8) were equipped with redundant automatic picture transmission (APT) cameras, and pictures from these cameras were directly transmitted to ground stations located around the world.

Improved TIROS Operational Satellite (ITOS) System 1970–1978. The new generation ITOS-1 satellite was launched on 23 January, 1970. The system carried both the AVCS and APT systems and a two-channel scanning radiometer (SR) that provided day and night coverage. The data from the SR were available by immediate transmission for local use and in a stored mode for later playback at the CDA station. The IR scanning radiometer made global observation of the atmosphere and surface areas available once every 12 hours from a single ITOS spacecraft. The second ITOS was launched on 11 December 1970, and it was named NOAA-1 (after the National Oceanic and Atmospheric Administration). The ITOS system evolved further from the development of ITOS-D satellites. These had a new redundant sensor complement to provide day and night imaging by the very-high-resolution radiometer (VHRR) and the medium-resolution scanning radiometer (SR). The VHRR and SR systems replaced the AVCS and APT cameras. The new ITOS system also carried the vertical temperature profile radiometer (VTPR) for obtaining the vertical temperature and moisture distribution in the atmosphere and a solar-proton monitor (SPM) for measuring solar protons and electron fluxes in the vicinity of the satellite. This second generation of satellite continued until 1978.

Third Generation of Operational Satellites: TIROS-N/NOAA-A to — D. These spacecraft covered a period from 1978 to 1981 and had a new and improved complement of systems. The advanced very-high-resolution radiometer (AVHRR) provided data for day and night imaging in the visible and infrared. It also provided observations to extract the sea surface temperature (SST), snow and ice distribution, and the Earth–atmosphere radiation budget. The TIROS operational vertical sounder (TOVS) provided vertical distribution of temperature and moisture in the atmosphere. The satellite also had a data collection system (DCS) to collect environmental data from stationary and moving platforms such as buoys, and remote hydrological stations. This satellite could broadcast data directly to local users and had a tape recorder to store data and transmit it to the CDA stations at Wallops Island and Fairbanks. The TIROS-N series of satellites operated in polar orbit at an altitude of approximately 850 km (528 miles).

The Advanced TIROS-N (ATN)/NOAA-E to –J System (1983–1994). These spacecraft were modified to add some new and improved sensors: a search-and-rescue (SAR) system, Earth radiation budget experiment (ERBE), and a solar backscatter ultraviolet (SBUV) radiometer to measure stratospheric ozone distribution. The system also consists of two polar-orbiting satellites; operating as a pair, they provide environmental data for the entire globe, four times a day.

NOAA-K Series (1996 to Present). This is the latest in the Advanced TIROS-N series that started with NOAA-14. This satellite system carried a new version of the AVHRR-3 and is a six-channel instrument. It has an improved HIRS-3 instrument and an advanced microwave sounding unit-A (AMSU-A) to measure temperature and moisture from the surface to the upper stratosphere. The satellite also carried the British-built AMSU-B to measure the vertical distribution of water vapor in the atmosphere, a space-environment monitor (SEM) to measure the charged particles entering Earth's atmosphere, SAR instruments, and data collection instruments.

Geostationary Environmental Satellites History

The NOAA GOES program was a direct outgrowth of NASA's Applications Technology Satellite (ATS) program. It was initiated in 1966 to demonstrate communications technology by using a satellite in a geostationary orbit. The major objective of the early ATS satellites was to test whether gravity would anchor the satellite in a 24-hour synchronous orbit (22,300 miles above Earth's surface) over the equator, allowing it to orbit at the same rate as Earth turns, thus seeming to remain stationary. The excess capacity of the spacecraft allowed including meteorological sensors for experimental observations of Earth from a geosynchronous altitude. A spin-scan camera developed by Professor V. Suomi of the University of Wisconsin provided continuous images of the sunlit Earth disk every half hour. The nearly continuous imagery proved the ability of the spacecraft to monitor the evolution of weather systems in real time, particularly severe weather. Another satellite in this series, ATS-3, was launched in 1967 to cover the Western Hemisphere. The next in this series, ATS-6, was totally different; it was a three-axis-stabilized spacecraft intended primarily for communication experiments from geostationary orbit. It carried a meteorological sensor, the geostationary very-high-resolution radiometer (GVHRR), a two-channel radiometer scanning in the visible range (0.55–0.75 micron) and the IR (10.5–12.5 micron). Because of the IR, it was possible to image during the day and night.

Synchronous Meteorological Satellites. NASA launched two synchronous meteorological satellites (SMS), SM-1 in May 1974 and SMS-2 in February 1975, to demonstrate their use for weather forecasting. After the successful launch of these satellites, NASA turned the program over to NOAA for operation, and they were renamed geostationary operational environmental satellites (GOES).

Geostationary Operational Environmental Satellites (GOES). GOES satellites are a mainstay of weather forecasting in the United States. They are the backbone of short-term forecasting or "now casting." The real-time weather data gathered by GOES satellites, combined with data from Doppler radars and automated surface observing systems, greatly aid weather forecasters in providing warnings of thunderstorms, winter storms, flash floods, hurricanes, and other severe weather. These warnings help to save lives and preserve property.

The United States operates two meteorological satellites in geostationary orbit, one over the East Coast and one over the West Coast, that give overlapping coverage of the United States. Currently, GOES-8 and GOES-10 are in operation. The GOES satellites are a critical component of the ongoing National Weather Service modernization program, aiding forecasters in providing more precise and timely forecasts. The next GOES-11 satellite (GOES-L) launched in 2000 is stored in orbit, and GOES-12 launched in 2001 is also stored in orbit. They will be activated when one of the current GOES satellites fails. They are the first of the NOAA satellites equipped with a solar X-ray imager (SXI), an instrument that can detect solar storms.

See also **Geostationary Operational Environmental Satellite (GOES)**.

Defense Meteorological Satellite Program (DMSP)

Since the mid-1960s, the U.S. Air Force has operated polar-orbiting meteorological satellites. The observations have emphasized high-resolution and low-light imaging rather than atmosphere profiling. The DMSP system maintained two satellites at any given time that crossed the equator in mid-morning and late evening. Some of the later satellites carried microwave imaging and sounding units; some improved versions of these instruments were incorporated in the NOAA polar operational satellites. So far, about 20 DMSP satellites have been flown, primarily for use by the Defense Department.

International Program Cooperation

In the 1980s, NOAA had to balance the high cost of space systems and the growing need to provide a complete and accurate description of the atmosphere at regular intervals as inputs to numerical weather prediction and climate monitoring support systems. This led NOAA to enter into discussions and agreements at the international level with the European Organization for the Exploitation of Meteorological Satellites (EUMETSAT). The goal of this cooperation is to provide continuity of

measurements from polar orbits, cost sharing, and improved forecast and monitoring capabilities by introducing new technologies.

Several countries recognized the advantages of monitoring Earth and its environment from space and have launched both polar-orbiting and geosynchronous satellites. The operators include the European Space Agency (a consortium of several European countries), Japan, Russia, India, and China. Under an agreement reached by the satellite operators under the auspices of the World Meteorological Organization (a U.N. agency in Geneva, Switzerland), the locations of geosynchronous satellites were distributed to provide global coverage. Thus, the two U.S. satellites, a European satellite, a Japanese satellite, and a satellite from India provide complete coverage continuously from about 60°N to 60°S. Satellite data sets and products were coordinated to ensure maximum compatibility among the operators of the geosynchronous satellites.

Russia (the former Soviet Union) has launched a series of polar-orbiting satellites in the Meteor series to obtain cloud cover, snow and ice extent, and the Earth radiation budget, and also a few sounding instruments to measure the vertical distribution of temperature and moisture for weather prediction models.

Remote Sensing

Satellites by their nature have to rely on remote sensing. The fundamentals are elaborated in a number of books. We will discuss the subject in four topics:

1. reflection and scattering of solar radiation
2. thermal emission from the surface and from the atmosphere
3. active probing using radar and lidar
4. other applications

Reflection and Scattering of Incident Solar Radiation. This can take place at wavelengths ranging from the near-infrared (IR) around 3 microns down to the near-ultraviolet of about 0.28 microns. Beyond 2 microns, there are important IR absorption bands, principally from water vapor, carbon dioxide, and from other minor atmospheric constituents (Fig. 3)

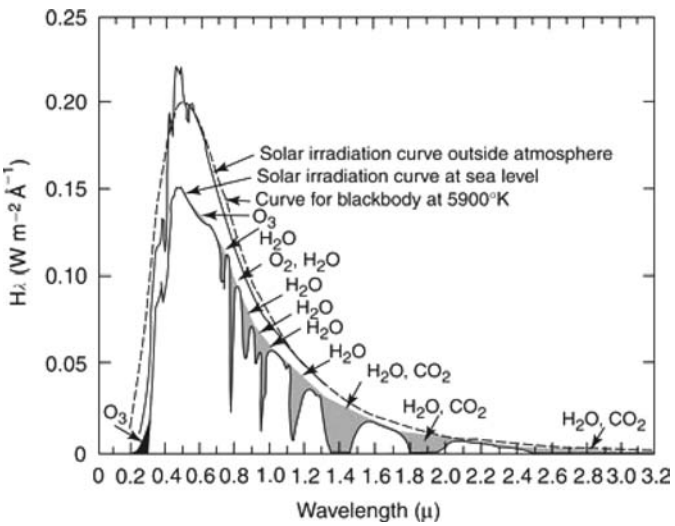

Fig. 3. Spectral curves of solar radiation incident at the top of the atmosphere and at the surface of Earth for the Sun at zenith on a clear, cloud-free day (*courtesy of Air Force Cambridge Research Laboratories, 1965*).

The most important reflection comes from clouds in the atmosphere and snow and ice on the surface. The reflection coefficient, the so-called albedo, approaches 100% in many cases. On the other hand, the albedo of the ocean is less than 10% except for areas of "sun glint" where the reflection is specular. The patterns of reflection and their changes with time lend themselves to meteorological analysis, as discussed in the next section.

In addition to meteorological applications for weather prediction, observations of so-called aerosols, including dust, smoke, and even locust swarms, yield important information for a variety of purposes. In addition, spectral data at different wavelengths (color) can give information about agricultural crops, the health of forest systems, ocean productivity, and even about the mineral content of the soil. As discussed in specialized texts, measurement of the polarization of reflected and scattered light yields additional information about the optical and physical properties of the scattering medium.

Backscattered radiation in the near UV region between 0.28 and 0.32 microns can be used to measure the amount and vertical distribution of stratospheric ozone. This technique was analyzed before satellites were launched and was first tested on Nimbus. It has now become operational and is used to monitor ozone worldwide, including tracking the Antarctic ozone hole. Sulfur dioxide gas emitted by volcanoes into the stratosphere also absorbs strongly in the near ultraviolet; but by choosing the right wavelengths and adequate spectral resolution, one can distinguish between ozone and sulfur dioxide.

Emission from the Atmosphere and Surface. Corresponding to the lower temperature of the surface and atmosphere, compared to the Sun, the emission wavelength range covers from about 4 microns into the far infrared beyond 20 microns and also the microwave region. The important feature here is the so-called "window" of the atmosphere. In the absence of clouds, IR emission from the surface in the region between 8 to 12 microns can penetrate the atmosphere and escape into space where it is observed by a satellite. (Fig. 4). Outside the window region, the atmosphere is opaque in the infrared because of strong absorption bands, principally from water vapor and carbon dioxide. (There is also absorption by stratospheric ozone at 9.6 microns in the window region.) Water droplets absorb and emit strongly in the infrared so that IR detectors from the satellite view only the tops of clouds. Because temperature decreases sharply in the troposphere, the IR emitted from cloud tops can be used to obtain an estimate of the pressure and altitude of the cloud tops.

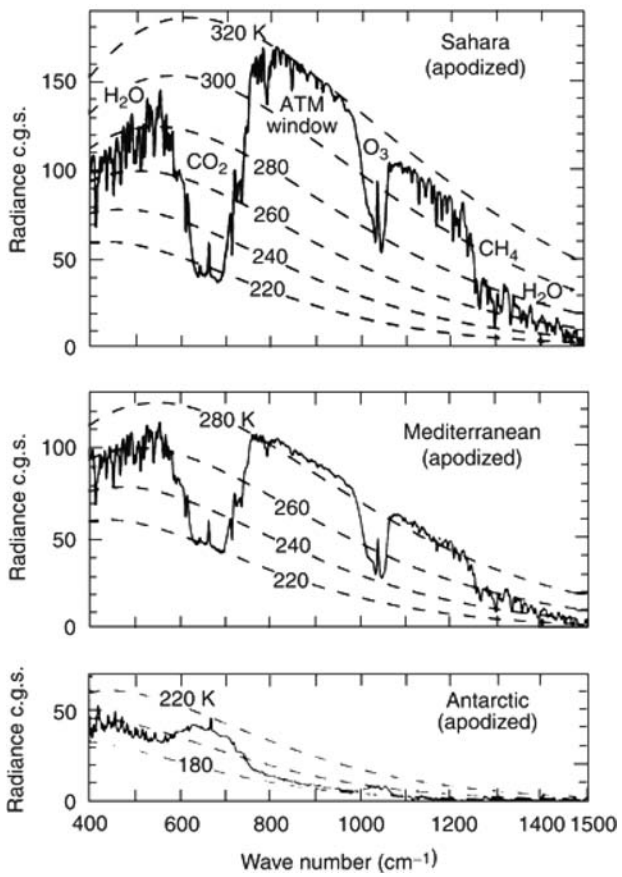

Fig. 4. Spectra of the radiation emitted by the Earth–atmosphere system, as seen by the Nimbus satellite above three different points on Earth. Radiance units (cgs) are erg·s^{-1} · cm^{-2} · sr^{-1}/cm^{-1} (*from Conrath, B.J., et al. Vertical sounding of the atmosphere with the Nimbus IV infrared experiment. Proc. 21st Astronaut. Congr., 1971, North Holand, p. 1010*).

The great advantage of infrared emissions is that they can be measured at night and are easier at that time. During the day, there is some interference from solar radiation in the infrared. In the absence of clouds, under clear sky conditions, one can measure the surface temperatures of the ground and soil and get some determination of soil moisture from the diurnal variation. Information from the surface of the ocean provides a measure of temperature; however, it relates to the skin of the sea surface and is heavily influenced by the sea state, foam, wave action, and therefore surface winds. In addition, one has to be careful in comparing IR measurements of SST with measurements from ships because they refer to different layers of the upper ocean.

When the atmosphere is clear, and there are no clouds, infrared emissions from the 15-micron band of carbon dioxide can be used to derive the vertical distribution of temperature in the atmosphere. This method was first suggested by Lewis Kaplan and was worked out in greater detail by David Wark and others at the NWSC and by Rudolph Hanel and Wm Bandeen at NASA. Mathematically, the problem is that of determining the kernel of an integral, when the integrals are observed at several wavelengths around 15 microns. This deconvolution problem also enters into the determination of atmospheric temperature distribution from microwave measurements. (The latter have an advantage over IR measurements because they can be carried out in the presence of clouds.) A similar problem occurs in measuring the vertical distribution of ozone; it is somewhat simpler because in the UV, only scattering and absorption are important but not emission.

Infrared radiation from the surface can provide interesting information on ground cover vegetation and can measure desertification. The Hyperion instrument on the NASA Earth Observing-I satellite, launched in November 2000, collects reflected radiance in 220 spectral bands covering the range from 0.4–2.5 microns. Preliminary research results are reported in the Asner and Green Ref.; it is not clear yet whether this will lead to operational use of the technique.

Measuring the emission of microwaves from the surface and from the atmosphere has proven to be immensely useful. An early experiment in 1964 measured emission from the sea surface and demonstrated that the energy emitted, hence the emissivity, depended primarily on the sea state.

Microwaves can measure such quantities as snow cover, precipitation, and thunderstorms. Thermal microwave emission from water vapor can be used to measure atmospheric humidity, an important quantity for studying global climate change. Microwave emission from molecular oxygen can be used to measure the bulk temperature of the troposphere and the lower stratosphere, as demonstrated in careful analyses by Christy and Spencer. As discussed later, satellite microwave data indicate that the atmosphere has not warmed perceptibly since global temperature observations began in 1979.

Active Probing with Laser and Radar. Radar reflection from the sea surface can determine the sea state and thereby surface winds. This has become an operational application because wind field patterns play an important role in weather prediction. Radar reflection from the land surface can produce accurate determinations of topography, including even snow depth. Finally, radar can be used to measure precipitation, especially useful over the oceans where other observations are not available. Satellite-borne synthetic aperture radar (SAR) has been used in many applications (see the Applications Section below). A recently reported use is detecting of urban sewage and storm water runoff from urban areas that cause marine pollution.

Radar scatterometers have provided nearly continuous coverage of Earth since 1991 on satellites of NASA, European Space Agency (ESA), and Japan. Frequencies have ranged from 5.3 to 14.6 GHz, and both vertical and horizontal polarization were measured. Applications include Greenland and Antarctic ice sheets, sea ice, soil moisture, and vegetative coverage.

Laser measurements are still in their infancy. Ideally, one would like to measure the Doppler shift of reflections from particles in the atmosphere and thereby deduce horizontal wind velocities.

Another application, still on the drawing board, uses the absorption in the D-band of oxygen molecules around 0.76 microns to measure surface pressure in the absence of clouds. When clouds are present, the technique measures the pressure and altitude of cloud tops. Combined with the temperature of the cloud tops, this amounts to vertical probing of the atmosphere. Systems analysis shows that internal noise is negligible and that background is not serious, even in daylight. Compared with the corresponding passive method using the Sun as a source, the laser method can be used at night, can discriminate cloud versus surface reflections, and may be able to determine altitude, pressure, and (by IR flux measurement) the temperature at selected points in the atmosphere. If successful, the method will have important applications to cloud studies and to oceanography.

Other Applications of Remote Sensing. More refined measurements, based on wavelength dependence, polarization measurements, and time variability, can be used to deduce such important quantities as soil moisture, ocean productivity, and the properties and nature of aerosols, such as size distribution and their optical parameters.

Besides weather satellites, other kinds of satellites can also supply data important for meteorology. For example, the Global Positioning System can be used to measure upper tropospheric water vapor by studying the time delays at the two different radio frequencies used by GPS. The TOPEX satellite can be used to measure the height of the sea surface, from which one can derive the location and strength of ocean currents. Finally, astrophysical satellites can measure solar radiation, its variability in the visible and ultraviolet, and the nature and flux of solar particulate radiation impacting on Earth's atmosphere.

See also **Global Positioning System (GPS)**.

Applications

The earliest meteorological results from TIROS were published in three articles soon after launch. By the end of April 1960 (almost 30 days after launch), a number of case studies of meteorological phenomena observed by TIROS were begun by a team of meteorologists in the Meteorological Satellite Section of the USWB. These studies included several large-scale cyclonic vortices over the United States, the North Atlantic, and the North Pacific; cloudiness in the tropical regions of the South Pacific; cellular arrangements of cumulus clouds over the Atlantic and Pacific Oceans in temperate latitudes; cloud streets in the Caribbean, cloudiness associated with severe thunderstorms and tornadoes; ice in the Gulf of St. Lawrence; orographic clouds in various parts of the world; snow cover in mountain regions; and sun glitter on the ocean surface. Several technical reports were published by USWB and NASA in the following months.

The TIROS pictures received at the ground stations were recorded on 35-mm film by a kinescope camera, either during a satellite readout or by playing back the data recorded on magnetic tape. The film was processed immediately to make transparencies for projection and for prints. Geographic reference grids were overlaid on these pictures to determine the location where the pictures were taken. These overlay grids were generated by taking into account the position of the satellite, the time when the picture was taken, the direction in which the camera was pointing, and other parameters connected with the satellite spin axis. Once the grids were overlaid on the pictures, cloud analyses (called nephanalyses) could be performed, showing cloud types and extent of coverage. These maps were sent by facsimile to weather stations around the globe for immediate use. Within 48 hours of the TIROS-1 launch, such pictures and nephanalyses were made available to USWB meteorologists, the U.S. Air Weather Service, and the U.S. Naval Weather Service. The information was limited to areas where sunlight was available.

The introduction of infrared sensors in radiometers on TIROS-2 and the follow-on satellites, starting from November 1960, enabled continuous day and nighttime coverage. Three types of instruments were used: (*1*) a five-channel scanning radiometer, (*2*) a two-channel medium-resolution radiometer, and (*3*) a two-channel omnidirectional radiometer. Of the three instruments, the five-channel one was the most important. It consisted of the following:

1. 5.9–6.7 μm to measure atmospheric water vapor (based on strong absorption in this spectral region);
2. 8 to 12-μm atmospheric window to measure surface temperatures under cloud-free conditions and cloud temperatures and heights and to obtain nighttime images;
3. 0.2–5 μm to measure the albedo of the earth, clouds, etc. (reflectance);
4. 7.0–30 μm to measure the total outgoing long-wave radiation at the top of the atmosphere;

Fig. 5. This image of Hurricane Andrew approaching southwest Florida on August 23, 1992, was generated using the AVHRR instrument in its high-resolution imaging mode. (*courtesy of NOAA*).

5. 0.5–0.7 μm in the visible part of the spectrum to measure the reflected radiation and create images during the daytime.

The sensors were mounted in the satellite at an angle of 45° to the spin axis of the satellite. The scan was produced by the spin of the satellite. The movement of the satellite provided coverage along the track. Because of the spin of the satellite, the sensors looked alternatively at space and at Earth. The field of view of the radiometer was approximately 30 miles.

All of these radiometer measurements were stored in the tape recorder on board the satellite and transmitted to the ground station after each orbit. The data were processed after reception at the ground station. Based on the experience gained from these early measurements, various changes were made in the follow-on instruments, which will be discussed later.

The inclusion of infrared radiometers on TIROS added extra capabilities. For example, the measurements in the 8- to 12-μm channels provided an estimate of cloud top temperatures, and thus one could infer the cloud top heights. One of the early studies by Rao and Winston showed the cloud top temperatures and cloud heights determined over the United States using the TIROS-2 radiation data. The researchers compared the results with synoptic and aircraft data and found good agreement. It was also pointed out in this paper that the 8- to 12-μm window region is not clean and there is a considerable amount of absorption due to water vapor and ozone; thus appropriate corrections needed to be applied.

Satellite pictures were also used to observe and map the ice cover over the Gulf of St. Lawrence and the Great Lakes. These pictures were useful for navigation by showing the leads in the ice cover. Another important application was to monitor the extent of snow cover during winter and the melting of snow during spring. The snow cover information was useful for hydrological forecasting.

In the early days of the satellite program, it was realized that in addition to the cloud information, the temperature and moisture distribution with height in the atmosphere is essential for forecasting. Numerical modeling of the atmosphere was gaining momentum at this time, and observations over the vast oceanic regions and other data-void regions of the world were needed to fill the gaps in these models. A prototype instrument called the satellite infrared spectrometer (SIRS) was under development within the Meteorological Satellite Laboratory. The first sounder was on the Nimbus satellite launched in 1969. Observations from the SIRS instrument were used to derive the vertical distribution of temperature (and, to a limited extent, moisture) over the oceanic regions. The satellite-derived soundings were useful for numerical weather forecast models, particularly over the oceanic regions, where radiosonde data are not available. NASA was also developing another sounder at the same time, called the vertical temperature profiling radiometer (VTPR). Because of the high spectral resolution of the VTPR, it was superior to the SIRS. Immediate plans were made to improve the VTPR instrument to operational status and move it to the NOAA polar satellites. The first operational sounder was launched on NOAA-2 in 1972. The sounders continued on all polar-orbiting satellites from that period.

In addition to the visible and infrared portions of the spectrum, satellites also started to exploit the ultraviolet, using the backscatter technique to measure the amounts and vertical distribution of ozone. Such instruments as TOMS and SBUV were first flown on Nimbus. They were then transferred to the operational weather satellites.

Satellites have also exploited another region of the electromagnetic spectrum, measuring the passive (thermal) emission of microwaves from the surface and from atmospheric components. An early experiment, conducted from a blimp over Biscayne Bay, Florida, demonstrated the high emissivity from foam produced by waves (and thus the sea state). Nowadays, active microwave (radar) determines the sea state by scattering.

A comprehensive account of weather satellite applications is given in various references. Here we will provide three examples to demonstrate the wide range of results obtainable by remote sensing from satellites. These images were made using the advanced very high resolution radiometer on POES spacecraft. Figure 5 is a picture of Hurricane Andrew. Figures 6 and 7 is a picture of Hurricane Floyd. This is an example of the high-resolution pictures of various weather patterns that can be made by using satellite-borne instruments.

Climate Studies

Weather satellite instruments were not designed to determine long-term trends of atmospheric parameters. Changes over decadal timescales generally require using instruments from different satellites and careful calibration. Yet, with great care it has been possible to use much of the data for such purposes.

Four kinds of measurements are possible; the first two refer to the atmospheric energy balance:

1. Albedo measurements over long time spans can, in principle, determine any changes in the energy input to Earth. Calibration is quite difficult here, but attempts have been made to establish long-term trends in cloudiness and surface albedo through changes in human land use.
2. The converse measurement measures the outgoing long-wave radiation (OLR) from Earth, including the IR emitted from the surface through the atmospheric window and the IR emitted from the atmosphere, mainly from upper tropospheric water vapor, carbon dioxide, and clouds.
3. Rather than concentrate on the energy balance, a complementary technique monitors long-term changes in global atmospheric temperature.

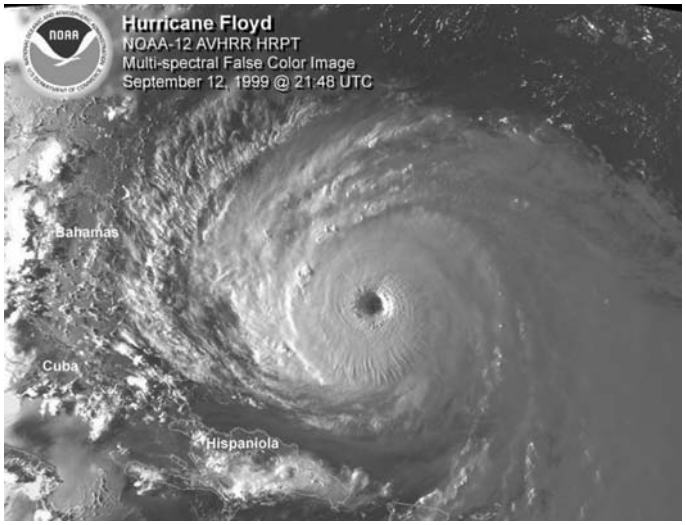

Fig. 6. Hurricane Floyd–impressive image of Floyd approaching the Bahamas on September 12, 1999. (*courtesy of NOAA*).

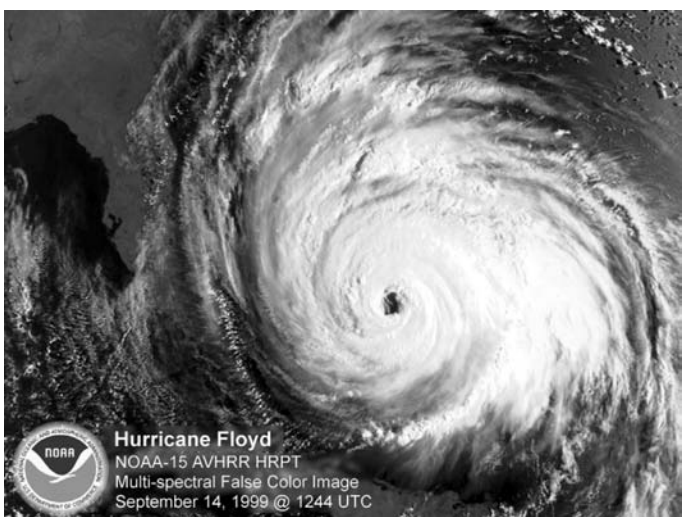

Fig. 7. Hurricane Floyd over the Bahamas on the morning of September 14, 1999. (*courtesy of NOAA*).

For this purpose, the microwave sounding unit (MSU) carried by weather satellites has turned out to be the principal instrument. There is no perceptible trend in global mean temperature since observations started in 1979. Surface observations from weather stations do show a warming during the same period; this discrepancy has not yet been resolved. However, independent data from radiosondes in weather balloons confirm the satellite data that there has been no atmospheric warming. Proxy data of surface temperature from tree rings and ice cores also show no surface warming trend since about 1940. Thus the preponderance of data indicates little if any warming in the last 60 years.

4. Finally, thanks to satellites, it may possible to measure long-term changes in global precipitation, particularly over the oceans where there are no good data. We do have long-term measurements of severe storms and tropical cyclones; land observations and also satellites have so far shown no clearly established trends. As reported, the intensity and frequency of North Atlantic hurricanes has decreased. There has been no report of discernible trends for severe storms, El Niños, and similar meteorological phenomena.

Continuity and Future of Operational Satellite Programs

Figure 8 shows the planned launch of polar-orbiting and geostationary operational satellites. It should be emphasized that the actual schedules will depend primarily on the need for replacement satellites, the availability of spacecraft, and a launch vehicle. It is also assumed that the new generation of satellites will have a 5-year life expectancy and that all launches are successful. It should be pointed out that the satellites designated by letter are designated by a number after a successful launch (e.g., GOES-N to GOES-13; NOAA-M to NOAA 17).

The U.S. government has traditionally maintained two operational weather satellite systems; each has a 30-plus year history of successful service: NOAA's polar-orbiting operational environmental satellite (POES) and DOD's Defense Meteorological Satellite Program (DMSP). Recent changes in world political events and declining agency budgets prompted a reexamination of combining the two systems.

In May 1994, President Clinton signed a presidential directive to merge the civilian POES system and the DMSP into a single system to reduce costs, while continuing to satisfy the U.S. operational requirements. On 3 October 1994, NOAA, DOD, and NASA created an Integrated Program Office (IPO) to develop, manage, acquire, and operate the NPOESS system. The Integrated Program Office concept provides each of the participating agencies with lead responsibility for one of three primary functional areas. NOAA has overall responsibility for the merged system and is also responsible for satellite operations. NOAA is also the primary interface with the international response and civil user communities. DOD is responsible for supporting the IPO for major systems acquisitions, including launch support. NASA has primary responsibility for facilitating the development and incorporation of new cost-effective technologies into the merged system. Although each agency provides certain key personnel in their lead roles, each functional division is staffed by triagency work teams to maintain the integrated approach.

As an early step in the merging process and the first tangible result of the NPOESS effort, Satellite Control Authority for the existing DMSP satellites was transferred in May 1998 from the U.S. Air Force Space Command to the NPOESS Integrated Program Office. The command, control, and communications functions for the DMSP satellites have been combined with the control for NOAA's POES satellites at NOAA's Satellite Operations Control Center (SOCC) in Suitland, Maryland. The DMSP satellites are being "flown" by civilian personnel at the SOCC. This is the first time in the 30-plus-year history of this DOD program that DMSP satellites have not been flown by Air Force personnel. A backup satellite operations center manned by USAF crews is also contemplated.

On 13 December 1999, a new Department of Defense meteorological satellite was launched by the U.S. Air Force and is being operated by NOAA. The satellite is the next in a series of the Defense Meteorological Satellite Program. This is the first DMSP whose postlaunch checkout was conducted from NOAA's Satellite Operations Control Center in Suitland, Maryland.

The NPOESS Preparatory Project (NPP) is a proposed joint mission to extend key measurements in support of long-term monitoring of climate trends and of global biological productivity. It extends the measurement series being initiated with EOS Terra (MODIS) and EOS PM (AIRS, AMSU, HSB) by providing a bridge between NASA's EOS missions and the NPOESS system. The NPP mission will provide operational agencies with early access to the next generation of operational sensors, thereby greatly reducing the risks incurred during the transition. This will permit testing of advanced ground operations facilities and validation of sensors and algorithms while the current operational systems are still in place. This new system will provide nearly an order of magnitude more data than the current operational system. Launch is planned for late 2005. As a result of 5-year design lifetime, NPP will provide data past the planned lifetime of EOS Terra and EOS PM and into the expected launch of the first NPOESS satellite. The proposed NPP mission is currently in the formulation phase.

The first merged NPOESS satellite is expected to be available for launch in the latter half of the decade, approximately 2008, depending on when the remaining POES and DMSP program satellite assets are exhausted. NPOESS will provide significantly improved operational capabilities and benefits to satisfy the nation's critical civil and national security requirements for space-based, remotely sensed environmental data. NPOESS will deliver higher resolution and more accurate atmospheric and oceanographic data to support improved accuracy in short-term weather forecasts and warnings and severe storm warnings, as well as to serve the data continuity requirements of the climate community for improved climate prediction and assessment. NPOESS will also provide improved measurements and

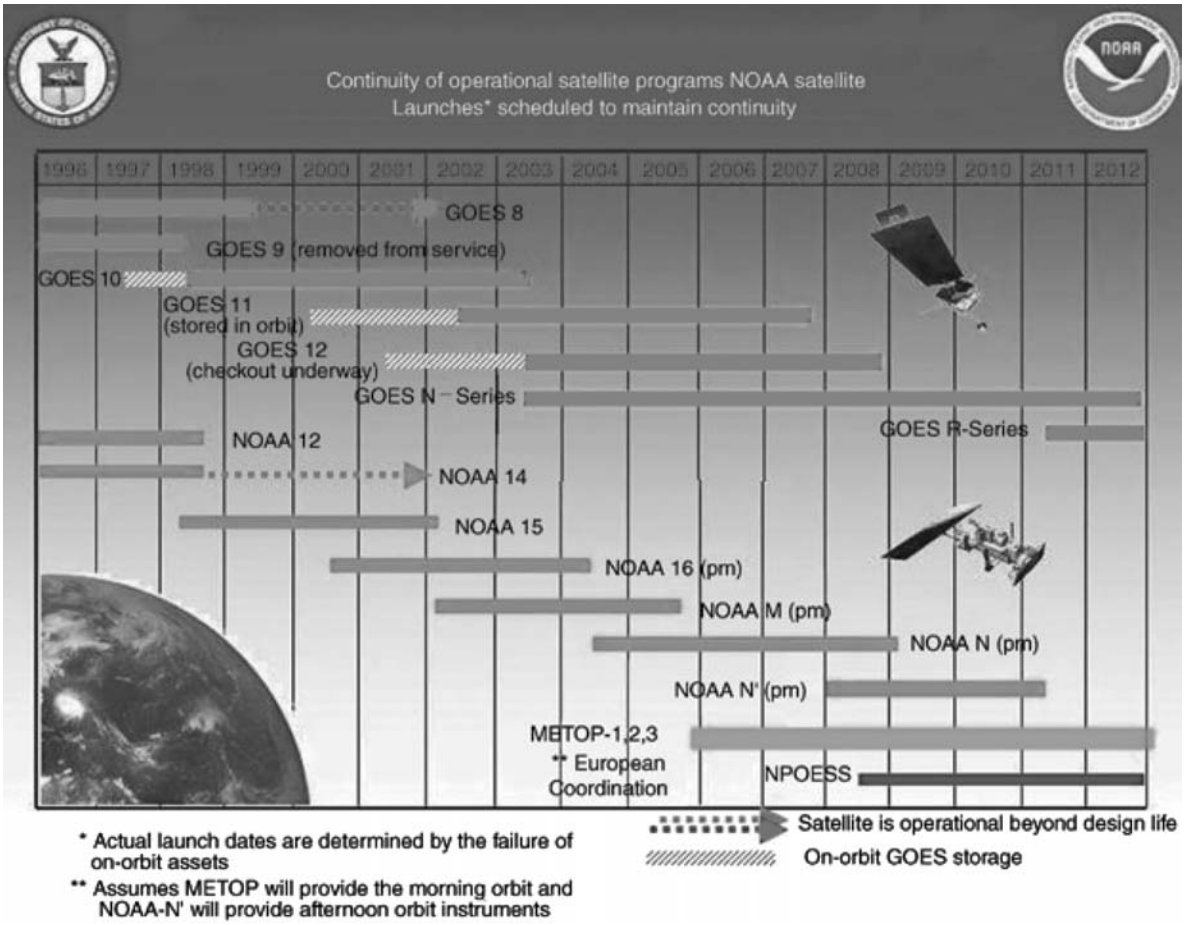

Fig. 8. Continuity of Operational Satellite Programs. NOAA satellite launches scheduled to maintain continuity (*courtesy of NOAA*).

information about the space environment necessary to ensure reliable operations of space-based and ground-based systems and will continue to provide surface data collection and search and rescue capabilities.

NPOESS Instruments

The NPOESS satellites will carry six instruments designed to revolutionize weather forecasting and climate research:

1. Visible/infrared imager/radiometer suite (VIIRS). This sensor is arguably the most important in the entire NPOESS blueprint. It will spot smoke from forest fires, ash from volcanoes, and the rain bands of hurricanes. Images from VIIRS will show up on the nightly news and the Weather Channel. VIIRS will replace the advanced very-high-resolution radiometer (AVHRR) on the existing POES satellites. VIIRS will divide light into 22 channels, compared to six for AVHRR.
2. Conical microwave imager/sounder (CMIS). The advantage of CMIS is that it can see through clouds. It will detect microwave radiation emitted from the surface of the ocean and from the atmosphere. It will replace the special sensor microwave imager on DMSP and the microwave imager on NASA's TRMM satellite.
3. Crosstrack infrared sounder (CrIS). CrIS is the primary instrument for measuring the temperature, moisture, and pressure of the atmosphere. It will replace the high-resolution infrared sensor on POES.
4. GPS occultation sensor (GPSOS). GPSOS will measure the atmospheric refraction of radio signals from the GPS satellite constellation and from the Russian Global Navigation Satellite System.
5. Ozone mapping and profiler suite (OMPS). OMPS measures the vertical and horizontal distribution of ozone. It will aid studies of the seasonal ozone hole over Antarctica and the thinning ozone layer over the Arctic.
6. Space environment sensor suite (SESS). SESS measures particles in the upper reaches of the atmosphere that can damage satellites. It will measure neutral and charged particles, electrons, and magnetic fields, and the optical signatures of the aurora phenomenon.

The European Organization for the Exploitation of Meteorological Satellites (EUMETSAT) has also joined the consortium and will provide the first European meteorological operational satellite in polar orbit, called METOP, in 2004. It is planned to carry many instruments provided by the United States and will provide early morning and late evening coverage. Initially three satellites are planned in this series.

WEATHER SURVEILLANCE RADAR-1988 DOPPLER (WSR-88D). The weather radar, sometimes called NEXRAD (Next Generation Weather Radar Program) that became the operational network radar for the U.S. National Weather Service, U.S. Air Force, and Federal Aviation Administration during the early and middle 1990s. It is a general-purpose weather radar with a wavelength of 10.5 cm, a peak power of 750 kW, selectable pulse duration of 1.57 or 4.0 μs, and selectable pulse repetition frequency from 318 to 1304 Hz. A coherent Doppler radar, it employs a center-fed parabolic antenna with a diameter of 8.5 m, producing a beamwidth of 0.95°. Received signals are analyzed using the method of pulse-pair processing to give as fundamental data the reflectivity factor, mean Doppler velocity, and Doppler spread as functions of time and location relative to the radar. The maximum unambiguous range is ordinarily 460 kilometers (286 miles) for reflectivity and 115 kilometers (71 miles) for Doppler information. Many kinds of computer algorithms are employed for identifying features such as vortices, downbursts, and fronts.

WEATHER TECHNOLOGY. The practical application of the disciplines of meteorology, hydrology, and climatology, greatly assisted by the computer and communication sciences, to short- and medium-term forecasting of the weather. Forecasting responsibilities in the United States fall under the umbrella of the **National Oceanic and Atmospheric Administration** (NOAA, pronounced *Noah*) http://www.noaa.gov/ of which, the **National Weather Service** (NWS) http://www.nws.noaa.gov/, is a part. Day-to-day operations for NWS are handled by the **National Centers for Environmental Prediction** (NCEP) http://www.ncep.noaa.gov/ located in Camp Springs, Maryland. The National Centers for Environmental Prediction (NCEP) is . . . Where America's Climate and Weather Services Begin". Virtually all the meteorological data collected over the globe arrives at NCEP, where environmental scientists analyze this information and generate a wide variety of environmental guidance information. NCEP delivers national and global weather, water, climate and space weather guidance, forecasts, warnings and analyses to a broad range of users and partners. These products and services respond to user needs to protect life and property, enhance the nation's economy, and support the nation's growing need for environmental information.

Under the direction of Dr. Louis W. Uccellini, NCEP has embarked on a Strategic Plan for 2005-2009 http://www.ncep.noaa.gov/director/strategic_plan/strategic_plan.pdf. To meet the future needs of the ever-broadening user community and address the strategic climate-water-weather issues, NCEP is developing a "Seamless Suite of Products". The "Seamless Suite" describes a set of related products that are integrated and consistent throughout time and space, as well as across forecast applications and domains. It spans service programs and benefits from enhancements derived from the unprecedented and ongoing explosion of scientific and technological advances within the research community.

Aviation Weather Center (AWC). The function of the Aviation Weather Center (AWC) is to save lives, protect property and enhance commerce by issuing warnings of hazardous conditions within the domestic and international airspace and by issuing operational aviation forecasts and analyses of relevant atmospheric variables. The AWC prepares all NWS domestic and international aviation products, except for terminal forecasts and transcribed weather broadcasts, which are produced by the Weather Forecast Offices, and for certain products for the Alaska and Pacific Regions. The AWC serves as a national source for aviation weather information. http://aviationweather.gov/.

Climate Prediction Center (CPC). http://www.cpc.ncep.noaa.gov/ The Climate Prediction Center's products are operational predictions of climate variability, real-time monitoring of climate and the required data bases, and assessments of the origins of major climate anomalies. The products cover time scales from a week to seasons, extending into the future as far as technically feasible, and cover the land, the ocean, and the atmosphere, extending into the stratosphere.

These climate services are available for users in government, the public and private industry, both in this country and abroad. Applications include the mitigation of weather related natural disasters and uses for social and economic good in agriculture, energy, transportation, water resources, and health. Continual product improvements are supported through diagnostic research, increasing use of models, and interactions with user groups.

The roots of modern climate prediction can be traced to the late 1700's. One of the nation's first applied climatologists was Thomas Jefferson, the third President of the United States. A century later, the federal government assigned to the Army Signal Corps the mission to define the climate of the regions of the country being opened for farming.

In 1890, the United States Department of Agriculture (USDA) created the Weather Bureau climate and crops services which began publishing the Weather and Crops Weekly Bulletin, which the CPC in conjunction with the USDA still publishes today.

In 1970, various federal weather and climate functions were consolidated into the National Weather Service (NWS) and placed in a new agency called the National Oceanic and Atmospheric Administration (NOAA). In the 1980's the National Weather Service established the Climate Prediction Center (CPC), known at the time as the Climate Analysis Center (CAC). The CPC is best known for its United States climate forecasts based on El Niño and La Niña conditions in the tropical Pacific.

6–10 Day, and 8–14 Day Temperature and Precipitation outlooks, are issued daily between 3pm & 4pm Eastern Time. All forecasts issued on weekends are completely automated while all weekday outlooks are modified by the forecaster. http://www.cpc.ncep.noaa.gov/products/predictions/610day/ and www.cpc.ncep.noaa.gov/products/predictions/814day/

Official 90-day Forecasts are released on the third Thursday of the month, which varies from as early as the 15th to as late as the 21st, depending on the calendar. While the forecast is generally released and available on the WWW around 8:30AM Eastern Time on a scheduled release date, users are reminded that the Internet is not recommended for time-critical applications as it is not maintained by the National Weather Service as an operationally dependable distribution venue. http://www.cpc.ncep.noaa.gov/products/predictions/schedule.html

The U.S. Hazard Assessment is intended to provide emergency managers, planners, forecasters and the public advance notice of potential hazards related to climate, weather and hydrological events. It integrates existing NWS official medium (3-5 day), extended (6-10 day) and long-range (monthly and seasonal) forecasts and outlooks, and hydrological analyses and forecasts, which use state-of-the-art science and technology in their formulation. http://www.cpc.ncep.noaa.gov/products/predictions/threats/threats.html

On each Thursday, the CPC, together with the United States Department of Agriculture, the National Drought Mitigation Center in Lincoln, Nebraska, and NOAA's National Climatic Data Center, issues a weekly drought assessment called the United States Drought Monitor. The Monitor provides a consolidated depiction of national drought conditions based on a combination of drought indicators and field reports. The CPC issues the U.S. Seasonal Drought Outlook each month in conjunction with the release of the long-lead temperature and precipitation outlooks on the third Thursday of each month. Interim revisions of the Drought Outlooks may be issued at other times if conditions warrant. http://www.cpc.ncep.noaa.gov/products/expert_assessment/drought_assessment.shtml

Environmental Modeling Center (EMC). http://www.emc.ncep.noaa.gov/. The Environmental Modeling Center (EMC) improves numerical weather, marine and climate predictions at the National Centers for Environmental Prediction (NCEP), through a broad program of research in data assimilation and modeling. In support of the NCEP operational forecasting mission, the EMC develops, improves and monitors data assimilation systems and models of the atmosphere, ocean and coupled system, using advanced methods developed internally as well as cooperatively with scientists from Universities, NOAA Laboratories and other government agencies, and the international scientific community.

The Global Climate and Weather Modeling Branch, conducts a program of research and development in support of the National Centers for Environmental Prediction (NCEP) operational forecasting mission for global prediction. This research and development in global modeling includes four dimensional data assimilation of satellite and conventional observations on a global scale, advanced numerical techniques for modeling the atmosphere and interactions between the atmosphere, ocean and land surfaces, parameterization of sub-grid scale processes in the atmosphere, ocean and land surfaces, development of a climate data assimilation system and reanalysis studies for archival and use by the scientific community, international aviation product development, diagnostic studies of global model performance, data quality control and evaluation of new observing systems, and support for tropical prediction. The Global Climate and Weather Modeling Branch publishes research results in various media for dissemination to the world oceanographic and meteorological community. http://www.emc.ncep.noaa.gov/gc_wmb/

The Mesoscale Modeling Branch conducts a program of research and development in support of the National Centers for Environmental Prediction (NCEP) operational forecasting mission for mesoscale prediction. This research and development includes mesoscale four-dimensional data assimilation of domestic satellite and conventional observations, advanced numerical techniques applied to mesoscale modeling problems, parameterization of mesoscale atmospheric processes and interactions between the atmosphere, ocean and land surfaces, diagnostic studies of model performance, domestic aviation product development, support for hurricane prediction, mesoscale data quality control and data impact studies to evaluate potential improvements in forecast skill with new observing systems. The Mesoscale Modeling Branch publishes research results in various media for dissemination to the world oceanographic and meteorological community. http://polar.ncep.noaa.gov/

The Marine Modeling and Analysis Branch is part of the Environmental Modeling Center, which is responsible for the development of improved numerical weather and marine prediction modeling systems within NCEP/NWS. It provides analysis and real-time forecast guidance (1-16 days) on marine meteorological, oceanographic, and cryospheric parameters over the global oceans and coastal areas of the US. The branch evaluates quality of retrievals of ocean surface data from satellite borne sensors, improve their quality as needed, and examine the impacts of the data on forecast models, and monitor performance of operational guidance products. http://polar.ncep.noaa.gov/

Hydrometeorological Prediction Center. http://www.hpc.ncep.noaa.gov/ The mission of the HPC is to provide forecast, guidance, and analysis products and services to support the daily public forecasting activities of the NWS and its customers, and to provide tailored support to other government agencies in emergency and special situations. The primary functions of the HPC include:

Quantitative Precipitation Forecasts (QPF). The QPF desk prepares and issues forecasts of accumulating (quantitative) precipitation, heavy rain, heavy snow, and highlights areas with the potential for flash flooding. The basic QPF products are primarily directed to the NWS's forecast offices, but are available for anyone to use. The heavy snow forecast products, in association with the short-range public forecast products (described below), serve as a coordinating mechanism for the NWS's winter storm watch and warning program. Through a continuous watch for excessive rainfall, heavy snow, and winter storms, this desk ensures that the highest quality forecast products are constantly available. http://www.hpc.ncep.noaa.gov/qpf/qpf2.shtml

The QPF desk is co-located with the National Environmental Satellite Data and Information Service (NESDIS), and together they comprise the National Precipitation Prediction Unit (NPPU). NESDIS meteorologists prepare estimates of rainfall and current trends, based on satellite data and this information is used by the QPF short term forecaster as part of the input for individual 6-hourly forecasts that cover the next 12 hours. With access to WSR-88D/Doppler radar data, satellite estimates, and NCEP model forecast data as well as current weather observations and HPC analyses, the forecaster has the latest data for use in preparation of short-range precipitation forecasts. Meteorological reasoning discussions are regularly written and issued with the forecast packages to explain and support the forecast.

Medium-Range (Days 3-7) Public Forecasts. The medium range forecasters are responsible for preparing forecasts for the 3 to 7 day period. These forecasts are issued twice per day using guidance from the NWS's medium range forecast model (GFS) as well as models from the European Center for Medium Range Weather Forecasting (ECMWF), the United Kingdom's Meteorology Office (UKMET), Canadian model, the Navy's NOGAPS model, and ensembles. The medium range forecast products include: 1) surface pressure patterns, circulation centers and fronts for days 3-7, 2) daily maximum and minimum temperatures and anomalies for days 3-7, 3) daily precipitation probabilities for days 3-7, and 4) total 5-day precipitation for days 1 through 5. In addition, a narrative

is issued for each set of forecasts highlighting forecast reasoning and significant weather over the Continental United States and Alaska. Separate forecasts, similar to the 5-day mean products, are prepared for Hawaii. http://www.hpc.ncep.noaa.gov/medr/medr.shtml\

Numerical Model Diagnostics and Interpretation. The purpose of the HPC Model Diagnostic Discussion is to provide objective information and subjective interpretation concerning the current runs of the NCEP short range numerical models. The HPC model diagnostic meteorologist prepares the Model Diagnostic Discussion twice per day corresponding to the 0000 UTC and 1200 UTC model runs. http://www.hpc.ncep.noaa.gov/html/model2.shtml#diagnostics

This narrative consists of three sections: 1) An evaluation of the analyses of the three primary models (Eta, NGM, AVN). The meteorologist compares the model analyses with available observed data (radiosondes, aircraft, surface observations, satellite imagery, etc.), and notes any features that do not appear to be properly represented, and thus could have an adverse impact on the models' forecasts after the analysis time. 2) A review of model trends and biases. This section describes how the models are trending in their evolution and progression of important features when compared to previous runs. This section also includes any significant persistent errors that recent model forecasts have been making with respect to a particular feature or over a general region. 3) A description of model differences and preferences. The meteorologist reviews how the models from the latest cycle differ from each other in their forecasts for significant features. Where differences exist, he or she takes into account other available models from previous cycles (ECMWF, UKMET, Canadian, NOGAPS, MM5, etc.) and the information in 1) and 2) above to formulate a preferred model or model blend.

Surface Analysis. The HPC Surface Analysts issue manual analyses of surface fronts and pressure systems over North America and adjacent oceans at 3 hour intervals. Analysts utilize a variety of weather data in addition to observations of surface weather conditions, such as upper air observations, global satellite imagery, and Doppler radar to ensure that all analysis products are meteorologically consistent and of the highest quality. http://www.hpc.ncep.noaa.gov/html/sfc2.shtml

International Desks. The International desks have a variety of responsibilities, the main one being the training of foreign visitors in the use of Numerical Weather Prediction products. The International desk routinely host visitors from South America, the Caribbean, and the Middle East. http://www.hpc.ncep.noaa.gov/international/intl2.shtml

NCEP Central Operations sustains and executes the operational suite of numerical analyses and forecast models and prepares NCEP products for dissemination.

Ocean Prediction Center (OPC). http://www.opc.ncep.noaa.gov/. The Ocean Prediction Center (OPC) is an integral component of the NCEP. The primary responsibility is the issuance of marine warnings, forecasts, and guidance in text and graphical format for maritime users. Also, the OPC quality controls marine observations globally from ship, buoy, and automated marine observations for gross errors prior to being assimilated into computer model guidance. The Ocean Prediction Center also provides forecast points in coordination with the National Hurricane Center (NHC) for Tropical Cyclones in the Atlantic Ocean E of 65W.

OPC originates and issues marine warnings and forecasts, continually monitors and analyzes maritime data, and provides guidance of marine atmospheric variables for purposes of protection of life and property, safety at sea, and enhancement of economic opportunity. These products fulfill U.S. responsibilities with the World Meteorological Organization and Safety of Life at Sea Convention (SOLAS) [International Convention for the Safety of Life at Sea, 1960 and 1974 http://www.imo.org/Conventions/contents.asp?topic_id=257&doc_id= 647]. In emergency situations OPC acts as a backup to the Tropical Prediction Center (TPC), and the Honolulu National Weather Service Office taking over the marine functions. The Offices also act as backups to the OPC marine functions.

I. Areal extent: Region of coverage is the over marine areas of the Northern Hemisphere S of 67N to 15 degrees S (except Indian Ocean).
II. Temporal extent: Guidance and forecasts are issued for time periods where useful skill exists out to 96 hours for seas and 120 hours for weather systems.
III. Application activities: Conducted to support the civilian maritime community and other government agencies in support of safety of life at sea , ie. U.S. Coast Guard.
IV. Product suite: Support for transoceanic, fishing, and recreational marine users, coastal communities, marine navigation, and other marine interests.
V. Product distribution: Direct support for all national and international marine users. MPC produces principal guidance for National Weather Forecast Offices with offshore and coastal responsibilities, and other marine related programs.

Both graphical and text products are disseminated covering these geographical regions: synoptic scale coverage over the entire North Atlantic and North Pacific Oceans, and mesoscale coverage for the coastal and offshore portions of the eastern and western United States.

Space Environment Center (SEC). http://www.sec.noaa.gov/index.html The Space Environment Center continually monitors and forecasts 24 hours a day, 7 days a week, Earth's space environment; provides accurate, reliable, and useful solar-terrestrial information; conducts and leads research and development programs to understand the environment and to improve services; advises policy makers and planners; plays a leadership role in the space weather community; and fosters a space weather services industry. The Space Environment Center is the Nation's official source of space weather alerts and warnings.

The center has three functional areas:

- Forecast and Analysis Branch
- Science and Technology Infusion Branch
- Technology Support Group

Forecast and Analysis Branch. Every day the Forecast Center is staffed by the Duty Forecaster and the Duty Operations Specialist. Banks of displays showing current solar, solar wind, geomagnetic, energetic particle, and radio data continuously show the state of the environment to the staff. A large window at the Center gives the touring public a view of the daily operations.

Science and Technology Infusion Branch. The Science and Technology Infusion Branch emphasizes understanding of the fundamental physical processes governing the regime from the solar surface, through the interplanetary medium, into the magnetospheric-ionospheric regions, and ending in Earth's upper atmosphere. These processes are manifest in the climatology and disturbances of Earth's magnetic field, the ionosphere, the charged particle populations at satellite orbits, and the atmospheric density at high altitudes (including low-Earth orbit). Our research is focused on areas where advanced applications can be developed and prototyped to improve space weather services, whereby the Nation is served through alerts and warnings of those conditions that can be often hazardous to technological systems in space and on the ground and human activities in space.

Solar Terrestrial Models and Theory. This department is devoted to research of Earth's space environment and the application of this research to space weather operations. The staff has expertise spanning from solar physics to Earth's upper atmosphere, and maintains close collaborations throughout the research community.

Solar Terrestrial Instrumentation and Data. This department ensures that space environment data are processed, validated, interpreted, and disseminated in an efficient and timely fashion. Analysis tools are developed for working with data from a variety of spacecraft, including the NOAA geosynchronous and polar orbiters, and spacecraft in the solar wind. The staff explore sources of new data and improved monitoring to support Forecast and Analysis Branch.

Responsibilities for Data and Information

Satellites. End-to-end system responsibility for universally used space environment data acquired by the U.S. geostationary and polar environmental satellites. Includes requirements, algorithm and product development, and data and instrument validation. Includes real-time solar wind data from the NASA ACE satellite which alert users of impending space weather

storms on Earth. Participation in programs to test and evaluate new national and international observational capabilities that can benefit space weather operations.

Rapid Prototyping Center. A testbed facility dedicated to moving space environment models from a research-development mode to an operational mode. Includes assembly of data sets for use in operational, assimilative, and numerical models.

Cooperative Science Programs. SEC scientists are actively involved in the wider scientific community in scientific collaborations, model development, observational capabilities, and participation on national and international committees.

Technology Support Group. SEC's IT Architecture and Infrastructure are integral to the Center's mission, supporting the day to day operations of SEC's Forecast Center, product delivery to customers and the on-going infusion of new science and technology into SEC products and data systems. The Technology Support Group (TSG) is responsible for the overall management, development and maintenance of this architecture and infrastructure.

The TSG staff includes system administrators, engineers and software developers that perform IT functions for all SEC's software and equipment, both operational and non-operational. Because of the critical nature of SEC's mission, the TSG maintains on-call staff that responds to operational issues on a 24 hour, 7 day a week basis. In addition, TSG staff performs regular backups of data as well as data archiving to the NOAA Geophysical Data Center (NGDC).

Storm Prediction Center (SPC). http://www.spc.noaa.gov/. The mission of the SPC is to provide timely and accurate forecasts and watches for severe thunderstorms and tornadoes over the contiguous United States. The SPC also monitors heavy rain, heavy snow, and fire weather events across the U.S. and issues specific products for those hazards. We use the most advanced technology and scientific methods available to achieve this goal.

The SPC uses its suite of products to relay forecasts of organized severe weather as much as three days ahead of time, and continually refines the forecast up until the event has concluded. All products issued by the Storm Prediction Center are available on the World Wide Web. Our products are commonly used by local National Weather Service offices, emergency managers, TV and radio meteorologists, private weather forecasting companies, the aviation industry, storm spotters, agriculture, educational institutions and many other groups. A detailed description of all of the SPC products is available online. http://www.spc.noaa.gov/misc/about.html.

Our very specialized mission requires meteorologists with a high level of expertise in convective storm forecasting, as well as excessive precipitation, winter weather, and conditions leading to high fire dangers. The SPC staff also is active in scientific research into severe and dangerous weather. All SPC forecasters have at least a Bachelor of Science degree in atmospheric science, and several have done graduate-level studies or hold a Master of Science degree. Most of the forecasters at the center have at least 5 years of specialized experience, with our more veteran forecasters having over 20 years of severe storm forecasting wisdom. We have participated in several major scientific experiments and field programs in recent years, including the V.O.R.T.EX. project. The SPC is located in Norman, Oklahoma, home of the National Severe Storms Laboratory, University of Oklahoma School of Meteorology and other weather centers. Our co-location with these groups should yield even greater scientific opportunities in the future. Several SPC meteorologists make severe storms their hobby as well — being heavily involved with storm spotting and storm chasing on their own time.

Tropical Prediction Center (TPC). http://www.nhc.noaa.gov/. The Tropical Prediction Center (TPC) is located at Florida International University in Miami, Florida. The TPC mission is to save lives, mitigate property loss, and improve economic efficiency by issuing the best watches, warnings, forecasts and analyses of hazardous tropical weather, and by increasing understanding of these hazards. The TPC vision is to be America's calm, clear and trusted voice in the eye of the storm and, with its partners, enable communities to be safe from tropical weather threats.

Through international agreement, the TPC has responsibility within the World Meteorological Organization http://www.wmo.ch/index-en.html, to generate and coordinate tropical cyclone analysis and forecast products for twenty-four countries in the Americas, Caribbean, and for the waters of the North Atlantic Ocean, Caribbean Sea, Gulf of Mexico, and the eastern North Pacific Ocean. TPC products are distributed through a close working relationship with the media and emergency management communities.

To meet its mission the TPC is composed of three branches. The maintains a continuous watch on tropical cyclones from 15 May in the eastern Pacific and 1 June in the Atlantic through November 30. The Center prepares and issues forecasts, watches and warnings within text advisories and graphical products. Although many countries issue their own warnings, they generally base them on direct discussions with, and guidance from, the NHC. During the "off-season", the NHC conducts an extensive outreach and education program, training U.S. emergency managers and representatives from many other countries affected by tropical cyclones.

Tropical Analysis and Forecast Branch (TAFB). The TAFB provides year-round marine weather analysis and forecast products over the tropical and subtropical waters of the eastern North and South Pacific and the North Atlantic basin. The branch also produces satellite-based weather interpretation and rainfall estimates for the international community. The TAFB provides support to NHC through manpower and tropical cyclone position and intensity estimates based on the Dvorak technique. TAFB Atlantic Forecasts and Analyses: http://www.nhc.noaa.gov/tafb-atl.shtml. TAFB East Pacific Forecasts and Analyses: http://www.nhc.noaa.gov/tafb-pac.shtml.

Technical Support Branch (TSB). The TSB provides support for TPC computer and communications systems. The TSB also maintains a small applied research and techniques development unit which develops tools for hurricane and tropical weather analysis and prediction. TSB also has a storm surge group which provides information for developing evacuation procedures for coastal areas.

The TPC collaborates with universities, government research laboratories, international tropical weather centers, the private sector and other National Weather Service components to maintain its leading edge in tropical meteorology through coordinated operations, research, training, and forecast development techniques.

Weather forecasting of the kind carried out by NCEP also is pursued at other world locations, of which the European Center for Medium Range Weather Forecasts (Reading, England) is one http://www.ecmwf.int/.

Centers that engage more in long-term climatological trends are exemplified by the University Corporation for Atmospheric Research (sponsored by the National Science Foundation) and whose main facility, the National Center for Atmospheric Research (UCAR) is located in Boulder, Colorado. http://www.ucar.edu/.

Many professional weather forecasters today acknowledge that long-term weather forecasts are indeed tenuous at best — and for at least two fundamental reasons:

1. An inadequate database and the inherently small errors present in measurements. Recalling that the surface of the Earth is about 200 million square miles ($581 km^2$), it is immediately obvious that the Earth's largest, interactive dynamic system is not adequately measured — because weather formation is not regional, but is worldwide. With expansion and refinement of weather measurements and aided by supercomputers, meteorologists, until the last decade or two, envisioned that reasonably accurate, long-term weather forecasting could become a reality. But more and better instrumentation and computer power no longer appear to offer the ultimate solution. This goal may be theoretically impossible.
2. The concept of chaos, presently accepted by many weather scientists, has demonstrated that very small differences in model input data, as may be caused by instrumental errors or intuitive biases introduced into a computer simulator, can grow into greatly exaggerated errors with the passage of time. Findings thus far have shown that, with weather systems, these tiny errors do not create marked inaccuracies for about two weeks, but after that any forecast may be skewed to one of sheer inaccuracy and thus is worthless.

Weather satellites have been invaluable in terms of forecasting in the immediate and short term. They have been very helpful in tracking hurricanes, but unfortunately the prediction of landfall remains largely a judgmental call on the part of knowledgeable hurricane specialists who have years of experience. Hurricanes and tornadoes are described in article on **Fronts and Storms**.

Computer models continue to be developed, if not for long-term weather forecasting, then in the interest of developing a better understanding of the processes that go on in very-short-term weather phenomena, such as tornadoes. In 1989, Kelvin Droegermeier (University of Oklahoma), a meteorologist, introduced the Piecewise Parabolic Method (PPM) to "build into" a weather problem a knowledge of physics and an understanding of fluid flows. PPM initially was developed by P. Goodward (University of Minnesota) and P. Colella (University of California, Berkeley). The concept is based upon the work of S.K. Godunov (Russia) and Bram van Leer (Netherlands). They desired a numerical technique that could process the shock discontinuities found in supersonic fluid flow problems.

Woodward observes that the equations originally developed were for astrophysical applications (jets from the nuclei of galaxies and motions of fluids in stars) also describe some weather phenomena on Earth. Instead of the standard techniques where an attempt is made to keep track of numerous variables and using a finite set of grid points, PPM tracks the average of a variable at each grid cell. A given variable at each grid cell is represented by a parabola. Some details of the PPM method are described by Cipra (see reference listed).

Mesoscale and Microscale Meteorology

Considerable research is being undertaken toward understanding atmospheric phenomena on space scales of millimeters to a megameter and on time scales of seconds to a day. Key research activities include the study of:

1. The physical mechanisms that govern the behavior of mesoscale weather systems and the factors that determine their predictability.
2. The basic nature of moist atmospheric convection, its interaction with topography and other lower boundary effects, and how cloud and precipitation microphysics and large-scale dynamical factors influence its behavior.
3. The fundamental atmospheric processes that operate on scales of up to a few kilometers, including boundary-layer processes, turbulence, and cloud and precipitation microphysics.

Such programs, as conducted at the National Center for Atmospheric Research laboratory http://www.ncar.ucar.edu/ and at university laboratories in the United States and Europe, include the conduction of major field experiments and numerical model development.

Accomplishments have included the following:

- Large-eddy simulations have shown how radiative cooling generates turbulence in cloud-topped mixed layers, which has important implications for the dissipation of stratiform clouds through the entrainment of warm, dry air from above.
- Observational studies, using satellites and airborne data gathering, have revealed that horizontal inhomogeneity in marine stratiform cloud regimes is commonly observed and has a significant effect on cloud formation and dissipation.
- Measured changes in the size spectra of sulfuric acid droplets in the arctic stratosphere indicate, contrary to previous assumptions, that the majority of the droplets are supercooled at the temperature at which polar stratispheric clouds could begin to form, but that they freeze homogeneously at slightly colder temperatures. This observation alters the view of the mechanisms important in the formation of polar stratospheric clouds that are directly involved in polar ozone loss.
- High-resolution mesoscale model simulations have reproduced the remarkable structure of recently documented warm-core marine cyclones that are in contradiction to the classical Norwegian cyclone model.
- Studies of how echoes and downbursts identify mechanisms producing these significant storm features.
- Initiation of convection along the Colorado Front Range in the presence of southerly flow has been shown to occur through complex nonlinear interactions involving boundary-layer instabilities, tropospheric gravity waves, and nocturnal low-Froude-number flow effects.
- Momentum transport by organized convection in both idealized models and the real atmosphere has been represented by a comprehensive nonlinear theory and applied to represent momentum transport in general circulation models.
- Entrainment and mixing along the interface between the cloud and its environment have been shown to occur through convective and shearing instabilities and vorticity generation.
- Techniques have been developed to assimilate precipitable water measurements into a mesoscale model. The assimilation of precipitable water produces a much-improved estimate of the vertical structure of water vapor than statistical methods based on climatology and improves the precipitation forecast of the model.

Computer Modeling. The principle behind modeling is that many natural processes can be described by mathematical equations. These equations, which describe everything from basic tenets (such as Newton's laws) to detailed processes (such as how solar radiation is absorbed or reflected by the Earth and clouds), can be solved using a computer. Obviously, to perform accurately a model requires both good equations that describe the world realistically and good data. Models come in all scales, from a single cloud to the entire planet and the atmosphere above it, and in many levels of complexity. Each is designed for a certain research target. See Fig. 1.

Computer modeling does have limitations. For example, climate modelers would not use a weather-forecasting model because such a model

Chaos as Related to Weather Forecasting

Much has been written pertaining to the concept of *chaos* in recent years. As early as 1963, Edward Lorenz (Massachusetts Institute of Technology), when speaking before an assembly of meteorologists, described what he termed, "The Butterfly Effect." The speaker related that when he thought about weather forecasting (which he had done for some years), he thought about butterflies. Lorenz observed, "Imagine a butterfly stirring deep in the Amazon forest. Its delicate motion alters tiny air currents that influence large eddies ever so slightly. Can those eddies transform a Texas tornado days later?" His comment was taken seriously by professionals in the field of weather predicting. Aksel Winn- Nelson (European Center for Medium Range Weather Forests) responded, "If the weather is sensitive to such minute influences, no one could predict its course."

Lorenz initiated a new way for meteorologists to look at the weather system. Prior theories had been based on the traditional "clockwork" universe, which was championed by Laplace and Descartes in the 18th century, to the effect that a full comprehension of each part of a system can yield a prediction of the future of that system. This led to a conclusion that, within reason and tempered with judgment, supercomputers could assist in predicting the weather. Winn-Nelson observed, "We thought if you just knew the state of the atmosphere sufficiently well and if you built the right models with powerful enough computers, there should be no limit in predicting the weather. Lorenz's work came as quite a shock."

Chaos is an important factor in weather systems. As explained in the article on *Chaos* it is a topic that also has been applied to the study of numerous other complex phenomena, one being turbulence, which, prior to his announcement in 1963, Lorenz had attempted to create computer models for, long-term weather prediction. In one experiment, he rounded off the input numbers and found that this produced very serious changes in the end results. Lorenz learned a fundamental of chaos, namely, that tiny changes in the input information grossly exaggerate the final result.

Weather scientists, as well as researchers in other disciplines, have found some "order" in chaos. Characteristic patterns of different phenomena appear repetitive and represent what may be termed a "signature" of various unique kinds of behavior. They are called *strange attractors*. A strange attractor may be described as a system's "preference" for behavior. As explained by Robert Pool (see reference), "The most important quantity associated with a strange attractor is its dimensions, which indicates how complicated the pattern is and gives a rough indication of how many variables it takes to describe the behavior of the system. If a strange attractor is low dimensional, it indicates that the weather under consideration is simple enough to model with only a few variables. Also, since the strange attractor contains the system's preference for behavior, it is possible to use the strange attractor to predict the system's future actions."

This, then, may become an index to those weather systems that may be predicted correctly over longer periods than others whose index is greater."

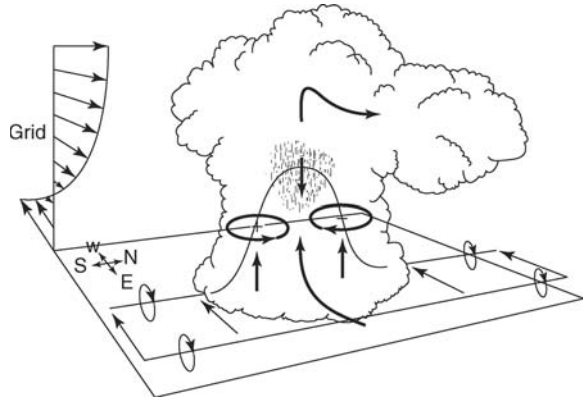

Fig. 1. Computer modeling enables scientists to visualize the processes they are investigating. Air motions in and around a thunderstorm are shown schematically in this diagram. (*National Center for Atmospheric Research*.)

does not have to account for long-term chances, such as variations in the extent of the polar ice caps. In contrast, forecasters would not use a climate model because it might average or ignore other short-term variations that affect weather. A cloud physicist or solar scientist would not use a climate nor a weather model because these models would not include the specialized equations needed. The impracticality of using weather models for time spans exceeding several days is mentioned earlier in this article. More detail on climate modeling is given in article on **Climate**.

Weather Forecasting

The data base for a weather projection consists of as complete a description as possible of all the interrelated parameters that define the atmosphere and, in particular, its relation to human activities. These parameters are obtained from meteorological observations at fixed times, usually known as "time zero." The basic structure of the atmosphere is projected stepwise by integrating the time rate of change of the descriptive parameters. For many years, the stepwise project was done manually by use of linear or accelerated extrapolation. In recent years, these tasks have been assigned to computers. Most forecasting in the early 1990s is a mix of computer outputs with human refinements. The trend is to turn over almost all of the task to computers.

Forecasts deviate from actual weather increasingly as the increments of time increase. Forecasts for 12 hours are reasonably reliable. Forecasts for 24 hours verify within the range of 75 to 85%. Forecasts for 96 hours are nearer the 60% level of validity. There are two causes for deterioration: (1) The original data base is faulty and incomplete; and (2) the projection formula does not contain all the terms that actually exist in the atmosphere. When the data base is complete and sufficient and the time rate of change equations are in a one-to-one correspondence with nature, the forecasts are accurate. Tide and moonrise/moonset forecasts are an example, of course, of accurate forecasting. Future trends are toward increasing accuracy in weather forecasting because the data base is constantly improving and projection formulas are undergoing continual modification and refinement. A factor frequently reported today is the wind-chill factor. See Table 1.

TABLE 1. WIND-CHILL FACTOR

	Actual Temperature (°F)									
Wind Speed (mph)	50	40	30	20	10	0	−10	−20	−30	−40
5	48	37	27	16	6	−5	−15	−26	−36	−47
10	40	28	16	4	−9	−24	−33	−46	−58	−70
15	36	22	9	−5	−18	−32	−45	−58	−72	−85
20	32	18	4	−10	−25	−39	−53	−67	−82	−96
25	30	16	0	−15	−29	−44	−59	−74	−88	−104
30	28	13	−2	−18	−33	−48	−63	−79	−94	−109
35	27	11	−4	−21	−35	−51	−67	−82	−98	−113
40	26	10	−6	−21	−37	−53	−69	−85	−100	−116
	Equivalent chill temperature (°F)									

Note : °C = (°F − 32) × 5/9. kph = 0.6214 mph.

Types of Forecasts. There are several categories of forecasts, divided according to the period of time, the geographical areas, and the special purposes for which they are made, as well as by the considerations or techniques upon which they are based.

In categorizing weather forecasts according to geographic areas, the broadest categories may be thought of in terms of local or *microforecasts* (highly detailed forecasts of conditions over relatively limited areas, such as cities or airports) and district or *macroforecasts* (general forecasts for conditions over relatively large areas of tens- or hundreds-of-thousands of square miles). In terms of periods of time, forecasts, in general, may be thought of as daily or *short-range forecasts*, extending from 12 to 48 hours in advance, and being usually detailed for specific geographic areas; *medium-range forecasts*, extending from about 2 days to a week in advance; and *long-range* or *extended forecasts* for periods greater than 2 days or a week in advance. The longest-range and the most general of all types is the *climatic forecast*, which predicts future climate and general weather conditions for a specified region over a period of years.

Aviation Forecasts. These reports are required for periods of several hours to 1 day. Most aircraft flights are of less than 6 hours duration; commercial airliners seldom remain aloft more than 12 hours. Forecasts of fog and low clouds, turbulence, thunderstorms and accompanying severe weather, freezing rain and snow, aircraft icing, and of winds aloft at cruise levels are paramount to aviation. In addition to maps, updated aviation weather information is available from specific stations via sequence reports. See also **Precipitation and Hydrometeors**. See also Figs. 2–5.

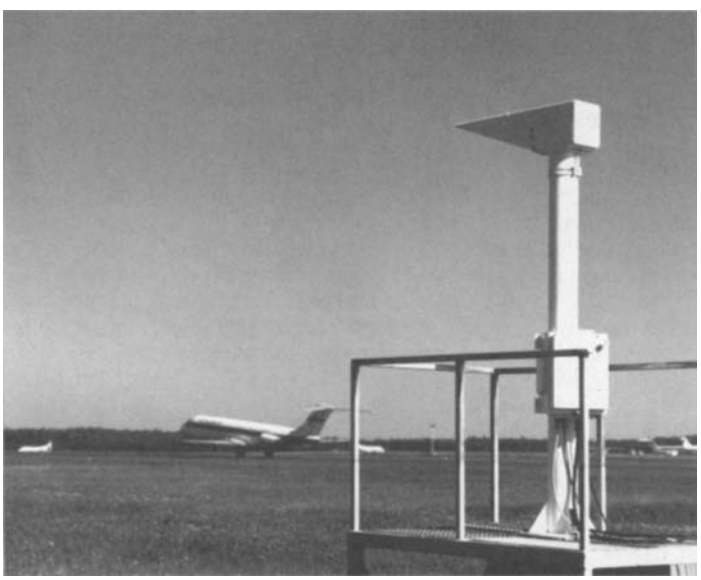

Fig. 2. Airports utilize a number of local weather sensors. Shown here is a fully automated runway visual range measurement and reporting system. The system consists of a light projector, a background luminance sensor, a light receiver, and a data-processing unit. Measuring range is 0–100% transmittance. Resolution is 0.02% of transmittance. Accuracy is ±1% of transmittance value through whole measuring range verified by calibrated optical filters. (*Vaisala*.)

Terminal Aerodrome Forecasts. These contain information for specific airports on expected ceiling, cloud heights, cloud amounts, visibility, weather and obstructions to vision and surface wind. In the U.S., TAFs are produced four times a day starting at approximately 30 minutes before each main synoptic hour (00Z, 06Z, 12Z, and 18Z). All the forecasts produced starting one hour before the main synoptic hour up to four hours past the main synoptic hour are considered to be for the same cycle. For example, forecasts produced between 1100Z and 1600Z are all considered to be 12Z forecasts. In reality, forecasts contain the starting and ending times for which the forecast is valid. Our rule of thumb is that all forecasts produced between (**hh**−1)00Z to (**hh**+**4**)44Z are considered to be for the **hh** cycle. The following Table 2 summarizes the relationship between forecast production time and cycle:

Fig. 3. Automatic weather station suitable for airport use or any local site. The instrument measures up to 60 weather parameters. Available with a wide range of weather data inputs. Data may be analog in several ranges of sensitivity. Or digital and pulse frequency inputs or serial inputs from intelligent sensors can be accommodated. Customized software is available. (*Vaisala*.)

Fig. 4. UHF telemetry antenna designed for reception of radio signals in the 403MHz band. Antenna ensures reliable operation for both low- and high-altitude radiosonde observations even under the highest of wind conditions. Operating range is from 0 to 200km. (*Vaisala*.)

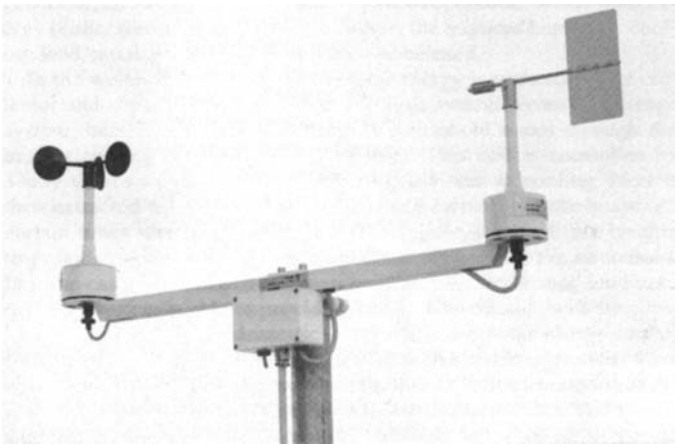

Fig. 5. Microprocessor-based wind-measurement system useful for airport or other local weather stations. Minimum and maximum displays provide instant, 5-second, and 2- or 10-minute average maximum and minimum wind speeds and direction. Meters per second, km/h, knots, and mph can be selected for display. The system also incorporates a wind speed alarm in both audible and visual means. Accuracy: ±1.5% full scale (*Vaisala*)

TABLE 2. FORECAST CYCLES

	Forecast Production Range	
Forecast Cycle	From	To
00Z	2300	0459
06Z	0500	1059
12Z	1100	1659
18Z	1700	2259

Cycle files are deleted ten minutes before the start of cycle, for example, the file 15Z.TXT will be deleted at 1435Z in preparation for receipt of new data. This means that data up to 23 hours old is available. The last 3 hours (or when necessary) of each forecast are covered by a categorical statement indicating whether VFR (Visual Flight Rules), MVFR (Marginal Visual Flight Rules), IFR (Instrument Flight Rules), or LIFR (Low Instrument Flight Rules) conditions are expected. Terminal forecasts are written in the following form:

Ceiling Identified by the letter C.
Cloud Heights In hundreds of feet above the station (ground).
Cloud Layers Stated in ascending order of height.
Visibility In statute miles, but omitted if over 6 miles.
Weather and Obstruction to Vision Standard weather and obstruction to vision symbols are used.
Surface Wind In tens of degrees and knots.

Area Forecasts. Each FA contains a regional synopsis, 12-hour geographic specific forecasts, and an 18-hour outlook for each geographic area. Forecast weather elements are sky condition, cloud height, mountain obscuration, visibility, weather and/or obstructions to visibility, strong surface winds (direction & speed), icing, freezing level, and mountain pass conditions. Hazards and flight precautions, including AIRMETs and SIGMETs, may be found in their respective geographic area. All times unless stated otherwise are Coordinated Universal Time (UTC) denoted by the suffix Z. UTC is commonly known as Greenwich Mean Time (GMT) or Zulu time. Heights of cloud tops and icing are referenced ABOVE SEA LEVEL (ASL); ceiling heights, ABOVE GROUND LEVEL (AGL); bases of cloud layers are ASL unless indicated. Each SIGMET or AIRMET affecting an FA (Flight Advisory) area will also serve to amend the Area Forecast.

SIGMET or AIRMET[1] messages warn aircraft personnel in flight of potentially hazardous weather, such as squall lines, thunderstorms, fog,

[1] SIGMET is an acronym for Significant Meteorological Information; AIRMET, Airman Meteorological Information.

TABLE 3. WINDS ALOFT FORECAST PERIODS

Data available	Model Run	6 hour 'FOR USE' times	12 hour 'FOR USE' times	24 hour 'FOR USE' times
~0200 UTC	0000 UTC	0200-0900 UTC	0900-1800 UTC	1800-0600 UTC
~0800 UTC	0600 UTC	0800-1500 UTC	1500-0000 UTC	0000-1200 UTC
~1400 UTC	1200 UTC	1400-2100 UTC	2100-0600 UTC	0600-1800 UTC
~2000 UTC	1800 UTC	2000-0300 UTC	0300-1200 UTC	1200-0000 UTC

icing, and turbulence. SIGMET concerns severe and extreme conditions of importance to all aircraft. AIRMET concerns less severe conditions which may be hazardous to some aircraft or to relatively inexperienced pilots. Both are broadcast by FAA (Federal Aviation Agency) on NAVAID (Navigational Aid) voice channels.

Winds and Temperatures Aloft (FB) Forecasts[2]. Winds aloft forecast periods are given in Table 3. Winds aloft are computer prepared and contain forecast wind direction and speed as well as forecast temperatures. The standard FB levels are as follows:

Low Level	High Level
• 3,000 feet	• 45,000 feet
• 6,000 feet	• 53,000 feet
• 9,000 feet	
• 12,000 feet	
• 18,000 feet	
• 24,000 feet	
• 30,000 feet	
• 34,000 feet	
• 39,000 feet	

All levels through 12,000 feet are true altitude (MSL). The levels 18,000 feet and above are pressure altitude. Wind direction is from true north. No winds are forecast within 1,500 feet of station elevation. Also, no temperatures are forecast for the 3,000 foot level or for any level within 2,500 feet of station elevation. Temperature is in whole degrees Celsius and assumed to be negative above 24,000 feet.

Wind direction is indicated in tens of degrees (two digits) with reference to true north, and wind speed is given in knots (two digits). Light and variable wind or wind speeds of less than 5 knots are expressed by "9900." Forecast wind speeds of 100 through 199 knots are indicated by subtracting 100 from the speed and adding 50 to the coded direction. For example, a forecast of 250 degrees, 145 knots, is encoded as 7545. Forecast wind speeds of 200 knots or greater are indicated as a forecast speed of 199 knots.

Temperature is indicated in degrees Celsius (two digits) and is preceded by the appropriate algebraic sign for the levels from 6,000 through 24,000 feet. Above 24,000 feet, the sign is omitted since temperatures are negative.

The Impact of Computed Weather Forecasts on Accuracy. The weather forecasts issued by the National Weather Service have been much more accurate in the last ten years than those that were issued previously. This is due to improvements, in the several models programmed to make numerical weather predication forecasts and the application of the methods of ensemble of forecasting to several models to get the official forecast.

Ensemble forecasts are made with several models, each of which are very good at forecasting but suffers from the universal curse of being a chaotic system. This is due to the fact that some time inside or outside the life of the official forecast, and in some areas, it has a disturbance that does not appear in the verifying weather or a disturbance that does not occur that does appear in the verifying weather map.

The ensemble forecast in its simplest form uses five to more than ten forecasts computed with different models and most of the time the pattern that the majority of the forecasts have displayed can be chosen as the forecasts. This method has improved the forecasts and stretched out the time that they are useful. Sometimes it uses forecasts that start on day 1 and compare these with forecasts from the same model that star on day 2.

Contrast this with the condition 30 to 40 years ago when a forecast for this afternoon was all right but any forecast for tomorrow had about a 50/50 chance of being right. A five-day forecast was experimental and gave very little useful information.

The use of ensemble forecasts is a direct result of improved computing power. As computing power has grown, the number of different models that can be run has grown. Computing power has been growing due to the number of weather services that perform daily weather forecasts and develop models; and the computing capacity at one computing establishment being capable of running two or three simultaneous computations with three or more models.

Commercial Forecasts. These forecasts are directed to commercial and public interests.

Agricultural weather forecasting requires a varied time span — from a day or less to a whole season. Day-to-day agricultural operations, such as planting or harvesting specific crops, require a 24-hour forecast. Other agricultural operations require longer advance planning and forecasting of relevant weather conditions must extend to 72 hours or longer. Longer term planning has to be based upon a climatological forecast. The principal elements of concern to agriculture, of course, are precipitation, temperature, sunshine, and often, wind.

Outdoor construction weather forecasts fall mainly within the time frame of 12 to 72 hours. About a half-day advance warning is needed to guard against inclement conditions of wind, precipitation, and storms. Depending upon the nature of the construction project and accompanying economic and labor factors, reliable forecasting up to 48 or 72 hours is desired.

Forest and grassfire weather forecasts require lead times of from 24 to 72 hours. Elements of prime interest are wind, relative humidity, and temperature, i.e., the principal factors that contribute to producing a favorable combustible state for grass, brush, and trees. Precipitation is important because it virtually eliminates combustibility for the immediate period. Thunderstorms are significant because of the factor which lightning plays in starting such fires.

Public weather forecasts range from a few hours to a day. In addition to providing information for personal and family activity planning, warnings in short time frames are needed for prediction of actual or potential thunderstorms, hail, tornadoes, flash floods, excessive rainfall, hurricanes, and other tropical storms. A variety of public interests are involved wherein low or high temperatures, strong winds, snow, and glaze icing are relevant. Outdoor recreational weather forecasts are needed primarily in the time frame of 24 to 96 hours to assist planning by recreational facility operators and the using public. Weather forecasts are also important to merchandisers who sell weather-oriented gear, such as rainwear, air conditioners, etc.

Satellite imagery, computer graphics, computer simulations, and the ability to stop, reverse, speed up, or slow down images literally has combined serious meteorological information with showmanship and entertainment. Laypeople are much better acquainted with the rudimentary principles of meteorology than they were just a decade ago, mainly because of the interesting way weather is reported by television and the amount of television time devoted to covering it. Special TV weather channels made their appearance in the late 1970s, and there were many doubts that a weather channel could find sufficient commercial advertising sponsorship. These doubts were disproved.

Weather data reporting and forecasting requires a vast array of sensors and an extensive telecommunications network. The system undergoes continuous modernization in an effort to keep up with technological

[2] FB is an arbitrary designation for these forecasts.

improvements. The consequence at any given time is a mixture of traditional and advanced support facilities.

Special Weather Alerts. The National Weather Service in the United States issues special alerts and reports pertaining to particularly hazardous conditions, such as flood watches and hurricane, thunderstorm, and tornado alerts, usually on a local or regional basis, as required. A special radio communications band has been established for both routine and alert reporting that operates continuously on a 24-hour basis. Local radio and television channels also will interrupt regular broadcasts to carry such information.

These topics are described in much more detail in article on **Fronts and Storms**.

Types of Weather Observations

The principal categories of weather observations are: (1) *surface observations*, and (2) *upper air observations*.

Surface Observations. These data are used to evaluate the state of the atmosphere as observed from one or several points on the surface of the Earth. Usually the term applies to observations that are made primarily for the purpose of preparing surface synoptic charts. There are several subcategories of surface weather observations:

Synoptic Weather Observations. These are made, usually, at 3-hour and 6-hour intervals, of sky cover, state of the sky, cloud height, atmospheric pressure reduced to sea level, temperature, dew point, wind speed and direction, amount of precipitation, hydrometeors and lithometeors, and special atmospheric phenomena that prevail at the time of the observation or have been observed since the previous specified observation.

Aviation Weather Observations. These pertain to the operation of aircraft. Included are the cloud height or vertical visibility, sky cover, visibility, obstructions to vision, precipitation and thunderstorms, and wind speed and direction that prevail at the time of the observation. Complete observations include the sea-level pressure, temperature, dewpoint temperature, and altimeter setting, and are made at regular, equal intervals, usually on the hour. Local extra observations may be taken every 15 minutes when there are impending aircraft operations and when weather conditions are near certain operational weather limits established as safety minimums for aircraft landings and take-offs. See also articles on **Gust Front**; and **Wind Shear**.

Marine Weather Observations. The weather on land is grossly affected by the weather over the oceans. See also **Atmosphere-Ocean Interface**. Marine observations include those made from a ship at sea or from a buoy that is equipped to telemeter instrumental reading. They may include total cloud amount; wind direction and speed; visibility; weather, pressure; temperature; selected cloud-layer data (amount, type, and height); pressure tendency; seawater temperature; dew-point temperature; state of the sea (waves); and sea ice.

Climatological Weather Observations. These data essentially serve as part of the database used for the science of climatology, including very long period weather forecasting. Measurements are made at least once daily from climatological substations and include the evaluation of minimum and maximum temperature, of total precipitation since the previous observation, of weather (cloudy, clear, etc.), and of atmospheric phenomena. Such observations comprise the bulk of climatological data in the United States and in much of the world. There are about 10,000 climatological substations in the United States. See also **Climate**.

Upper Air Observations. These are observations of atmospheric conditions that are beyond the effective range of a surface weather observatory. The term is usually applied to those observations that are used in the analysis of upper air charts and the display of upper air conditions. The first data level of upper air observations is usually 850 millibars pressure (approximately 5000 feet: 1524 meters). Upper air observations by balloon-carried instruments regularly reach altitudes of 100,000 feet (30,480 meters). Observations by rockets reach as high as 250 miles (402 kilometers). The usual elements observed include temperature, water content of the air, wind direction and speed, and altitude and pressure. See also **Balloon**; and **Upper Air Observations**.

Weather Data Collection

Most of the weather observatories collect surface data, but some sophisticated installations collect upper air and radar data. Inasmuch as an average of at least six elements is observed and recorded at each observation, the total amount of data observed and recorded in any given 24-hour period is monumental. Yet, compared with the size of the atmosphere and the ocean areas, the data collected are entirely too few to adequately describe the whole atmosphere.

Weather data are collected by numerous means, some of which are described in the following paragraphs.

Radar Meteorology. *Weather radar* is applied to any radar suitable for the detection of precipitation or clouds. The general qualifications for weather radars are: (a) wavelength between one and 30 centimeters; (b) pulse transmission with high peak power (several megawatts); (c) relatively narrow beam widths; (d) pulse lengths of a few microseconds or less; (e) pulse repetition frequencies that are hertz of several hundred; and (f) automatic azimuth and/or elevation angle scanning. Electronic circuits that permit the quantitative measurement of the signal strength of the returned signal are necessary for more comprehensive studies. Since hydrometeors can scatter radio energy, weather radars operating on certain frequency bands can detect the presence of precipitation at distances up to several hundred miles from the radar, depending upon meteorological conditions and the type of radar. Evaluation of the echoes that appear on the indicator of a weather radar are made in terms of orientation, coverage, intensity, tendency of intensity, height, movement, and unique characteristics of echoes, which may be indicative of certain types of severe storms (such as hurricanes, tornadoes, or thunderstorms).

Cloud-detection radar is a type of weather radar designed specifically for the detection of clouds. It operates on radio frequencies near 30,000 megahertz/sec. corresponding to a wavelength of about one cm. (K band). Short wavelengths are essential to these radars in order to obtain appreciable scatter from the small drops of which clouds are formed. The beam is usually directed toward the zenith: thus, only clouds and precipitation passing directly above the radar are detected. It is capable, in its present form, of detecting clouds in multiple layers to an altitude of about 50,000 feet (15,240 meters).

Height-finding radar, designed specifically for the accurate measurement of target altitudes, is extremely useful as a weather radar in studying vertical cross-section of clouds and precipitation areas. The beam width in the vertical is generally significantly smaller than in the horizontal. Target information is presented on a *range-height indicator scope*, a type of radarscope on which echoes are displayed in coordinates of slant range and elevation angle, simulating, thereby, a vertical cross-section of the atmosphere along some azimuth from the radar.

Certain radars are used in connection with the balloon-borne radiosonde observations, by means of which meteorological data is measured and transmitted. Also useful as weather radars are the radar signal spectrograph, and, as mentioned above, the radarscope.

A considerable number of weather surveillance radar observatories have been established in the United States and nearly all of the airspace comes under the umbrella of radar surveillance. The equipment used operates near the 10 centimeter wavelength. The observational range is 250 miles (402 kilometers), although at this distance the radar beam passes above some target material because of the curvature of the earth. Within an operational range of 125 miles (201 kilometers), the weather surveillance radar is very effective in detecting air space that contains liquid and solid water particles larger than small cloud droplets. The radar hardware is also able to stand at one azimuth to scan vertically to depict the height of echoes. Most radar installations are equipped with electronic capability to transfer the scope picture to the carrier wave of good quality communications land lines.

Airborne Radar. Weather detecting radars operating in the wavelength range of 3 to 5.5 centimeters have been installed in most commercial airlines. The range of these sets varies from 150 to 300 miles (241 to 483 kilometers), which allows ample time for weather detection and avoidance planning. The scope viewing area is an arc of 45 to 60° directly ahead of the plane. These installations have uptilt and downtilt capability to provide for vertical scanning. Most aircraft radars have the capability to display two levels of echo intensity. The lowest level covers the range of precipitation from one through three on a scale of seven. The upper level cuts in at the

level four and is related to moderate and heavy precipitation. The purpose of the upper level is to "contour" areas of more intense precipitation because there is a good correlation between turbulence and precipitation intensity in storms. The scope depiction, in black-and-white, is one of a whitish area where the lower-level intensity is detected. The upper level of heavier precipitation is dark, surrounded by the whitish area. The heavy precipitation thus is "contoured." Scope depiction in color utilizes two or more colors to outline the relative intensity of precipitation.

The primary purpose of airborne radar on airliners as or weather avoidance. The automated lateral scan and the uptilt/downtilt permits the crewmen to analyze a storm and plan an avoidance flight path that will keep the plane away from the storm.

Airborne radar can also be used for mapping and navigation. Bodies of water, shorelines, and islands are clearly depicted even though the plane may be well above a thick cloud layer.

Weather Surveillance Radars. These systems depict several levels of echo intensity. In most installations, the electronic circuitry is arranged to distinguish up to seven levels of intensity, ranging from very light precipitation to very intense torrential downpours. The levels of intensity are separated by the degree of shading of the scope, the least intense being very light. Successive levels repeat the shading from white to black. Surveillance radar thus can depict the core of thunderstorms, can evaluate the rate of rainfall, and determine the total rainfall over specific areas. The radar is also very effective in depicting the leading edge of rain or snow and the ending edge as a storm moves along. Weather surveillance radar is able to observe all the air space between the standard widely separated observatories and thereby provide complete surveillance of precipitation.

Inadequate funding in recent years has slowed improvements in weather radar. One meteorologist has observed that "Radars that now track violent storms, for example, are so old (most were installed in 1957) that they rely on vacuum tubes. The systems fail frequently and can be put of commission for days, even weeks. Radars have been down when storms ripped through areas with disastrous consequences." After a disastrous experience in parts of North Carolina, where radar had been out of service for ten days, federal investigators were prompted to upgrade and replace the aged U.S. system of weather radars. Over 160 modern technology weather radars are scheduled for the NWS by 1997.

Weather Satellite Technology

The first weather-observing satellite launched in the United States was placed in orbit on April 1, 1960. This satellite was a television infrared observing satellite (TIROS I). Pictures of clouds taken in the infrared were telemetered to earth stations where they were analyzed and reconstructed in the form of cloud-cover maps. A total of ten TIROS satellites were placed in orbit. A NIMBUS series of satellites was commenced about two years after TIROS I. The NIMBUS satellite observatories were placed in a sun-synchronous polar orbit. This series introduced the automatic picture transmission (APT) from its television cameras. They also introduced an advanced videcon camera system. The ESSA series of weather-observing satellite was begun in 1966. This series embraced all of the advanced features of earlier satellites, plus newer technological innovations. Infrared scanning, as represented by the ESSA series, had become a fine technological art during a comparatively short period of eight years. See Fig. 6.

A series of "applications technology satellites" was commenced in Pictures of clouds taken in the infrared were telemetered to earth stations where they were analyzed and reconstructed in the form of cloud-cover maps. A total of ten TIROS satellites were placed in orbit. A NIMBUS series of satellites was commenced about two years after TIROS I. The NIMBUS satellite observatories were placed in a sun-synchronous polar orbit. This series introduced the automatic picture transmission (APT) from its television cameras. This series embraced all of the advanced features of earlier satellites, plus newer technological innovations. Infrared scanning, as represented by the ESSA series, had become a fine technological art during a comparatively short period of eight years.

A series of "applications technology satellites" commenced in 1966. The satellites, known as ATS, were placed in orbit near the equator at approximately 23,000 miles (37,000 kilometers). At this altitude, the eastward speed of the satellite matched the rotational speed of the earth, thus making the satellite to appear to "stand" over a fixed point on the earth. The cameras on the ATS were timed to scan the earth below and return the picture within a little less than one-half hour. Successive pictures of cloud structures displayed cloud movements and for the first time these could be pieced together to make, in essence, a "movie" of cloud movements.

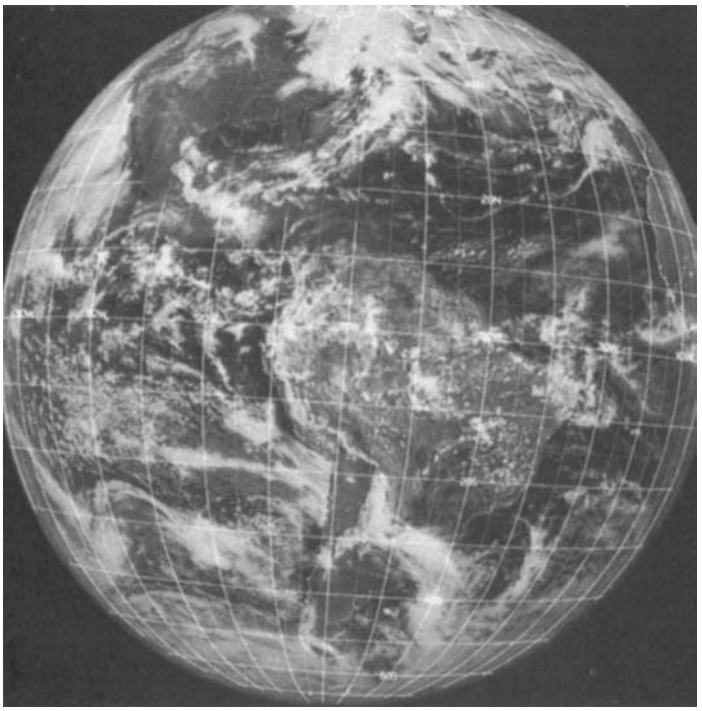

Fig. 6. View of Western Hemisphere taken by an early weather satellite. (*National Aeronautics and Space Administration*.)

Satellite weather observation continued to advance. By using a number of select, narrow-band frequencies in the infrared, satellite hardware is now able to measure temperatures down to the Earth's surface. Data are telemetered to earth receiving stations for analysis and display in graphic form as maps or in alphanumeric form as desired. Within the realm of present technological capability limitations is a weather observing satellite that can scan the earth below for cloud cover, measure temperature and water vapor content of the air, and provide a readout of the cloud tops. A series of polar orbiting satellites, fully equipped, can put the whole atmosphere under surveillance continuously.

Weather-observing satellites are powered by solar energy and, therefore, can continue to function so long as their energy systems function properly. The longevity of the systems continues to improve with each newly added orbiting satellite. Most of the earlier weather satellites have failed or fallen back into the Earth's atmosphere where they were destroyed. See also **Nimbus Satellite Program**; and **Polar-Orbiting Environmental Satellite (POES)**.

Geostationary Operational Environment Satellites (GOES). This series of weather satellites commenced in the early 1980s. After a failure of one of two satellites, in July 1984, another GOES was launched by a Delta rocket on February 26, 1987 after several postponements. With coverage by only one performing satellite during the period, it was necessary to shift the satellite position so that the eastern and western portions of North America could be under surveillance by giving up portions of coverage to the east and west of the continent. Loss of another satellite again reduced the system to one GOES-7 satellite in the early 1990s.

With the expiration of GOES-7 in the early 1990s, arrangements were made to utilize other available satellites for procuring weather information. The first of the GOES-NEXT series of weather satellites is scheduled for launching in the spring of 1994, with plans to complete the full series in 1994–1995.

Liquid water and ice clouds are routinely tracked on imagery from all geostationary satellites around the world at least twice per day, and the resultant wind data are fed into global weather forecast models.

Geostationary satellites operated by the United States, the European Space Agency (ESA), Japan, and India are used to obtain the cloud wind data.

The GOES-NEXT Program. Plans for this next series of weather satellites commenced in 1985, but as of early 1994 the program had not come to fruition. The GOES-NEXT series was designed to simultaneously record visual images and take soundings of both temperature and moisture. See Fig. 7. The GOES satellite can accomplish both of these operations, but not simultaneously. The program has experienced numerous difficulties. NOAA gave NASA the responsibility to run the program, and NASA selected contractors as early as 1985. Total cost of the program has risen from about $640 mil to $1.7 bil, largely because of cost overruns and technical problems. See also **Geostationary Operational Environmental Satellite (GOES)**; **Satellites (Scientific and Reconnaissance)**; and **Weather Satellites**.

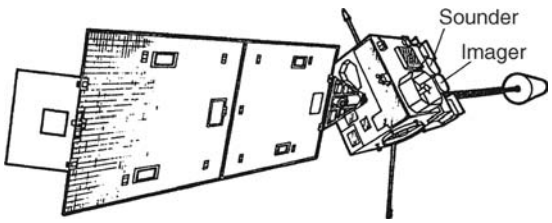

Fig. 7. Artist's concept of a GOES-NEXT satellite. (*National Aeronautics and Space Administration.*)

Sunspots and Weather

For several years, some meteorologists have claimed a strong connection between sunspots and weather events on Earth. There may be a connection, but not of the magnitude once considered. There was strong statistical evidence of the connection over a 40-year period — that is, until the winter of 1989, at which time a close correlation was tested. There was unusually heavy sunspot activity during that time. There should have been an exceptionally cold winter in the east-central United States. Actually, the exact opposite occurred. But, at a conference on the Climate Impact of Solar Variability sponsored by NASA in April 1990, one professional observed, "The jury is still out on the 110-year solar effect. We're going to have to wait longer." Part of the reasoning is that any impact of solar activity on the winter of 1989 was overwhelmed by the effects of the El Niño cycle. Searching through past records relative to El Niño and sunspot activity has shown that a week case for sunspot effects on the weather may remain valid. See also **Atmosphere-Ocean Interface**; **El Niño**; and **Sun (The)**.

Testing the Effects of Weather (Weatherability)

Numerous artificially created weather-condition test chambers are used by manufacturers of various machines and systems, notably in the transportation vehicle field. Considered the largest of such facilities, the Center Scientifique et Technique du Batiment (CSTM), located in Nantes, France, was dedicated in October 1990. Sometimes referred to as the Jules Verne wind tunnel, the 54,000-square-foot ($5000m^2$) facility is available to meet long-unfulfilled needs of researchers in government laboratories, universities, and industry for conducting tests under simulated extreme climatic conditions. The building is equipped with six fans, having a total power capability of 3.2MW. These fans are capable of generating winds up to a top speed of 195mph (310km/hr). The fans are designed to operate independently and simulate sudden changes in wind speed. The facility also has a sand-input system for simulating sandstorms at speeds up to 60mph (100km/hr). Rain also can be simulated up to a precipitation level of 0.1in/min (3mm/min) in the presence of winds up to 60mph (100km/hr). Sunlight can be simulated through use of metallic-halogen lamps for sunlight effects up to 1.1kW/square meter.

Weather Terminology Glossary, Abbreviations and Acronyms

AC — Convective outlook issued by the Storm Prediction Center. Abbreviation for **A**nticipated **C**onvection; the term originates from the header coding [ACUS1] of the transmitted product.

ACCAS — (usually pronounced ACK-kis) — **A**lto**C**umulus **CAS**tellanus; mid-level clouds (bases generally 8 to 15 thousand feet), of which at least a fraction of their upper parts show cumulus-type development. These clouds often are taller than they are wide, giving them a turret-shaped appearance. ACCAS clouds are a sign of instability aloft, and may precede the rapid development of thunderstorms.

Accessory Cloud — a cloud which is dependent on a larger cloud system for development and continuance. Roll clouds, shelf clouds, and wall clouds are examples of accessory clouds. See also **Clouds and Cloud Formation**.

ADVY — Advisory.

Advection — Transport of an atmospheric property by the wind. See cold advection, or warm advection.

AFTN — Afternoon.

Air-Mass Thunderstorm — Generally, a thunderstorm not associated with a front or other type of synoptic-scale forcing mechanism. Air mass thunderstorms typically are associated with warm, humid air in the summer months; they develop during the afternoon in response to insolation, and dissipate rather quickly after sunset. They generally are less likely to be severe than other types of thunderstorms, but they still are capable of producing downbursts, brief heavy rain, and (in extreme cases) hail over 3/4 inch in diameter.

Since all thunderstorms are associated with some type of forcing mechanism, synoptic-scale or otherwise, the existence of true air-mass thunderstorms is debatable.

Anticyclonic Rotation — Rotation in the opposite sense as the Earth's rotation, i.e., clockwise in the Northern Hemisphere as would be seen from above. The opposite of cyclonic rotation.

Anvil — The flat, spreading top of a Cb (cumulonimbus), often shaped like an anvil. Thunderstorm anvils may spread hundreds of miles downwind from the thunderstorm itself, and sometimes may spread upwind.

Anvil Crawler — [Slang], a lightning discharge occurring within the anvil of a thunderstorm, characterized by one or more channels that appear to crawl along the underside of the anvil. They typically appear during the weakening or dissipating stage of the parent thunderstorm, or during an active MCS.

Anvil Dome — A large overshooting top or penetrating top.

AOA — At or Above

AOB — At or Below

Approaching — (severe levels) — A thunderstorm which contains winds of 35 to 49 knots (40 to 57 mph), or hail 1/2′ or larger but less than 3/4″ in diameter.

Arcus — A low, horizontal cloud formation associated with the leading edge of thunderstorm outflow (i.e., the gust front). Roll clouds and shelf clouds both are types of arcus clouds.

ATTM — At This Time.

AVN — The Aviation Model (120-hour numerical model of the atmosphere).

Back-Building Thunderstorm — A thunderstorm in which, new development takes place on the upwind side (usually the west or southwest side), such that the storm seems to remain stationary or propagate in a backward direction.

Backing Winds — Winds which shift in a counterclockwise direction with time at a given location (e.g. from southerly to southeasterly), or change direction in a counterclockwise sense with height (e.g. westerly at the surface but becoming more southerly aloft). The opposite of veering winds.

In storm spotting, a backing wind usually refers to the turning of a south or southwest surface wind with time to a more east or southeasterly direction. Backing of the surface wind can increase the potential for tornado development by increasing the directional shear at low levels.

Baroclinic Zone — A region in which a temperature gradient exists on a constant pressure surface. Baroclinic zones are favored areas for strengthening and weakening systems; barotropic systems, on the other hand, do not exhibit significant changes in intensity. Also, wind shear is characteristic of a baroclinic zone.

Barotropic System — a weather system in which temperature and pressure surfaces are coincident, i.e., temperature is uniform (no temperature gradient) on a constant pressure surface. Barotropic systems are characterized by a lack of wind shear, and thus are generally unfavorable areas for severe thunderstorm development. See baroclinic zone.

Usually, in operational meteorology, references to barotropic systems refer to *equivalent* barotropic systems — systems in which temperature gradients exist, but are parallel to height gradients on a constant pressure surface. In such systems, height contours and isotherms are parallel everywhere, and winds do not change direction with height.

As a rule, a true equivalent barotropic system can never be achieved in the real atmosphere. While some systems (such as closed lows or cutoff lows) may reach a state that is close to equivalent barotropic, the term barotropic system usually is used in a relative sense to describe systems that are really only close to being equivalent barotropic, i.e., isotherms and height contours are nearly parallel everywhere and directional wind shear is weak.

BECMG — Becoming

BKN — Broken

BL — Boundary Layer

Blizzard — a blizzard means that the following conditions are expected to prevail for a period of 3 hours or longer . . .

- Sustained wind or frequent gusts to 35 miles an hour or greater; **and**
- considerable falling and/or blowing snow (i.e., reducing visibility frequently to less than 1/4 mile).

BLO — Below (refers to cloud coverage).

Blowing Dust or Sand — Strong winds over dry ground, that has little or no vegetation, can lift particles of dust or sand into the air. These airborne particles can reduce visibility, cause respiratory problems, and have an abrasive affect on machinery. A concentration reducing the visibility to 1/4 mile or less often poses hazards for travelers.

Blowing Snow — Blowing snow is wind-driven snow that reduces surface visibility. Blowing snow can be falling snow or snow that has already accumulated but is picked up and blown by strong winds. Blowing snow is usually accompanied by drifting snow.

Boundary Layer — In general, a layer of air adjacent to a bounding surface. Specifically, the term most often refers to the *planetary boundary layer*, which is the layer within which the effects of friction are significant. For the earth, this layer is considered to be roughly the lowest one or two kilometers of the atmosphere. It is within this layer that temperatures are most strongly affected by daytime insolation and nighttime radiational cooling, and winds are affected by friction with the earth's surface. The effects of friction die out gradually with height, so the "top" of this layer cannot be defined exactly.

There is a thin layer immediately above the earth's surface known as the *surface boundary layer* (or simply the surface layer). This layer is only a part of the planetary boundary layer, and represents the layer within which friction effects are more or less constant throughout (as opposed to decreasing with height, as they do above it). The surface boundary layer is roughly 10 meters thick, but again the exact depth is indeterminate. Like friction, the effects of insolation and radiational cooling are strongest within this layer.

Bow Echo — a radar echo which is linear but bent outward in a bow shape. Damaging straight-line winds often occur near the "crest" or center of a bow echo. Areas of circulation also can develop at either end of a bow echo, which sometimes can lead to tornado formation — especially in the left (usually northern) end, where the circulation exhibits cyclonic rotation.

CAA — Cold Air Advection

Cap — (or Capping Inversion) — A layer of relatively warm air aloft (usually several thousand feet above the ground) which suppresses or delays the development of thunderstorms. Air parcels rising into this layer become cooler than the surrounding air, which inhibits their ability to rise further. As such, the cap often prevents or delays thunderstorm development even in the presence of extreme instability. However if the cap is removed or weakened, then explosive thunderstorm development can occur. See CIN.

The cap is an important ingredient in most severe thunderstorm episodes, as it serves to separate warm, moist air below and cooler, drier air above. With the cap in place, air below it can continue to warm and/or moisten, thus increasing the amount of potential instability. Or, air above it can cool, which also increases potential instability. But without a cap, either process (warming/moistening at low levels or cooling aloft) results in a faster release of available instability — often before instability levels become large enough to support severe weather development.

CAPE — **C**onvective **A**vailable **P**otential **E**nergy. A measure of the amount of energy available for convection. CAPE is directly related to the maximum potential vertical speed within an updraft; thus, higher values indicate greater potential for severe weather. Observed values in thunderstorm environments often may exceed 1,000 joules per kilogram (j/kg), and in extreme cases may exceed 5,000 j/kg.

However, as with other indices or indicators, there are no threshold values above which severe weather becomes imminent. CAPE is represented on an upper air sounding by the area enclosed between the environmental temperature profile and the path of a rising air parcel, over the layer within which the latter is warmer than the former. (This area often is called positive area.) See **CIN**.

Cb — **C**umulonim**b**us cloud, characterized by strong vertical development in the form of mountains or huge towers topped at least partially by a smooth, flat, often fibrous anvil. Also known colloquially as a "thunderhead."

CC — Cloud-to-Cloud lightning.

Cell — Convection in the form of a single updraft, downdraft, or updraft/downdraft couplet, typically seen as a vertical dome or tower as in a towering cumulus cloud. A typical thunderstorm consists of several cells.

The term "cell" also is used to describe the radar echo returned by an individual shower or thunderstorm. Such usage, although common, is technically incorrect.

CG — Cloud-to-Ground lightning flash.

CHC — Chance.

Channeled High Winds — In mountainous areas or in cities with tall buildings, air may be channeled through constricted passages producing high winds. Santa Ana winds and winds through passes from the cold Alaskan interior to the sea are examples of these winds. Channeled high winds are local in nature but can be extremely strong. These winds generally occur in well-defined areas

Chinook or Foehm Wind — These are warm, dry winds that occur in the lee of high mountain ranges. It is a fairly common wintertime phenomena in the mountainous west and in parts of Alaska. These winds develop in well-defined areas and can be quite strong. See also **Chinook**.

CIN — **C**onvective **IN**hibition. A measure of the amount of energy needed in order to initiate convection. Values of CIN typically reflect the strength of the cap. They are obtained on a sounding by computing the area enclosed between the environmental temperature profile and the path of a rising air parcel, over the layer within which the latter is cooler than the former. (This area sometimes is called negative area.) See **CAPE**.

Cl — Cirrus clouds.

Cirrus — High-level clouds (16,000 feet or more), composed of ice crystals and appearing in the form of white, delicate filaments or white or mostly white patches or narrow bands. Cirrus clouds typically have a fibrous or hairlike appearance, and often are semi-transparent. Thunderstorm anvils are a form of cirrus cloud, but most cirrus clouds are not associated with thunderstorms.

Closed Low — a low pressure area with a distinct center of cyclonic circulation which can be completely encircled by one or more isobars or height contour lines. The term usually is used to distinguish a low pressure area aloft from a low-pressure trough. Closed lows aloft typically are partially or completely detached from the main westerly current, and thus move relatively slowly (see **cutoff low**).

Cloud Streets — Rows of cumulus or cumulus-type clouds aligned parallel to the low-level flow. Cloud streets sometimes can be seen from the ground, but are seen best on satellite photographs.

Cold Advection — Transport of cold air into a region by horizontal winds.

Cold-Air Funnel — a funnel cloud or (rarely) a small, relatively weak tornado that can develop from a small shower or thunderstorm when the air aloft is unusually cold (hence the name). They are much less violent than other types of tornadoes. See also **Tornado**.

Cold Pool — a region of relatively cold air, represented on a weather map analysis as a relative minimum in temperature surrounded by closed isotherms. Cold pools aloft represent regions of relatively low stability, while surface-based cold pools are regions of relatively stable air.

Condensation Funnel — a funnel-shaped cloud associated with rotation and consisting of condensed water droplets (as opposed to smoke, dust, debris, etc.).

Confluence — A pattern of wind flow in which air flows inward toward an axis oriented parallel to the general direction of flow. It is the opposite of difluence. Confluence is not the same as convergence. Winds often accelerate as they enter a confluent zone, resulting in speed divergence which offsets the (apparent) converging effect of the confluent flow.

CONUS — Continental U.S.

Convection — Generally, transport of heat and moisture by the movement of a fluid. In meteorology, the term is used specifically to describe vertical transport of heat and moisture, especially by updrafts and downdrafts in an unstable atmosphere. The terms "convection" and "thunderstorms" often are used interchangeably, although thunderstorms are only one form of convection. Cbs, towering cumulus clouds, and ACCAS clouds all are visible forms of convection. However, convection is not always made visible by clouds. Convection which occurs without cloud formation is called dry convection, while the visible convection processes referred to above are forms of moist convection. See also **Clouds and Cloud Formation**.

Convective Temperature — The approximate temperature that the air near the ground must warm to in order for surface-based convection to develop, based on analysis of a sounding.

Calculation of the convective temperature involves many assumptions, such that thunderstorms sometimes develop well before or well after the convective temperature is reached (or may not develop at all). However, in some cases the convective temperature is a useful parameter for forecasting the onset of convection.

Convergence — a contraction of a vector field; the opposite of divergence. Convergence in a horizontal wind field indicates that more air is entering a given area than is leaving at that level. To compensate for the resulting "excess," vertical motion may result: upward forcing if convergence is at low levels, or downward forcing (subsidence) if convergence is at high levels. Upward forcing from low-level convergence increases the potential for thunderstorm development (when other factors, such as instability, are favorable). Compare with **confluence**.

COORD — Coordination.

CU — Cumulus clouds.

Cutoff Low — a closed low which has become completely displaced (cut off) from basic westerly current, and moves independently of that current. Cutoff lows may remain nearly stationary for days, or on occasion may move westward opposite to the prevailing flow aloft (i.e., retrogression).

"Cutoff low" and "closed low" often are used interchangeably to describe low pressure centers aloft. However, not all closed lows are completely removed from the influence of the basic westerlies. Therefore, the recommended usage of the terms is to reserve the use of "cutoff low" only to those closed lows which clearly are detached completely from the westerlies.

CWA — County Warning Area

CWFA — County Warning and Forecast Area

Derecho — (Pronounced day-RAY-cho), a widespread and usually fast-moving windstorm associated with convection. Derechos include any family of downburst clusters produced by an extratropical MCS, and can produce damaging straight-line winds over areas hundreds of miles long and more than 100 miles across.

Dew Point — (or Dew-point Temperature) — A measure of atmospheric moisture. It is the temperature to which air must be cooled in order to reach saturation (assuming air pressure and moisture content are constant). See also **Dew Point**.

Difluence — (or Diffluence) — A pattern of wind flow in which air moves outward (in a "fan-out" pattern) away from a central axis that is oriented parallel to the general direction of the flow. It is the opposite of confluence.

Difluence in an upper level wind field is considered a favorable condition for severe thunderstorm development (if other parameters are also favorable). But difluence is not the same as divergence. In a difluent flow, winds normally decelerate as they move through the region of difluence, resulting in speed convergence which offsets the apparent diverging effect of the difluent flow.

Diurnal — Daily; related to actions which are completed in the course of a calendar day, and which typically recur every calendar day (e.g., diurnal temperature rises during the day, and diurnal falls at night).

Divergence — The expansion or spreading out of a vector field; usually said of horizontal winds. It is the opposite of convergence. Divergence at upper levels of the atmosphere enhances upward motion, and hence the potential for thunderstorm development (if other factors also are favorable).

Down burst — a strong downdraft that induces an outburst of damaging winds on or near the ground.

Drifting Snow — Drifting snow is an uneven distribution of snowfall/snow depth caused by strong surface winds. Drifting snow may occur during or after a snowfall. Drifting snow is usually associated with blowing snow.

Dry Line — a boundary separating moist and dry air masses, and an important factor in severe weather frequency in the Great Plains. It typically lies north-south across the central and southern high Plains states during the spring and early summer, where it separates moist air from the Gulf of Mexico (to the east) and dry desert air from the southwestern states (to the west). The dry line typically advances eastward during the afternoon and retreats westward at night. However, a strong storm system can sweep the dry line eastward into the Mississippi Valley, or even further east, regardless of the time of day.

A typical dry line passage results in a sharp drop in humidity (hence the name), clearing skies, and a wind shift from south or southeasterly to west or southwesterly. (Blowing dust and rising temperatures also may follow, especially if the dry line passes during the daytime. These changes occur in reverse order when the dry line retreats westward. Severe and sometimes tornadic thunderstorms often develop along a dry line or in the moist air just to the east of it, especially when it begins moving eastward.

Dry Microburst — a microburst with little or no precipitation reaching the ground; most common in semi-arid regions. They may or may not produce lightning. Dry microbursts may develop in an otherwise fair-weather pattern; visible signs may include a cumulus cloud or small Cb with a high base and high-level virga, or perhaps only an orphan anvil from a dying rain shower. At the ground, the only visible sign might be a dust plume or a ring of blowing dust beneath a local area of virga.

Dry Slot — a zone of dry (and relatively cloud-free) air which wraps east- or northeastward into the southern and eastern parts of a synoptic scale or mesoscale low pressure system. A dry slot generally is seen best on satellite photographs.

Dynamics — Generally, any forces that produce motion or affect change. In operational meteorology, dynamics usually refer specifically to those forces that produce vertical motion in the atmosphere.

DVV — Downward Vertical Velocity (sinking air)

DZ — Drizzle.

ECMWF — **E**uropean **C**enter for **M**edium-Range **W**eather **F**orecasting. Operational references in forecast discussions typically refer to the ECMWF's medium-range forecast model. See **MRF**, **UKMET**.

Elevated Convection — Convection occurring within an elevated layer, i.e., a layer in which the lowest portion is based above the earth's surface. Elevated convection often occurs when air near the ground is relatively cool and stable, e.g., during periods of isentropic lift, when an unstable layer of air is present aloft.

In cases of elevated convection, stability indices based on near-surface measurements (such as the lifted index) typically will underestimate the amount of instability present. Severe weather is possible

from elevated convection, but is less likely than it is with surface-based convection.

Enhanced Wording — An option used by the SPC in tornado and severe thunderstorm watches when the potential for strong/violent tornadoes, or unusually widespread damaging straight-line winds, is high.

The statement "THIS IS A PARTICULARLY DANGEROUS SITUATION WITH THE POSSIBILITY OF VERY DAMAGING TORNADOES" appears in tornado watches with enhanced wording. Severe thunderstorm watches may include the statement "**THIS IS A PARTICULARLY DANGEROUS SITUATION WITH THE POSSIBILITY OF EXTREMELY DAMAGING WINDS**," usually when a derecho event is occurring or forecast to occur.

Entrance Region — The region upstream from a wind speed maximum in a jet stream (jet max), in which air is approaching (entering) the region of maximum winds, and therefore is accelerating. This acceleration results in a vertical circulation that creates divergence in the upper-level winds in the right half of the entrance region (as would be viewed looking along the direction of flow).

This divergence results in upward motion of air in the right rear quadrant (or right entrance region) of the jet max. Severe weather potential sometimes increases in this area as a result. See also exit region, left exit region.

Equilibrium Level — (or EL) — On an upper air sounding, the level above the level of free convection (LFC) at which the temperature of a rising air parcel again equals the temperature of the environment.

The height of the EL is the height at which thunderstorm updrafts no longer accelerate upward. Thus, to a close approximation, it represents the height of expected (or ongoing) thunderstorm tops. However, strong updrafts will continue to rise past the EL before stopping, resulting in storm tops that are higher than the EL. This process sometimes can be seen visually as an overshooting top or anvil dome.

The EL typically is higher than the tropopause, and is a more accurate reference for storm tops.

ERN — Eastern.

ETA — The Eta Model (60-hour numerical model of the atmosphere).

Exit Region — The region downstream from a wind speed maximum in a jet stream (jet max), in which air is moving away from the region of maximum winds, and therefore is decelerating. This deceleration results in divergence in the upper-level winds in the left half of the exit region (as would be viewed looking along the direction of flow).

This divergence results in upward motion of air in the left front quadrant (or left exit region) of the jet max. Severe weather potential sometimes increases in this area as a result. See also entrance region, right entrance region.

Excessive Heat — Excessive heat occurs from a combination of high temperatures (significantly above normal) and high humidities. At certain levels, the human body cannot maintain proper internal temperatures and may experience heat stroke. The "Heat Index" is a measure of the effect of the combined elements on the body.

FA — Forecast Area.

F Scale — See **Fujita Scale**. **FCST** — Forecast.

Flash Flood — a flood which is caused by heavy or excessive rainfall in a short period of time, generally less than 6 hours. Also, at times a dam failure can cause a flash flood, depending on the type of dam and time period during which the break occurs.

Flood — The inundation of a normally dry area caused by an increased water level in an established watercourse, such as a river, stream, or drainage ditch, or ponding of water at or near the point where the rain fell. See also **Floods**.

Fog — Fog is water droplets suspended in the air at the Earth's surface. Fog is often hazardous when the visibility is reduced to 1/4 mile or less. See also **Fog and Fog Clearing**.

Front — a boundary or transition zone between two air masses of different density, and thus (usually) of different temperature. A moving front is named according to the advancing air mass, e.g., cold front if colder air is advancing. See also **Fronts and Storms**.

FROPA — Frontal Passage.

Freeze — A freeze is when the surface air temperature is expected to be 32 °F (0 °C) or below over a widespread area for a climatologically significant period of time. Use of the term is usually restricted to advective situations or to occasions when wind or other conditions prevent frost. "Killing" may be used during the growing season when the temperature is expected to be low enough for a sufficient duration to kill all but the hardiest herbaceous crops. See also **Climate**.

Freezing Rain or Drizzle — This occurs when rain or drizzle freezes on surfaces, such as the ground, trees, power lines, motor vehicles, streets, highways, etc. Small accumulations of ice can cause driving and walking difficulties while heavy accumulations produce extremely dangerous and damaging situations primarily by pulling down trees and utility lines.

Frost — Frost describes the formation of thin ice crystals on the ground or other surfaces in the form of scales, needles, feathers, or fans. Frost develops under conditions similar to dew, except the temperatures of the Earth's surface and earthbound objects falls below 32 °F (0 °C). As with the term "freeze," this condition is primarily significant during the growing season. If a frost period is sufficiently severe to end the growing season or delay its beginning, it is commonly referred to as a "killing frost." Because frost is primarily an event that occurs as the result of radiational cooling, it frequently occurs with a thermometer level temperature in the mid-30s. See also **Frost**.

Funnel Cloud — a condensation funnel extending from the base of a towering cumulus or Cb, associated with a rotating column of air that is *not* in contact with the ground (and hence different from a tornado). A condensation funnel is a tornado, *not* a funnel cloud, if either a) it is in contact with the ground or b) a debris cloud or dust whirl is visible beneath it.

Fujita Scale — (or F Scale) — A scale of wind *damage* intensity in which wind speeds are inferred from an analysis of wind damage:

F0 (weak)	40-72 mph, light damage
F1 (weak)	73-112 mph, moderate damage
F2 (strong)	113-157 mph, considerable damage
F3 (strong)	158-206 mph, severe damage
F4 (violent)	207-260 mph, devastating damage
F5 (violent)	261-318 mph, (rare) incredible damage

All tornadoes, and most other severe local windstorms, are assigned a single number from this scale according to the most intense damage caused by the storm. See also **Tornado**.

Gradient High Winds — These high winds usually cover a large area and are due to synoptic-scale, extra-tropical low pressure systems.

Gustnado — (or Gustinado) — [Slang], gust front tornado. A small tornado, usually weak and short-lived, that occurs along the gust front of a thunderstorm. Often it is visible only as a debris cloud or dust whirl near the ground. Gustnadoes are not associated with storm-scale rotation (i.e. mesocyclones); they are more likely to be associated visually with a shelf cloud than with a wall cloud.

Heavy Snow — This generally means . . .

- snowfall accumulating to 4″ or more in depth in 12 hours or less; or
- snowfall accumulating to 6″ or more in depth in 24 hours or less.

In forecasts, snowfall amounts are expressed as a range of values, e.g., "8 to 12 inches." However, in heavy snow situations where there is considerable uncertainty concerning the range of values, more appropriate phrases are used, such as ". . . up to 12 inches . . ." or alternatively ". . . 8 inches or more . . .".

Helicity — A property of a moving fluid which represents the potential for helical flow (i.e. flow which follows the pattern of a corkscrew) to evolve. Helicity is proportional to the strength of the flow, the amount of vertical wind shear, and the amount of turning in the flow (i.e. vorticity).

Atmospheric helicity is computed from the vertical wind profile in the lower part of the atmosphere (usually from the surface up to 3 km), and is measured relative to storm motion. Higher values of helicity (generally, around 150 m^2/s^2 or more) favor the development of mid-level rotation (i.e. mesocyclones). Extreme values can exceed 600 m^2/s^2.

High Wind — Sustained wind speeds of 40 mph or greater lasting for 1 hour or longer, or winds of 58 mph or greater for any duration.

Hook — (or Hook Echo) — A radar reflectivity pattern characterized by a hook-shaped extension of a thunderstorm echo, usually in the right-rear part of the storm (relative to its direction of motion). A hook often is associated with a mesocyclone, and indicates favorable conditions for tornado development.

HP Storm — or HP Supercell — High-Precipitation storm (or High-Precipitation supercell). A supercell thunderstorm in which heavy precipitation (often including hail) falls on the trailing side of the mesocyclone.

Precipitation often totally envelops the region of rotation, making visual identification of any embedded tornadoes difficult and very dangerous. Unlike most classic supercells, the region of rotation in many HP storms develops in the front-flank region of the storm (i.e., usually in the eastern portion). HP storms often produce extreme and prolonged downburst events, serious flash flooding, and very large damaging hail events.

Humidity — Generally, a measure of the water vapor content of the air. Popularly, it is used synonymously with relative humidity. See also **Humidity**.

Instability — The tendency for air parcels to accelerate when they are displaced from their original position; especially, the tendency to accelerate upward after being lifted. Instability is a prerequisite for severe weather — the greater the instability, the greater the potential for severe thunderstorms. See **lifted index**.

Inversion — Generally, a departure from the usual increase or decrease in an atmospheric property with altitude. Specifically it almost always refers to a temperature inversion, i.e., an increase in temperature with height, or to the layer within which such an increase occurs. An inversion is present in the lower part of a cap.

IR — Infrared.

Isentropic Lift — Lifting of air that is traveling along an upward-sloping isentropic surface.

Isentropic lift often is referred to erroneously as overrunning, but more accurately describes the physical process by which the lifting occurs. Situations involving isentropic lift often are characterized by widespread stratiform clouds and precipitation, but may include elevated convection in the form of embedded thunderstorms.

Isentropic Surface — a two-dimensional surface containing points of equal potential temperature.

Isobar — a line connecting points of equal pressure.

Isodrosotherm — a line connecting points of equal dew point temperature. See also **Dew Point**.

Isopleth — General term for a line connecting points of equal value of some quantity. Isobars, isotherms, etc. all are examples of isopleths.

Isotach — a line connecting points of equal wind speed.

Isotherm — a line connecting points of equal temperature.

Jet Max — (or Speed Max, Jet Streak) — a point or area of relative maximum wind speeds within a jet stream.

Jet Streak — a local wind speed maximum within a jet stream.

Jet Stream — Relatively strong winds concentrated in a narrow stream in the atmosphere, normally referring to horizontal, high-altitude winds. The position and orientation of jet streams vary from day to day. General weather patterns (hot/cold, wet/dry) are related closely to the position, strength and orientation of the jet stream (or jet streams). A jet stream at low levels is known as a low-level jet. See also **Jet Streams**.

KT(S) — Knots(s).

Landspout — [Slang], a tornado that does not arise from organized storm-scale rotation and therefore is not associated with a wall cloud (visually) or a mesocyclone (on radar). Landspouts typically are observed beneath Cbs or towering cumulus clouds (often as no more than a dust whirl), and essentially are the land-based equivalents of waterspouts. See also **Waterspout**.

Left Front Quadrant (LFQ) — (or Left Exit Region) — The area downstream from and to the left of an upper-level jet max (as would be viewed looking along the direction of flow). Upward motion and severe thunderstorm potential sometimes are increased in this area relative to the wind speed maximum. See **entrance region**, **right rear quadrant**.

Lifted Index (or LI) — a common measure of atmospheric instability. Its value is obtained by computing the temperature that air near the ground would have if it were lifted to some higher level (around 18,000 feet, usually) and comparing that temperature to the actual temperature at that level. Negative values indicate instability — the more negative, the more unstable the air is, and the stronger the updrafts are likely to be with any developing thunderstorms. However there are no "magic numbers" or threshold LI values below which severe weather becomes imminent.

Low-Level Jet — (abbrev. LLJ) — A region of relatively strong winds in the lower part of the atmosphere. Specifically, it often refers to a southerly wind maximum in the boundary layer, common over the Plains states at night during the warm season (spring and summer).

The term also may be used to describe a narrow zone of strong winds *above* the boundary layer, but in this sense the more proper term would be low-level jet *stream*.

Macroburst — A convective downdraft with an affected outflow area of at least 21/2 miles wide and peak winds lasting between 5 and 20 minutes. Intense macrobursts may cause tornado-force damage of up to F3 intensity.

MB — Millibar.

MCC — **M**esoscale **C**onvective **C**omplex. A large MCS, generally round or oval-shaped, which normally reaches peak intensity at night. The formal definition includes specific minimum criteria for size, duration, and eccentricity (i.e., "roundness"), based on the cloud shield as seen on infrared satellite photographs:

- Size: Area of cloud top −32 degrees C or less: 100,000 square kilometers or more (slightly smaller than the state of Ohio), and area of cloud top −52 degrees C or less: 50,000 square kilometers or more.
- Duration: Size criteria must be met for at least 6 hours.
- Eccentricity: Minor/major axis at least 0.7.

MCCs typically form during the afternoon and evening in the form of several isolated thunderstorms, during which time the potential for severe weather is greatest. During peak intensity, the primary threat shifts toward heavy rain and flooding.

MCS — **M**esoscale **C**onvective **S**ystem. A complex of thunderstorms which becomes organized on a scale larger than the individual thunderstorms, and normally persists for several hours or more. MCSs may be round or linear in shape, and include systems such as tropical cyclones, squall lines, and MCCs (among others). MCS often is used to describe a cluster of thunderstorms that does not satisfy the size, shape, or duration criteria of an MCC.

Medium Range — in forecasting, (generally) three to seven days in advance.

Meridional Flow — Large-scale atmospheric flow in which the north-south component (i.e., longitudinal, or along a meridian) is pronounced. The accompanying zonal (east-west) component often is weaker than normal. Compare with zonal flow.

Mesonet — A regional network of observing stations (usually surface stations) designed to diagnose mesoscale weather features and their associated processes.

Mesoscale — Size scale referring to weather systems smaller than synoptic-scale systems but larger than storm-scale systems. Horizontal dimensions generally range from around 50 miles to several hundred miles. Squall lines, MCCs, and MCSs are examples of mesoscale weather systems.

Mesoscale High Winds — These high winds usually follow the passage of organized convective systems and are associated with wake depressions or strong mesohighs.

Microburst — A convective downdraft with an affected outflow area of less than 21/2 miles wide and peak winds lasting less than 5 minutes. Microbursts may induce dangerous horizontal/vertical wind shears, which can adversely affect aircraft performance and cause property damage.

Moisture Convergence — A measure of the degree to which moist air is converging into a given area, taking into account the effect of converging winds and moisture advection. Areas of persistent moisture convergence are favored regions for thunderstorm development, if other factors (e.g., instability) are favorable.

MOS — Model Output Statistics.

MRF — Medium-Range Forecast model; one of the operational forecast models run at NCEP. The MRF is run once daily, with forecast output out to 240 hours (10 days).

NCEP — **N**ational **C**enters for **E**nvironmental **P**rediction; the modernized version of NMC.

NGM — The Nested Grid Model (48-hour numerical model of the atmosphere).

NM — Nautical Mile(s).

NOGAPS — Navy Operational Global Atmospheric Prediction System (120-hour numerical model).

NVA — Negative Vorticity Advection.

NWS — National Weather Service.

OBS — Observations.

Outflow Boundary — a storm-scale or mesoscale boundary separating thunderstorm-cooled air (outflow) from the surrounding air; similar in effect to a cold front, with passage marked by a wind shift and usually a drop in temperature. Outflow boundaries may persist for 24 hours or more after the thunderstorms that generated them dissipate, and may travel hundreds of miles from their area of origin.

New thunderstorms often develop along outflow boundaries, especially near the point of intersection with another boundary (cold front, dry line, another outflow boundary, etc.; see triple point).

OVC — Overcast.

Outlook — An outlook is used to indicate that a hazardous weather or hydrologic event may develop. It is intended to provide information to those who need considerable lead time to prepare for the event.

Overrunning — a weather pattern in which a relatively warm air mass is in motion above another air mass of greater density at the surface. Embedded thunderstorms sometimes develop in such a pattern; severe thunderstorms (mainly with large hail) can occur, but tornadoes are unlikely.

Overrunning often is applied to the case of warm air riding up over a retreating layer of colder air, as along the sloping surface of a warm front. Such use of the term technically is incorrect, but in general it refers to a pattern characterized by widespread clouds and steady precipitation on the cool side of a front or other boundary.

Overshooting Top — (or Penetrating Top) –A dome-like protrusion above a thunderstorm anvil, representing a very strong updraft and hence a higher potential for severe weather with that storm. A persistent and/or large overshooting top (anvil dome) often is present on a supercell.

A short-lived overshooting top, or one that forms and dissipates in cycles, may indicate the presence of a pulse storm.

POP — Probability of Precipitation.

Positive-Tilt Trough — An upper level system which is tilted to the east with increasing latitude (i.e., from southwest to northeast). A positive-tilt trough often is a sign of a weakening weather system, and generally is less likely to result in severe weather than a negative-tilt trough if all other factors are equal.

PROG — Forecast.

Pulse Storm — A thunderstorm within which a brief period (pulse) of strong updraft occurs, during and immediately after which the storm produces a short episode of severe weather. These storms generally are not tornado producers, but often produce large hail and/or damaging winds. See **Overshooting Top**.

PVA — Positive Vorticity Advection

PW — Precipitable Water

PWAT — Precuoutabke Water

QG — Quasigeostrophic.

QPF — Quantitative Precipitation Forecast.

Relative Humidity (RH) — A dimensionless ratio, expressed in percent, of the amount of atmospheric moisture present relative to the amount that would be present if the air were saturated. Since the latter amount is dependent on temperature, relative humidity is a function of both moisture content and temperature. As such, relative humidity by itself does not directly indicate the actual amount of atmospheric moisture present. See **Dew Point**.

Retrogression — (or Retrograde Motion) — Movement of a weather system in a direction opposite to that of the basic flow in which it is embedded, usually referring to a closed low or a longwave trough which moves westward.

Right Entrance Region — (or Right Rear Quadrant) — The area upstream from and to the right of an upper-level jet max (as would be viewed looking along the direction of flow). Upward motion and severe thunderstorm potential sometimes are increased in this area relative to the wind speed maximum. See **exit region**, and **left front quadrant**.

Ridge — An elongated area of relatively high atmospheric pressure; the opposite of trough.

Right Mover — A thunderstorm that moves appreciably to the right relative to the main steering winds and to other nearby thunderstorms. Right movers typically are associated with a high potential for severe weather. (Supercells often are right movers.).

RRQ — Right Rear Quadrant.

Roll Cloud — a low, horizontal tube-shaped arcus cloud associated with a thunderstorm gust front (or sometimes with a cold front). Roll clouds are relatively rare; they are completely detached from the thunderstorm base or other cloud features, thus differentiating them from the more familiar shelf clouds. Roll clouds usually appear to be "rolling" about a horizontal axis, but should not be confused with funnel clouds.

Rope — (or Rope Funnel) — A narrow, often contorted condensation funnel usually associated with the decaying stage of a tornado. See **rope stage**.

Rope Cloud — In satellite meteorology, a narrow, rope-like band of clouds sometimes seen on satellite images along a front or other boundary. The term sometimes is used synonymously with rope or rope funnel.

Rope Stage — The dissipating stage of a tornado, characterized by thinning and shrinking of the condensation funnel into a rope (or rope funnel). Damage still is possible during this stage.

RUC — **R**apid **U**pdate **C**ycle, a numerical model run at NCEP that focuses on short-term (up to 12 h) forecasts and small-scale (mesoscale) weather features. Forecasts are prepared every 3 hours for the contiguous United States.

SAT — Satellite.

SCT — Scattered.

Severe Local Storm — A convective storm that usually covers a relatively small geographic area, or moves in a narrow path, and is sufficiently intense to threaten life and/or property. Examples include severe thunderstorms with large hail, damaging wind, or tornadoes. Although cloud-to-ground lightning is not a criteria for severe local storms, it is acknowledged to be highly dangerous and a leading cause of deaths, injuries, and damage from thunderstorms. A thunderstorm need not be severe to generate frequent cloud-to-ground lightning. Additionally, excessive localized convective rains are not classified as severe storms but often are the product of severe local storms. Such rainfall may result in related phenomena (flash floods) that threaten life and property.

Severe Thunderstorm — A thunderstorm that produces a tornado, winds of at least 58 mph (50 knots), and/or hail at least 3/4 in diameter. Structural wind damage may imply the occurrence of a severe thunderstorm. A thunderstorm wind equal to or greater than 40 mph (35 knots) and/or hail of at least 1/2 is defined as **approaching severe**.

Severe Thunderstorm Risk — The relative coverage and/or threat for severe thunderstorms in a specified area. The following describes the possible density/risk of severe thunderstorms in an outlook area . . .

- **APPROACHING** — A non-severe category that indicates an area of strong convection; used to highlight areas where strong thunderstorms are anticipated but not expected to become severe.
- **SLIGHT** risk — Severe thunderstorms are expected; the severe storms may not have a mesoscale organization or may be isolated in areal extent with between 2–5% aerial coverage.
- **MODERATE** risk — Severe thunderstorms are expected and are anticipated to be more organized on the mesoscale. They will be more numerous or widespread than in the SLIGHT category. The potential for personal injury and/or significant property damage is significantly enhanced with between 6 and 10 percent coverage. A moderate risk indicates the possibility of a significant severe weather episode.

- **HIGH** risk — Severe thunderstorms are expected and are anticipated to be widespread. A dangerous situation exists with the strong potential for killer tornadoes, devastating windstorms, and widespread property damage. This category generally is confined for use in anticipated tornado outbreaks with more than 10 percent coverage. A high risk is rare and implies the possibility of a major severe weather outbreak.

SFC — Surface.

SHRA — Rain Showers.

Shear — Variation in wind speed (speed shear) and/or direction (directional shear) over a short distance. Shear usually refers to vertical wind shear, i.e., the change in wind with height, but the term also is used in Doppler radar to describe changes in radial velocity over short horizontal distances.

Shelf Cloud — a low, horizontal wedge-shaped arcus cloud, associated with a thunderstorm gust front (or occasionally with a cold front, even in the absence of thunderstorms). Unlike the roll cloud, the shelf cloud is attached to the base of the parent cloud above it (usually a thunderstorm). Rising cloud motion often can be seen in the leading (outer) part of the shelf cloud, while the underside often appears turbulent, boiling, and wind-torn.

Short Term Forecast — a product used to convey information regarding weather or hydrologic events in the next few hours.

Sleet — Sleet is defined as pellets of ice composed of frozen or mostly frozen raindrops or refrozen partially melted snowflakes. These pellets of ice usually bounce after hitting the ground or other hard surfaces. Heavy sleet is a relatively rare event defined as an accumulation of ice pellets covering the ground to a depth of 1/2 or more. See also **Precipitation and Hydrometeors**.

Snow Flurries — Snow flurries are an intermittent light snowfall of short duration (generally light snow showers) with no measurable accumulation (trace category). See also **Precipitation and Hydrometeors**.

Snow Squalls — Snow squalls are intense, but limited duration, periods of moderate to heavy snowfall, accompanied by strong, gusty surface winds and possibly lightning (generally moderate to heavy snow showers). Snow accumulation may be significant.

Speed Shear — The component of wind shear which is due to a change in wind speed with height, e.g., southwesterly winds of 20 mph at 10,000 feet increasing to 50 mph at 20,000 feet. Speed shear is an important factor in severe weather development, especially in the middle and upper levels of the atmosphere.

Squall Line — a solid or nearly solid line or band of active thunderstorms.

Straight-line Winds — Generally, any wind that is not associated with rotation, used mainly to differentiate them from tornadic winds.

Stratiform — Having extensive horizontal development, as opposed to the more vertical development characteristic of convection. Stratiform clouds cover large areas but show relatively little vertical development. Stratiform precipitation, in general, is relatively continuous and uniform in intensity (i.e., steady rain versus rain showers).

Stratocummulus — Low-level clouds, existing in a relatively flat layer but having individual elements. Elements often are arranged in rows, bands, or waves. Stratocumulus often reveals the depth of the moist air at low levels, while the speed of the cloud elements can reveal the strength of the low-level jet.

Stratus — A low, generally gray cloud layer with a fairly uniform base. Stratus may appear in the form of ragged patches, but otherwise does not exhibit individual cloud elements as do cumulus and stratocumulus clouds. Fog usually is a surface-based form of stratus.

Surface-based Convection — Convection occurring within a surface-based layer, i.e., a layer in which the lowest portion is based at or very near the earth's surface. Compare with elevated convection.

SWEAT Index — **S**evere **W**eather Thr**EAT** index. A stability index developed by the Air Force which incorporates instability, wind shear, and wind speeds as follows: $\mathrm{SWEAT} = (12\,\mathrm{Td}\,850) + (20\,[\mathrm{TT} - 49]) + (2\,\mathrm{f}\,850) + \mathrm{f}\,500 + (125\,[\mathrm{s} + 0.2])$ where

- Td 850 is the dew point temperature at 850 mb,
- TT is the total-totals index,
- f 850 is the 850-mb wind speed (in knots),
- f 500 is the 500-mb wind speed (in knots), and
- s is the sine of the angle between the wind directions at 500 mb and 850 mb (thus representing the directional shear in this layer).

SWEAT values of about 250-300 or more indicate a greater potential for severe weather, but as with all stability indices, there are no magic numbers.

The SWEAT index has the advantage (and disadvantage) of using only mandatory-level data (i.e., 500 mb and 850 mb), but has fallen into relative disuse with the advent of more detailed upper air sounding analysis programs.

S/ WV — Short Wave.

THETAE — Equivalent Potential Temperature

Theta-e — (or Equivalent Potential Temperature) — The temperature a parcel of air would have if a) it was lifted until it became saturated, b) all water vapor was condensed out, and c) it was returned adiabatically (i.e., without transfer of heat or mass) to a pressure of 1000 millibars. Theta-e, which typically is expressed in degrees Kelvin, is directly related to the amount of heat present in an air parcel. Thus, it is useful in diagnosing atmospheric instability.

Theta-e Ridge — An axis of relatively high values of theta-e. Severe weather and excessive rainfall often occur near or just upstream from a theta-e ridge.

Total-Totals Index — A stability index and severe weather forecast tool, equal to the temperature at 850 mb plus the dew point at 850 mb, minus twice the temperature at 500 mb. The total-totals index is the arithmetic sum of two other indices: the Vertical Totals Index (temperature at 850 mb minus temperature at 500 mb) and the Cross Totals Index (dew point at 850 mb minus temperature at 500 mb). As with all stability indices there are no magic threshold values, but in general, values of less than 50 or greater than 55 are considered weak and strong indicators, respectively, of potential severe storm development.

Towering Cumulus (TCU) — A large cumulus cloud with great vertical development, usually with a cauliflower-like appearance, but lacking the characteristic anvil of a Cb. (Often shortened to "towering cu," and abbreviated TCU.)

Triple Point — The intersection point between two boundaries (dry line, outflow boundary, cold front, etc.), often a focus for thunderstorm development. Triple point also may refer to a point on the gust front of a supercell, where the warm moist inflow, the rain-cooled outflow from the forward flank downdraft, and the rear flank downdraft all intersect; this point is a favored location for tornado development (or redevelopment).

Tropopause — The upper boundary of the troposphere, usually characterized by an abrupt change in lapse rate from positive (decreasing temperature with height) to neutral or negative (temperature constant or increasing with height). See also **Atmosphere (Earth)**.

Troposphere — The layer of the atmosphere from the earth's surface up to the tropopause, characterized by decreasing temperature with height (except, perhaps, in thin layers — see inversion, cap), vertical wind motion, appreciable water vapor content, and sensible weather (clouds, rain, etc.). See also **Atmosphere (Earth)**.

Trough — An elongated area of relatively low atmospheric pressure, usually not associated with a closed circulation, and thus used to distinguish from a closed low. The opposite of ridge.

TSRA — Thunderstorms (with rain).

TSTM — Thunderstorm.

UKMET — A medium-range numerical weather prediction model operated by the **U**nited **K**ingdom **MET**eorological Agency. (72-hour numerical model of the atmosphere).

Updraft — A small-scale current of rising air. If the air is sufficiently moist, then the moisture condenses to become a cumulus cloud or an individual tower of a towering cumulus or Cb.

Upper Level System — A general term for any large-scale or mesoscale disturbance capable of producing upward motion (lift) in the middle or upper parts of the atmosphere. This term sometimes is used interchangeably with impulse or shortwave.

Upslope Flow — Air that flows toward higher terrain, and hence is forced to rise. The added lift often results in widespread low cloudiness and stratiform precipitation if the air is stable, or an increased chance of thunderstorm development if the air is unstable.

Upstream — Toward the source of the flow, or located in the area from which the flow is coming.

UTC — Universal Coordinated Time (same as Greenwich Mean Time). See also **Universal Coordinated Time (UTC)**.

UVV — Upward Vertical Velocity (rising air).

UVM — (or UVV) — **U**pward **V**ertical **M**otion (or **V**elocity).

VCNTY — Vicinity.

Veering Winds — Winds which shift in a *clockwise* direction with time at a given location (e.g., from southerly to westerly), or which change direction in a clockwise sense with height (e.g., southeasterly at the surface turning to southwesterly aloft). The latter example is a form of directional shear which is important for tornado formation. Compare with backing winds.

Vertically-stacked System — a low-pressure system, usually a closed low or cutoff low, which is not tilted with height, i.e., located similarly at all levels of the atmosphere. Such systems typically are weakening and are slow-moving, and are less likely to produce severe weather than tilted systems. However, cold pools aloft associated with vertically-stacked systems may enhance instability enough to produce severe weather.

VIL — **V**ertically-**I**ntegrated **L**iquid water. A property computed by RADAP II and WSR-88D units that takes into account the three-dimensional reflectivity of an echo. The maximum VIL of a storm is useful in determining its potential severity, especially in terms of maximum hail size.

VIP — **V**ideo **I**ntegrator and **P**rocessor, which contours radar reflectivity (in dBZ) into six VIP levels:

- VIP 1 (Level 1, 18-30 dBZ) — Light precipitation
- VIP 2 (Level 2, 30-38 dBZ) — Light to moderate rain.
- VIP 3 (Level 3, 38-44 dBZ) — Moderate to heavy rain.
- VIP 4 (Level 4, 44-50 dBZ) — Heavy rain
- VIP 5 (Level 5, 50-57 dBZ) — Very heavy rain; hail possible.
- VIP 6 (Level 6, >57 dBZ) — Very heavy rain and hail; large hail possible.

Virga — Streaks or wisps of precipitation falling from a cloud but evaporating before reaching the ground. In certain cases, shafts of virga may precede a microburst; see **dry microburst**.

VIS — Visible.

Volcanic Ash — a volcanic eruption can send an ash plume into the atmosphere reducing visibility at the ground and in the air. The chemical composition and abrasive characteristics of the particles varies widely and can seriously affect people and machinery on the ground and aircraft. See also Volcano.

Vorticity — A measure of the local rotation in a fluid flow. In weather analysis and forecasting, it usually refers to the vertical component of rotation (i.e., rotation about a vertical axis) and is used most often in reference to synoptic scale or mesoscale weather systems. By convention, positive values indicate cyclonic rotation.

Vort Max — (Slang; short for **vort**icity **max**imum), a center, or maximum, in the vorticity field of a fluid.

VWP — **V**AD **W**ind **P**rofile. A radar plot of horizontal winds, derived from VAD data, as a function of height above a Doppler Radar. The display is plotted with height as the vertical axis and time as the horizontal axis (a so-called time-height display), which then depicts the change in wind with time at various heights. This display is useful for observing local changes in vertical wind shear, such as backing of low-level winds, increases in speed shear, and development or evolution of nearby jet streams (including low-level jets).

WAA — Warm Air Advection.

Wall Cloud — A localized, persistent, often abrupt lowering from a rain-free base. Wall clouds can range from a fraction of a mile up to nearly five miles in diameter, and normally are found on the south or southwest (inflow) side of the thunderstorm. When seen from within several miles, many wall clouds exhibit rapid upward motion and cyclonic rotation.

However, not all wall clouds rotate. Rotating wall clouds usually develop before strong or violent tornadoes, by anywhere from a few minutes up to nearly an hour. Wall clouds should be monitored visually for signs of *persistent, sustained* rotation and/or rapid vertical motion. "Wall cloud" also is used occasionally in tropical meteorology to describe the inner cloud wall surrounding the eye of a tropical cyclone, but the proper term for this feature is eyewall.

Warm Advection — Transport of warm air into an area by horizontal winds. Low-level warm advection sometimes is referred to (erroneously) as overrunning. Although the two terms are not properly interchangeable, both imply the presence of lifting in low levels.

Watch — A watch is used when the risk of a hazardous weather or hydrologic event has increased significantly, but its occurrence, location, and/or timing is still uncertain. It is intended to provide enough lead time so that those who need to set their plans in motion can do so.

Waterspout — In general, a tornado occurring over water. Specifically, it normally refers to a small, relatively weak rotating column of air over water beneath a Cb or towering cumulus cloud. Waterspouts are most common over tropical or subtropical waters.

The exact definition of waterspout is debatable. In most cases the term is reserved for small vortices over water that are not associated with storm-scale rotation (i.e., they are the water-based equivalent of landspouts). But there is sufficient justification for calling virtually any rotating column of air a waterspout if it is in contact with a water surface. See also **Waterspout**.

Wind Chill — Increased wind speeds accelerate heat loss from exposed skin. No specific rules exist for determining when wind chill becomes dangerous. As a general rule, the threshold for potentially dangerous wind chill conditions is about -20 °F.

WFO — Weather Forecast Office.

WV — Water Vapor.

XSEC — Cross Section.

ZFP — Zone Forecast Product.

Zonal Flow — Large-scale atmospheric flow in which the east-west component (i.e., latitudinal) is dominant. The accompanying meridional (north-south) component often is weaker than normal. Compare with meridional flow.

88**D** — Doppler Radar.

Weather Research Center, TX

WEAVERBIRD *(Aves, Passeriformes).* A bird of a large group found in Africa, Australia, and tropical Asia. They build remarkable nests, weaving their materials intricately and sometimes in complex forms. Some species are gregarious, building large nests for the entire colony. Many species of weavers are brilliantly colored. The group includes the ox birds, whidah birds, bishop birds, munias, and weaver finches.

The blood weaver-finches represent a group of weaverbirds of Arabia and Africa, named from the prevalence of scarlet in their plumage.

WEBER EQUATION. The second-order equation

$$y'' + (n + \tfrac{1}{2} - \tfrac{1}{4}x^2)y = 0$$

It has an irregular singular point at ∞ and occurs in solving the wave equation in parabolic cylindrical coordinates. It is a special case of the confluent hypergeometric equation and its solutions are confluent hypergeometric series.

WEBER-FECHNER LAW. An approximate psychophysical law relating the degree of response or sensation of a sense organ and the intensity of the stimulus. The law asserts that equal increments of sensation are associated with equal increments of the logarithm of the stimulus, or that the just noticeable difference in any sensation results from a change in the stimulus which bears a constant ratio to the value of the stimulus. Also called *Weber law*.

WEBWORM *(Insecta, Lepidoptera).* A caterpillar that surrounds the site of its work on plants with a mixture of silk and debris. Several insects belonging to different families are known as webworms. The burrowing webworms (*Acrolophidae*) eat the roots of grass and may damage corn when planted on sod ground. The sod webworms work at the base of the stem and damage grasses, cereals, and other plants. They belong to the subfamily Crambinae of the family *Pyralidae*, which also contains the cabbage and garden webworms, members of a different subfamily, Pyraustinae. The former affects cabbage and related plants and the latter attacks corn, cotton, and various species of garden plants. The European corn borer is closely related to the last two species. See also **European Corn Borer**.

Cultural methods are the most important in controlling these pests. They vary according to the species, the crop, and the conditions.

Some of the specialists among the webworms are described in the rest of this entry.

Alfalfa webworm (Loxostege commixtalis, Walker). A small webbing-type caterpillar that can destroy an entire field of alfalfa within a very short period if not effectively controlled. Sometimes this insect marches as an army, much as the armyworm (see also **Armyworm**). Although a crop specialist, the alfalfa webworm will consume grains and garden crops.

Beet webworm (Loxostege stricticalis, Linne). Very similar to the alfalfa webworm. This insect is known to destroy many thousands of acres of sugarbeet in some years. The pest occurs from the Mississippi Valley westward to the Rocky Mountains. The insect winters as a larva in cells or tubes in the soil that are lined with silk. See accompanying illustration. The adults emerge in March and through June and are active at night. The wingspread ranges from 1 to 1.5 inches (2.5 to 4 centimeters). The insect devours leaves of sugarbeet and while doing this also spins a web that draws leaves together to form a tube that can be several inches long. This heads to their hiding place, often a lump of soil near the base of the plant. There may be 3 generations of beet webworm per year.

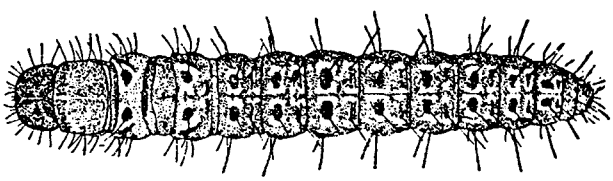

Fig. 1. Sod webworm larva.

Corn root webworm or sod webworm (Grambus sp.). This is a gray or brown caterpillar approximately $\frac{1}{2}$-inch (12 millimeters) long which habitates in silk-lined burrows in the soil near the base of the corn (maize) or other plant attacked. See Fig. 1. This insect thrives in grassland. It cuts off plants near the surface of the soil in a manner quite similar to various cutworms. Often parts of the injured plant will be dragged into the tunnel or burrow. In addition to injuring corn and other crops, the insects are very destructive to lawns. Frequently, the first sign of an invasion by these webworms will be the presence of various birds vigorously feeding on the worms.

Fruit webworm or tent caterpillar (Malacosoma americanum, Fabricius). This insect occurs throughout the United States and attacks a number of fruit trees, such as apple, peach, plum, and wild cherry, as well as certain forest and shade trees, such as beech, birch, oak, poplar, and willow. This insect was first noted in North America in 1646 and tends to occur in cycles of about every 10 years. The adult is a white-to-brown moth and very active near lights at night in June and July. The larva is a hairy caterpillar about 1 to 2 inches (2.5 to 5 centimeters) long. The caterpillar feeds on leaves, sometimes nearly fully defoliating a tree. It is characterized by the construction of tents of webbing on tree branches.

Nonchemical methods of control include removing the tents of webbing from branches by using a pole that has a cone-shaped brush or several nails on its end. The webs can be wound on the end of the pole and then should be immediately burned. The webs should not be burned on the tree because this almost always causes injury to the tree.

The eastern caterpillar lays its eggs on twigs of the tree during the summer. Eggs are laid in bands around the twigs and cover the twigs with a foamy secretion. This secretion dries to a firm, brown covering that looks like an enlargement of the twig. Larvae develop inside the egg, but do not hatch until spring. These egg masses can easily be removed from the branches and destroyed before they hatch and cause damage.

Garden webworm (Loxostege similalis, Guenee). This species of webworm may be described as a universal or general feeder, attacking a

wide variety of food crops as well as undesired weeds. Although it does not specialize on alfalfa or sugarbeet, as do the specialists previously described, the garden webworm will also attack these crops. However, it is not destructive of small grains and grasses. Distribution of the insect is throughout North America and much of South America, but notably Mexico. The insect winters in the pupal stage in the soil in the vicinity of the last plants to be attacked during the fall. In very southern climes, some larvae may pass the winter in that form. Quite early in the spring, the adult moth emerges from the pupa. Masses of eggs, ranging from just a few up to about 50, are laid by the females. The moths are active at night. Only 3 days to a week are required for the eggs to hatch, and the worms are fully grown in from 3 to 5 weeks. If there is a shortage of food supply, the garden webworms have been known to march as an army much like the armyworm.

Parsnip webworm (Depressaria heracliana, Linne). This insect is found in the northern United States and east of the Mississippi River; as well as in southern Canada. Preferred plants for attack include parsnip, celery, wild carrot, and certain weeds. The insect particularly impedes the production of celery and parsnip seed because it invades the flower heads of the plants, engulfing them with silken threads. The caterpillar is small, ranging from yellow to green to gray, with a covering of short hairs and tiny black spots. The adult grayish moth winters in loose bark and debris. The female lays eggs in late spring. When its destructive feeding on buds and seeds is complete, the worm seeks out a suitable place to pupate, emerging as an adult in late summer.

WEDDLE RULE. A procedure for numerical integration. If $y_0, y_1, y_2, \ldots, y_6$ are the values of $y = f(x)$ at seven equally-spaced values of $x_0, x_1, \ldots, x_6$ and $h = x_i - x_j$, then

$$\int_{x_1}^{x_6} f(x)\,dx = \frac{3h}{10}(y_0 + 5y_1 + y_2 + 6y_3 + y_4 + 5y_5 + y_6) + R$$

where R is a remainder term, giving the error in the value of the integral.

WEDGE. See **Machine (Simple)**.

WEED CONTROL. See **Herbicide**.

WEEPING SPRUCE. See **Spruce Trees**.

WEERMAN DEGRADATION. Formation of an aldose with one less carbon atom from and aldonic acid by a Hoffmann-type rearrangement of the corresponding amid. This is a general reaction of α-hydroxycarboxylic acids.

WEEVERFISHES *(Osteichthyes).* Of the family *Trachinidae*, weevers are found in the coastal waters of Europe, along the coast of Chile, and the waters of northern and western Africa. These fishes are probably best known for their poisonous spines, which contain a venomous nerve toxin. *Trachinus draco* prefers relatively deep waters and attains a length of about 17 inches (43 centimeters). Its habitat is from the Baltic to the Black Sea. The smaller *Trachinus viper* seldom exceeds 6 inches in length and is reasonably abundant in the North Sea southward to the Mediterranean. These fishes have the bad habit of burrowing in sandy bottoms and, because of their poisonous nature are a hazard to skin divers.

WEEVIL *(Insecta, Coleoptera).* Most weevils are members of a large suborder of *Coleoptera* known as Polyphaga. These insects, with some exceptions, have the head prolonged into a snout which bears the small mandibles at its tip. The snout is most conspicuous in the nut weevils, where it exceeds the length of the body and is very slender. Weevils are frequently termed *snout beetles*. See Fig. 1.

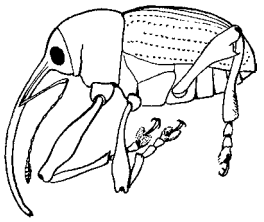

Fig. 1. Typical snout beetle.

A number of the weevils are important economic pests, notably the cotton boll weevil, the curculio (pear and plum), and the granary weevil. The first of these lives as a larva in the squares and bolls of the cotton plant, preventing the normal development of seeds and lint, and the last is found chiefly in stored grains. The grain weevil can live for hours in an atmosphere of carbon dioxide. Although the carbon dioxide acts as an anesthetic, the insect can survive because of the reserves of oxygen in its body. Other important economic weevils include the alfalfa weevil, the potato weevil, and the rice water weevil.

See also **Grain-Storage Insects**.

WEGENER, ALFRED LOTHAR (1880–1930). Alfred Wegener was born in Berlin on November 1, 1880. He studied the natural sciences at the University of Berlin, receiving a doctorate in astronomy in 1904. He did not pursue a career in astronomy, however, but turned instead to meteorology, where the telegraph, Atlantic cable, and wireless were fostering rapid advances in storm tracking and forecasting.

In 1905 Wegener went to work at the Royal Prussian Aeronautical Observatory near Berlin, where he used kites and balloons to study the upper atmosphere. He also flew in hot air balloons; indeed, in 1906 he and his brother Kurt broke the world endurance record by staying aloft for more than 52 hours.

Thanks to his upper-air work, Wegener was invited to join a 1906 Danish expedition to Greenland's unmapped northeast coast. He was thrilled: As a youth he had dreamed of exploring the Arctic, attracted by both the scientific and physical challenges. During this expedition Wegener became the first to use kites and tethered balloons to study the polar atmosphere.

When he returned to Germany, Wegener's Arctic research earned him a position at the small University of Marberg where, beginning in 1909, he lectured on meteorology, astronomy, and "astronomic-geographic position-fitting for explorers."

Both students and professors were impressed by the clarity of the young meteorologist's thinking, by his ability to explain difficult concepts in simple terms, and by the intuitive leaps of his nimble mind.

"With what ease he found his way through the most complicated work of the theoreticians, with what feeling for the important point!" a somewhat-awed colleague, physics professor Hans Benndorf, would later write.

In 1911, still only 30, Wegener collected his meteorology lectures into a book, *The Thermodynamics of the Atmosphere*, which soon became a standard text throughout Germany. After reading it, the distinguished Russian climatologist Alexander Woeikoff wrote that a new star had risen in meteorology.

In 1912, the year of his continental-drift presentations, Wegener again answered the siren call of Greenland. His four-man expedition "escaped death only by a miracle" while climbing a suddenly calving glacier on the northeast coast, then became the first to overwinter on the ice cap. The following spring, they barely survived the longest crossing of the great ice sheet ever made, traversing 750 miles of barren snow and ice rising to heights of 10,000 feet.

During these perilous adventures, Wegener collected volumes of unique scientific data. The resulting publications established him as one of the world's leading experts on polar meteorology and glaciology. According to fellow meteorologist and Greenland explorer Dr. Johannes Georgi, Wegener was the first to trace storm tracks over the ice cap.

When he returned to Marberg, Wegener resumed work on continental drift, marshaling all the scientific evidence he could find to support his theory. Using this pioneering interdisciplinary approach, Wegener wrote one of the most influential and controversial books in the history of science: *The Origin of Continents and Oceans*, published in 1915. Because of the First World War, Wegener's book went unnoticed outside Germany. In 1922, however, a third (revised) edition was translated into English, French, Russian, Spanish, and Swedish, pushing Wegener's theory of continental drift to the forefront of debate in the earth sciences.

Wegener began by demolishing the theory that large land bridges had once connected the continents and had since sunk into the sea as part of a general cooling and contraction of the Earth. He pointed out that the continents are made of a different, less dense rock (granite) than the volcanic basalt that makes up the deep-sea floor in which Wegener proposed that the continents floated somewhat like icebergs in water. Wegener also noted that the continents move up and down to maintain equilibrium in a process called *isostasy*. As an example he cited the sinking of Northern Hemisphere lands under the weight of continental ice sheets in the last ice age, and their rise since the ice melted some 10,000 years ago.

Given the difference in density between continents and sea floor, plus the process of isostasy, Wegener reasoned that if continent-size land bridges had existed and somehow been forced to the ocean bottom, they would have "bobbed-up" again when the force was released. Therefore, since fossil and geological evidence clearly showed the continents were once connected, the only logical alternative was that the continents themselves had been joined and had since drifted apart. See Fig.1.

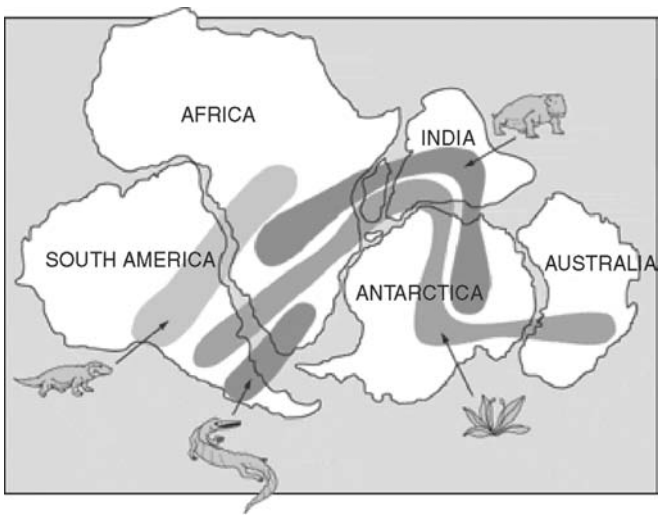

Fig. 1. Certain fossils appear in continuous bands across continents that are now separated by thousands of miles of ocean. Wegener believed this fact was one of the strongest pieces of evidence for his theory. (Map courtesy of the *United States Geological Survey*.)

Wegener also offered a more plausible explanation for mountain ranges. According to the cooling, contracting-Earth theory, they formed on the Earth's crust as wrinkles form on the skin of a drying apple. If this were so, however, they should be spread evenly over the Earth; instead mountain ranges occur in narrow bands, usually at the edge of a continent. Wegener said they formed when the edge of a drifting continent crumpled and folded — as when India hit Asia and formed the Himalayas.

He also noted that when Africa and South America are fitted together, mountain ranges (and coal deposits) run uninterrupted across both continents, writing:

> *It is just as if we were to refit the torn pieces of a newspaper by matching their edges and then check whether the lines of print ran smoothly across. If they do, there is nothing left but to conclude that the pieces were in fact joined in this way.*

By his third edition (1922), Wegener was citing geological evidence that some 300 million years ago all the continents had been joined in a supercontinent stretching from pole to pole. He called it Pangaea (all lands), and said it began to break up about 200 million years ago, when the continents started moving to their current positions.

Perhaps the best summary of Wegener's revolutionary theory was provided by countryman Hans Cloos: "It placed an easily comprehensible, tremendously exciting structure of ideas upon a solid foundation. It released the continents from the Earth's core and transformed them into icebergs of gneiss [granite] on a sea of basalt. It let them float and drift, break apart and converge. Where they broke away, cracks, rifts, trenches remain; where they collided, ranges of folded mountains appear."

Except for a few converts, and those like Cloos who could not accept the concept but was clearly fascinated by it, the international geological community's reaction to Wegener's theory was militantly hostile. American geologist Frank Taylor had published a similar theory in 1910, but most of his colleagues had simply ignored it. Wegener's more cogent and comprehensive work, however, was impossible to ignore and ignited a firestorm of rage and rancor. Moreover, most of the blistering attacks were aimed at Wegener himself, an outsider who seemed to be attacking the very foundations of geology.

Because of this abuse, Wegener could not get a professorship at any German university. Fortunately, the University of Graz in Austria was more tolerant of controversy, and in 1924 it appointed him professor of meteorology and geophysics.

In 1926 Wegener was invited to an international symposium in New York called to discuss his theory. Though he found some supporters, many speakers were sarcastic to the point of insult. Wegener said little. He just sat smoking his pipe and listening. His attitude seems to have mirrored that of Galileo who, forced to recant Copernicus' theory that the Earth moves around the sun, is said to have murmured, "Nevertheless, it moves!"

Scientifically, of course, Wegener's case was not as good as Galileo's which was based on mathematics. His major problem was finding a force or forces that could make the continents "plow around in the mantle," as one critic put it. Wegener tentatively suggested two candidates: centrifugal force caused by the rotation of the Earth, and tidal-type waves in the Earth itself generated by the gravitational pull of the sun and moon.

He realized these forces were inadequate. "It is probable the complete solution of the problem of the forces will be a long time coming," he predicted in his last (1929) revision. "The Newton of drift theory has not yet appeared."

Wegener noted, however, that one thing was certain:

> *The forces, which displace continents, are the same as those, which produce great fold-mountain ranges. Continental drift, faults and compressions, earthquakes, volcanicity, [ocean] transgression cycles and [apparent] polar wandering are undoubtedly connected on a grand scale.*

Wegener's final revision cited supporting evidence from many fields, including testimonials from scientists, who found his hypothesis resolved difficulties in their disciplines much better than the old theories. Climatology was one such discipline.

Fossils and geologic evidence show that most of the continents used to have startlingly different climates than they do today. Wegener thought continental drift was the key to these climatic puzzles, so he and Vladimir Koppen plotted ancient deserts, jungles, and ice sheets on paleogeographic maps based on Wegener's theory. Suddenly the pieces of the puzzles fell into place, producing simple, plausible pictures of past climates. Evidence of the Permo-Carboniferous ice-age era that peaked some 280 million years ago, for example, was scattered over almost half the Earth, including the hottest deserts. On Wegener's map, however, it clustered neatly around the South Pole, because Africa, Antarctica, Australia, and India had once comprised a Southern Hemisphere supercontinent (Gondwanaland).

Wegener considered such paleoclimatic validation one of the strongest proofs of his theory. Conversely, continental drift has since become the organizing principle of paleoclimatology and other paleosciences.

Unfortunately, though Wegener's explanation of the Permo-Carbonifer ous ice age impressed even his critics, the merit of much of the rest of his supporting evidence was not widely recognized at the time. As a result, most geologists eventually dismissed his theory as a fairy tale or "mere geopoetry."

Despite general rejection, Wegener's compelling concept continued to attract a few advocates over the next several decades. Then, beginning in the mid-1950s, a series of confirming discoveries in paleomagnetism and oceanography finally convinced most scientists that continents do indeed move. Moreover, as Wegener had predicted, the movement is part of a grandscale process that causes mountain-building, earthquakes, volcanic eruptions, sea-level fluctuations, and apparent polar wandering as it rearranges Earth's geography.

Geologists call the process "plate tectonics," after the large moving plates that form the planet's outer shell. These plates carry both continents and sea floor, but unlike the sea floor, the less-dense, buoyant continents resist subduction into the mantle. Thus, despite significant differences in detail, Alfred Wegener was right in most of his major concepts. Plate tectonics also confirms the accuracy of many of his paleogeographic reconstructions.

Ironically, though the lack of a credible driving force was the main objection to Wegener's theory, plate tectonics has been almost universally accepted despite the absence of scientific consensus as to its cause. Convection currents in the molten magma of the upper mantle are the favorite candidate; Wegener discussed this possibility in his 1929 revision.

During the last few decades, Alfred Wegener has finally gotten the recognition he deserves. Unfortunately, as with most visionaries, it must be posthumous praise.

WEIBULL DISTRIBUTION. The cumulative distribution function $F(t) = 1 - e^{-\alpha(t-\gamma)\beta}$ where $t > \gamma$, $\alpha > 0$, and $b > 0$ is referred to as the three-parameter Weibull distribution. The two-parameter Weibull distribution is obtained by setting $\gamma = 0$. The density function is $f(t) = F'(t) = \alpha\beta(t-\gamma)^{\beta-1}e^{-(t-\gamma)\beta}$. This distribution has become popular in statistical reliability problems. The moments of the Weibull distribution are given by

$$E(t) = \overline{t} = \frac{a}{\alpha} + \gamma$$

$$\sigma^2 = (b - a^2)/\alpha^2$$

$$\in_3 = (c - 3ab + 2a^3)/\alpha^3$$

where

$$a = \Gamma\left(1 + \frac{1}{\beta}\right)$$

$$b = \Gamma\left(1 + \frac{2}{\beta}\right)$$

$$c = \Gamma\left(1 + \frac{3}{\beta}\right)$$

and $\in_3$ is the third moment about the mean. In practice, the two parameter ($\gamma = 0$) distribution is simpler to use. In reliability problems the instantaneous failure rate $Z(t)$ is given by

$$Z(t) = F'(t)/(1 - F(t)) \quad t > 0$$

For the two parameter Weibull distribution $Z(t) = \alpha\beta t^{\beta-1} t > 0$. It is easily seen that if $\beta < 1$ the failure rate decreases with time, if $\beta > 1$ it increases with time and if $\beta = 1$ the failure rate equals α and the Weibull distribution is equal to the exponential distribution. It can be seen that $\ln\ln 1/(1 - F(t)) = \ln\alpha + \beta \ln t$. The right hand side is linear in $\ln t$. Special graph paper having its scales transformed so that the divisions on the horizontal axis are proportional to $\ln t$ and those on the vertical scale are proportional to $\ln\ln 1/(1 - F(t))$ can be obtained. To estimate α and β by graphical methods, one may use the following method:

If the ith unit fails at time t_i, estimate $F(t_i)$ by using the estimator

$$\hat{F}(t_i) = \frac{i - \frac{1}{2}}{n}$$

Plot the point corresponding to t_i, $\hat{F}(t_i)$ on Weibull paper. Draw a straight line fit to the points. If the points fall reasonably close to a straight line, it can be assumed that the underlying failure-time distribution is of the Weibull type. The graphically obtained answers will suffice for many applications. The parameters α and β may also be estimated by applying linear regression methods to fit a straight line to the transformed data.

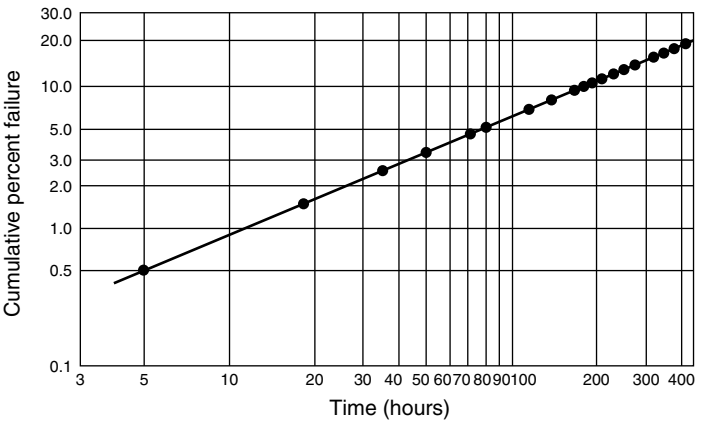

Fig. 1. Weibull failure-time distribution.

In some applications, failure times are observed independently. One orders the observations by ascending time to failure and then uses the Weibull distribution in the same manner as if zero time were identical for all observations. Figure 1 shows the use of the Weibull distribution. It can be seen that 5 hours is a good estimate for the time within which $\frac{1}{2}\%$ of the units of this type will fail.

DONALD R. HODGE, The BDM Corporation, Vienna, VA

WEIERSTRASS DEFINITION. See **Gamma Function**.

WEIERSTRASS FUNCTION. This function $\rho(z) = \rho(z/\omega, \omega')$ is an elliptic function of periods $2\omega, 2\omega'$ which: (1) is of order two; (2) has a double pole at $z = 0$, the principal part of the function at the pole being z^{-2}; (3) makes $\rho(z) - z^{-2}$ analytic in a neighborhood of, and vanish at $z = 0$. In this definition, the order of an elliptic function is its number of poles, each counted according to its multiplicity, in the parallelogram formed for fixed z_0 by the points

$$z = z_0 + 2\zeta\omega + 2\eta\omega', \quad 0 \le \zeta < 1; \quad 0 \le \eta < 1$$

Weierstrass' zeta function is a certain meromorphic function with simple poles, derivable from Weierstrass' function, but not itself doubly-periodic and hence not an elliptic function.

See also **Elliptic Integral**; and **Gamma Function**.

WEIGHING. A balance or a scale is an instrument with which the mass of a body is measured, where the force of gravity on the body — weight — is used as a basic for comparison. However, the strict physical definition of mass, i.e., the properties of gravity and inertia, is not stressed in weighing. The mass determined by weighing, in the broadest sense, serves more as measure for the quantity of substance in a body, from which are derived such practical measurements as market value, relative proportions in compounds, reaction equivalents, etc. Therefore, the result read from the balance is generally taken as a measure of the quantity weighed; corrective calculations (e.g., for air buoyancy) are done only in exceptional cases.

Mass and Weight. In everyday speech, weight is the preferred term for a mass determined by weighing. In scientific usage, however, there is adherence to the stricter physical understanding of the terms mass and weight.

By *mass* we understand that basic characteristics of matter which manifests itself on the one hand as inertia and on the other hand as mutual attraction or gravitation. The basic unit of mass is the kilogram, which is embodied in a standard (kilogram prototype) at the Bureau International des Poids et Mesures in Paris.

Weight, in a physical sense, is the force exerted on a body by the gravitational field of the earth. Defined this way, weight is the product of mass with local gravitational acceleration g, expressed by the force unit Newton (N), which is short for kg m/s^2.

Since it depends on geographic latitude, altitude above sea level and the density of the earth at the location, gravitational acceleration is not a constant. Expressed in m/s^2, g is equivalent to, for example: 9.80943 in Paris, France; 9.80267 in New York; 9.79524 in Atlanta, Georgia; and 9.79965 in San Francisco, California.

For this reason, the sensitivity of a balance should be fine adjusted on location by using a standard mass, as long as the weighing principle does not involve direct comparisons of mass.

In another context, weight — also called weight piece or weight stone — is the embodiment of a given amount of mass.

Classification of Balances and Scales

Balances and scales are differentiated in accordance with their (1) design, (2) weighing principle, (3) application, and (4) metrological criteria, including sensitivity, accuracy, resolution, and maximum load.

A laboratory instrument is commonly referred to as a "balance," but the term "scale" also is appropriate. They are designed for light loads, usually less than 1 pound or 0.5 kilogram. Industrial scales for accepting light to very heavy loads are usually referred to as *scales*.

Laboratory Balances

Figure 1 illustrates how balances are categorized into four accuracy classes, as recommended by the Organization Internationale de Métrologie Légale (OIML). With laboratory balances, there is also the following conventional nomenclature:

Ultramicroanalytical balances	$d_d = 0.1$ µg
Microanalytical balances	$d_d = 1$ µg
Semimicroanalytical balances	$d_d = 0.01$ mg
Macroanalytical balances	$d_d = 0.1$ mg
Top-loading precision balances	$d_d \geq 1$ mg

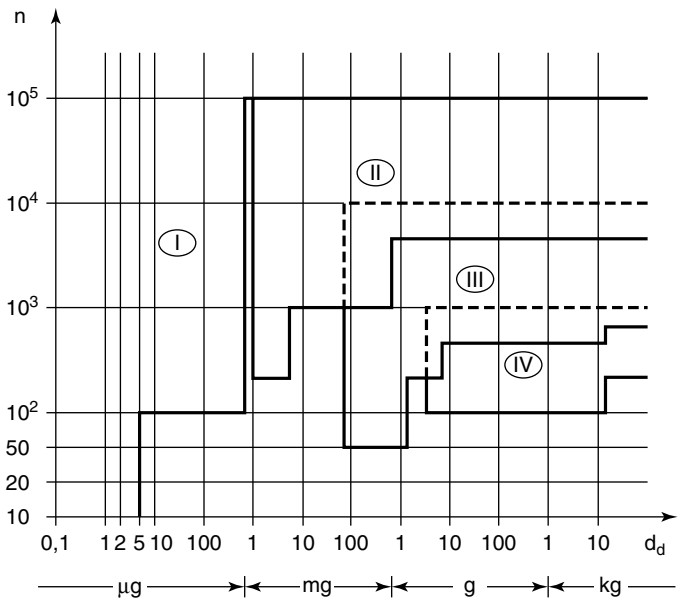

Fig. 1. Classification of balances into four accuracy groups: (I) special accuracy, (II) high accuracy, (III) medium accuracy, and (IV) ordinary accuracy.

With top-loading precision balances, the display range is 10^4 to 10^5 scale divisions, and with some analytical balances it can be over 10^7 scale divisions.

During the past few decades, hand-manipulated laboratory balances largely have been replaced by electronic designs. However, numbers of the older style balances still can be found in locations where weighing is not frequently required.

Electronic Balance Operating Principles. In a weighing system, there are three basic functions, as shown by Fig. 2. (1) The weight of the object to be weighed, in the form of a randomly distributed pressure p on the weighing pan, is the unknown input quantity. The *load transfer mechanism*, composed of mechanical levers and guides, translates the weighing load into a measurable single force F. (2) The measuring transducer (called a *load cell* in balances) produces an output signal proportional to the initial force, e.g., a voltage or frequency change. (3) The load cell signal is processed through analog and digital electronic circuitry where it undergoes certain computations and is finally displayed as a weighing result in digital form.

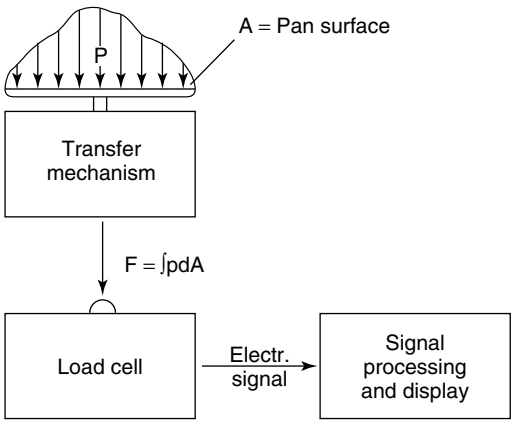

Fig. 2. Fundamental elements of a balance. (*Mettler*.)

With *hanging pan* balances (Fig. 3), the resulting single force F is generated by an inner reaction in the suspension bearing and is led to the load cell via the balance beam. Instead of the knife bearings shown, newer balances also make use of torsion band or crossflex bearings. All things being equal, the hanging pan design provides the highest accuracy and highest resolution of small weight differences. It is used in those cases where technical weighing capabilities are stretched to their limit, and the disadvantage of a pendulous pan must therefore be accepted.

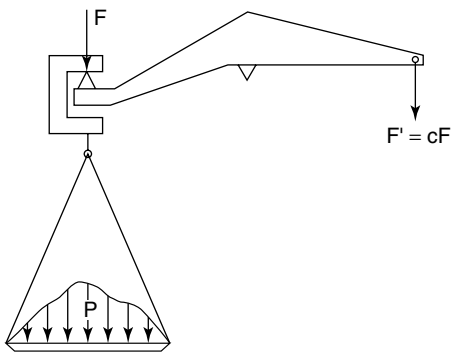

Fig. 3. Hanging pan showing weight transfer. (*Mettler*.)

The principle of *top pan* weighing (Fig. 4) is generally used in top-loading precision balances, but has recently been introduced in analytical balances as well. The support column of the weighing pan is held vertical

by two pairs of guides with elastic flex bearings. The weight force can be taken from any desired place by the support column and is led to the load cell either directly or by lever action.

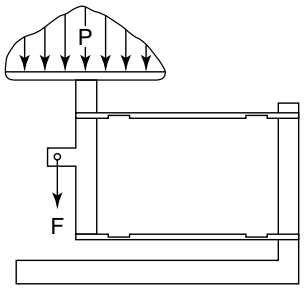

Fig. 4. Top pan, showing weight transfer. (*Mettler.*)

A basic requirement of this system is the parallelism of the guides with an accuracy of up to ±1 μm. Parallelism deviations cause so-called side-load errors. By that, we mean deviations in weighing results occurring when a test weight is moved from the center to the edge of the weighing pan. Side load errors can be caused by sharp blows to the pan and by overstressing the guides. As a result, many balances are protected against such blows and overstresses to the weighing pan.

Load-measuring cells in laboratory balances operate, for the most part, according to the electromagnetic force compensation principle. With a resolution of up to 1,600,000 scale divisions in analytical balances, this principle combines the accuracy of mechanical instruments with the advantage of an automatic reading of the weighing result. See Fig. 5. The movable system part (weighing pan, support column, coil, position indicator) and the load are held in constant floating equilibrium by a compensating force F equal to the weight. This compensating force F is generated by the current flowing through a coil which is located in the air gap of a cylindrical magnet, according to the following equation:

$$F = I \cdot l \cdot B$$

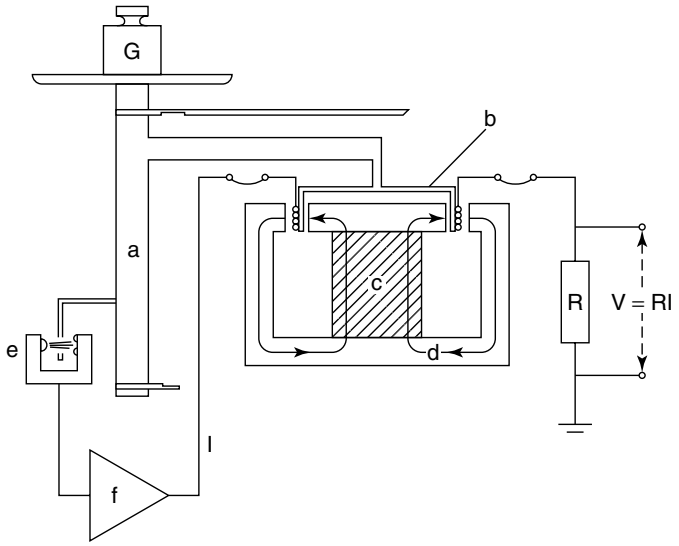

Fig. 5. Electromagnetic force compensation principle: (**a**) Movable system part, (**b**) coil (cross section), (**c**) cross section of cylindrical magnet with permanent magnet core and soft iron jacket, (**d**) field lines of force, (**e**) photoelectric position indicator, (**f**) servo amplifier. (*Mettler.*)

where I equals current, l equals total length of coil wire, and B equals the magnetic flux density in the air gap.

The following processes take place in the control loop of the cell:

1. With a change of the load, the movable system part at first responds to the weight change and moves vertically, usually by only fractions of a millimeter.
2. The light gate, which is part of the movable system component, changes the amount of light received by the photoelectric position indicator. An electrical signal is then passed on to the servo amplifier.
3. The amplifier changes the current flowing through the coil only as much as is required to bring the movable system component back to its state of equilibrium.

Weight now results from a measure of current l, e.g., by measuring voltage $V = R \cdot I$ across a precision resistance switched in series to the coil.

With another form and arrangement of coil and magnet, we also find this principle as a torque-compensation system, especially in micro balances. In a practical arrangement, such a system resembles conventional moving-coil instruments for measuring current and voltage. Here the balance beam is connected to the moving coil, which is suspended on a torsion band. The torque caused by the load on the balance beam is compensated by an opposite torque, generated by electromagnetic interaction between the current through the coil and the field of the permanent magnet that surrounds the coil. The coil current is regulated through the control loop in such a way that the beam stays in its prescribed horizontal position. This is analogous to the force compensation system, but here the current is proportional to the torque and therefore to the load. The previously described steps of the signal evaluation apply.

In the *pulse width modulation* principle, square-wave direct-current impulses of a constant amplitude I_0 and frequency v, flow through the coil, with a pulse duration t' as a control variable (Fig. 6). The compensation force is determined here by the time average of the current $I = I_0 \cdot v \cdot t'$ and is thus proportional to pulse duration t'. Pulse duration t' is added up over a large number of pulses, which increases the measuring resolution.

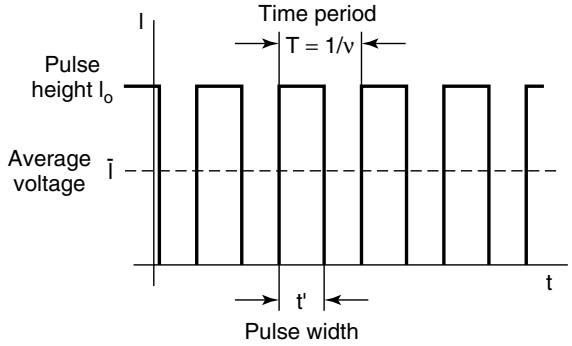

Fig. 6. Principle of pulse width modulation of compensating current. (*Mettler.*)

Finally, it should be noted that in addition to electromagnetic force compensation, the *oscillating string principle* is also sometimes used. The relationship between tension and oscillation frequency in a string

$$f_n = n/2l \cdot \sqrt{F/\mu} \quad (n = 1, 2, 3 \ldots)$$

provides the basis for the force/frequency converter. Here, n stands for the harmonic order of oscillation, l for the length of the string, and m for the string mass per unit length.

Electronic Signal Processing Part. By this term we encompass that function group which transforms the output of the measuring transducer into a numeric display or a data output. For the user, the most important items here are the control and calculating operations — depending on the degree of balance complexity.

Push-Button Tare. Resetting to zero of the display with any load within the weighing range.

Adjustable Integration Time. The weight values are averaged over a preselected time period. This is useful in weighing laboratory animals as well as for weighing under unstable conditions in general, e.g., with building vibrations or air drafts.

Rounding Off the Result. The digital electronics of Mettler balances produce internal weighing values of a higher resolution than are indicated by the display. In this way, an exact centering of the balance zero point is achieved when the balance is tared. The net internal value is numerically rounded off for display.

Stability Detector. Sequential weighing results are compared with one another. When a result stays the same, the data output is released and the validity of the display value is confirmed, e.g., when the weight unit symbol lights up.

In addition, with some of the newest balances, other useful values can be directly determined from the weighing result, e.g., parts count, percentage value, net total and target value for fill weighings. Necessary calculations are carried out by a built-in microprocessor; here the user enters control instructions and additional data into the balance via a push-button input instrument.

Special Applications. In a number of experimental processes, mass or a change in mass must be determined under special environmental conditions, or the effect of a force field superimposed on a weight must be measured. For these reasons, weighings are sometimes carried out under vacuum, under high- or low-temperature conditions, in special atmospheres, in magnetic or electrostatic fields, and in liquids.[1]

Industrial Scales

There are numerous industrial and commercial scales, ranging from those of small capacity, as may be found in retail operations, through multi-tonnage scales found in the process industries for weighing bulk materials or large discrete objects, such as a reel of wire. In terms of method, there are gravimetric scales in which other masses (weights) are used, usually via a mechanical lever system, to compare the mass of the unknown. There are spring scales, in which the gravitational force on the unknown is matched by a spring force of known constant; and, as with the much smaller balances previously described, there are electronic load-cell configurations. Pneumatic and hydraulic load cells are also used as the weight (force) sensors. The majority of scales operate on a batch, i.e., one-load-at-a-time basis. Continuous gravimetric feeders are described in **Feeder (Gravimetric)**. In batch weighing, the container for the load may range from a simple platform, as found in a retail operation, to numerous industrial configurations, including tank scales, floor scales, hopper scales, railway track, and highway vehicular scales.

Early scales required the manual movement of a sliding poise on a weigh beam that was connected directly to the load-reducing mechanical lever system. Industrial scales, over the years, have been built for rugged service and maintain their useful life for many years. Consequently, scales of old design still are found in parts of the world, frequently for the weighing of commodities in the third world countries. The simple steelyard still is found in isolated areas. A weigh beam with sliding poises is shown in Fig. 7.

Direct indication of weight, without manual manipulation of poises, was always available with spring scales for relatively small loads — because the spring "automatically" extended without any manual intervention. The first automatic pendulum-type scale appeared many decades ago and this largely replaced the weigh beam with its sliding poises. A comparison of the two methods is given in Figs. 7 and 8. Once a means was devised to achieve "automatic" positioning of the pointer to indicate weight directly, it was relatively easy to add accessory devices in the form of photoelectric pickups, mercury magnetic switches, etc. to sense the pointer position and then actuate automatically a printing device, or to control automatic feeding (unloading, loading) equipment. In other words, semicontinuous weighing could be achieved by automatically interlocking a series of batch weighings. Fully continuous weighing is achieved by belt scales in which a section of belt rides over weight-sensing devices and these are interlocked in numerous ways to effect a control over weight-flow. Frequently, a series of such weigh-belts will be interlocked to achieve a gravimetric blending of several ingredients, as may be encountered in the glass, rubber, feed, and other industries, where processing or final products are based upon closely maintaining proportions of materials on a weight basis.

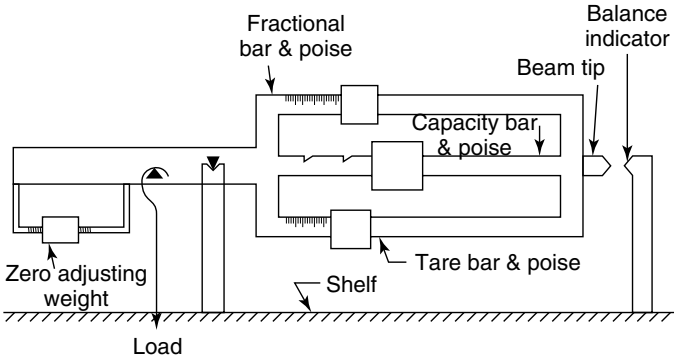

Fig. 7. Weigh beam with sliding poises.

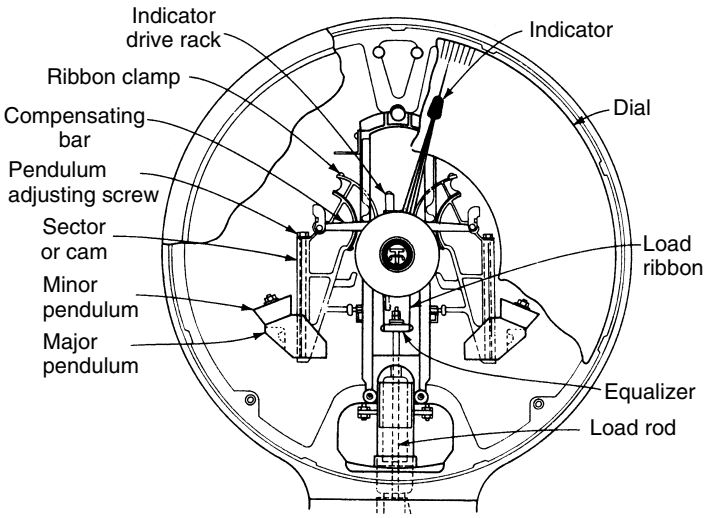

Fig. 8. Double-pendulum dial indicator, a classic design for industrial scales for many years.

The principal types of industrial scales are listed in Table 1.

Load Cells Revolutionize Industrial Scales. Most scales installed within the last few decades, instead of depending upon mechanical lever systems and counterbalancing systems, measure the deflection of supporting beam structures with hydraulic, pneumatic, or electronic (strain-gage) systems. Surprisingly, these substitutions were not made to achieve greater accuracy, but rather to reduce the bulk, weight, and iron content of scales and to provide means for remote weight data displays and ways to automatically control scale operations (as in batch processes) as one can manage any other sensor. At one time, the lever-type scale was one of the most accurate of sensors, though cumbersome.

WEIGHTING. 1. The artificial adjustment of measurements in order to account for factors which, in the normal use of the device, would

[1] Portions of the preceding part of this article were prepared by Dr. Walter Kupper, Research and Development Manager, Mettler Instrument Corporation, Hightstown, New Jersey.

TABLE 1. PRINCIPAL TYPES OF INDUSTRIAL SCALES

	Capacity Range		Load Receiving Element		
				Size	
Type of Scale	English Units	Metric Units	Type	Feet	~meters
Bench scale	5–300 pounds	2.3–136 kilograms	platform	5 × 5 to 24 × 24	1.5 × 1.5 to 7.3 × 7.3
Portable scale	100–5000 pounds	45–2268 kilograms	platform	2 × 2 to 6 × 6	0.6 × 0.6 to 1.8 × 1.8
Floor/warehouse scale	500–20,000 pounds	227–9072 kilograms	platform	3 × 3 to 10 × 10	0.9 × 0.9 to 3 × 3
Motor truck scale (axle load)	10–75 tons	9–68 metric tons	platform	8 × 10 to 10 × 100	2.4 × 3 to 3 × 30
Cement scale	20–100 tons	18–91 metric tons	platform	10 × 20 to 16 × 100	3 × 6.1 5 × 30
Railway track scale	100–200 tons	91–182 metric tons	track span	4 × 110	1.2 × 33.5
Hopper or tank scale	100 pounds–200 tons	45 kilograms–182 metric tons	hopper or tank	2 to 60 square feet	0.2 × 5.6 square meters
Hanging scale	5–200 pounds	2.2–91 kilograms	hook or suspended pan	—	—
Crane scale	1–100 tons	0.9–91 metric tons	hook	—	—
Monorail scale	50–5000 pounds	23–2268 kilograms	overhead track	2 × 8 overhead track	0.6 × 2.4 overhead track

otherwise be different from the conditions during measurement. For example, background noise measurements may be weighted by applying factors or by introducing networks to reduce measured values in inverse ratio to their interfering effects.

2. When several different determinations of the same physical quantity have been made, the more accurate of the measurements should be counted more heavily than the less accurate in estimating the most probable value of the quantity. Thus, if $q_1 \cdot q_2$, etc., are the individual values, the most probable value is

$$q = \frac{w_1 q_1 + w_2 q_2 + \cdots}{w_1 + w_2 + \cdots}$$

where w_1, w_2, etc., are weighting factors. The theory of the propagation of errors shows that the weighting factor for any individual determination is inversely proportional to the square of the uncertainty of that determination. The quantity q is called the weighted mean. 3. In statistical mechanics, certain states of a system are often more probable than others, especially when degeneracy is present. In computing average values, these states must be weighted with factors proportional to their probabilities, the computation then proceeding as in 2 above.

WEIGHTING AGENT. (1) In soft drink technology, an oil or oil-soluble compound of high specific gravity, such as a brominated olive oil, which is added to citrus flavoring oils to raise the specific gravity of the mixture to about 1.00, so that stable emulsions with water can be made for flavoring. (2) In the textile industry a compound used both to deluster and lower the cost of a fabric, at the same time improving its "hand" or feeling. Zinc acetylacetonate, clays, chalk, etc. are used.

WEIGHTLESSNESS. 1. A condition in which no acceleration, whether of gravity or other force, can be detected by an observer within the system in question. Any object falling freely in a vacuum is weightless, thus an unaccelerated satellite orbiting the earth is weightless although gravity affects its orbit. Weightlessness can be produced within the atmosphere in aircraft flying a parabolic flight path. See also **Gravitation**.

2. A condition in which gravitational and other external forces acting on a body produce no stress, either internal or external, in the body. See also **Astronautics**.

An astronaut is said to be in a state of weightlessness when in orbit. Strictly speaking, the astronaut still has weight, for the Earth's gravity still acts on the person. Otherwise, the individual would fly off into outer space. However, when in free fall, the local effects of the gravitational field are eliminated for the astronaut. Objects that are released fall together with the astronaut and hence remain in the vicinity, unlike the situation on the ground. Therefore, the organs of the body respond as though the gravitational field were absent and this gives the sensation of weightlessness. Conversely, one senses the earth's gravity and feels weight because we are supported by the earth's surface. See also **Gravity and Microgravity**.

Adverse Effects of Weightlessness

Unfortunately, long-term exposure to weightlessness leads to a chain-reaction of undesirable physiological adaptations. Countermeasures such as diet and exercise have been only partially effective in preserving health, even for well-trained highly-motivated crews. Use of therapeutic equipment is expensive in time and volume and may be unworkable with a large diverse population. It is ironic that, having gone to great expense to escape Earth gravity, it may be necessary to incur the additional expense of simulating gravity in orbit. Before opting for artificial gravity, it is worth reviewing the consequences of long-term exposure to weightlessness. See also **Artificial Gravity**.

Fluid Redistribution. Bodily fluids shift from the lower extremities toward the head. This precipitates many of the problems described below.

Fluid Loss. The brain interprets the increase of fluid in the cephalic area as an increase in total fluid volume. In response, it activates excretory mechanisms. This compounds calcium loss and bone demineralization. Blood volume may decrease by 10 percent, which contributes to cardiovascular deconditioning. Space crew members must beware of dehydration.

Electrolyte Imbalances. Changes in fluid distribution lead to imbalances in potassium and sodium and disturb the autonomic regulatory system.

Cardiovascular Changes. An increase of fluid in the thoracic area leads initially to increases in left ventricular volume and cardiac output. As the body seeks a new equilibrium, fluid is excreted, the left ventricle shrinks and cardiac output decreases. Upon return to gravity, fluid is pulled back into the lower extremities and cardiac output falls to subnormal levels. It may take several weeks for fluid volume, peripheral resistance, cardiac size and cardiac output to return to normal.

Red Blood Cell Loss. Blood samples taken before and after American and Soviet flights have indicated a loss of as much as 0.5 liters of red blood cells. Scientists are investigating the possibility that weightlessness causes a change in splenic function that results in premature destruction of

red blood cells. In animal studies there is some evidence of loss through microhemorrhages in muscle tissue as well.

Muscle Damage. Muscles atrophy from lack of use. Contractile proteins are lost and tissue shrinks. Muscle loss may be accompanied by a change in muscle type: rats exposed to weightlessness show an increase in the amount of "fast-twitch" white fiber relative to the bulkier "slow-twitch" red fiber. In 1987, rats exposed to 12.5 days of weightlessness showed a loss of 40 percent of their muscle mass and "serious damage" in 4 to 7 percent of their muscle fibers. The affected fibers were swollen and had been invaded by white blood cells. Blood vessels had broken and red blood cells had entered the muscle. Half the muscles had damaged nerve endings. The damage may have resulted from factors other than simple disuse, in particular: stress, poor nutrition, and reduced circulation — all of which are compounded by weightlessness; and radiation exposure — which is independent of weightlessness. There is concern that damaged blood supply to muscle may adversely affect the blood supply to bone as well.

Bone Damage. Bone tissue is deposited where needed and resorbed where not needed. This process is regulated by the piezoelectric behavior of bone tissue under stress. Because the mechanical demands on bones are greatly reduced in micro gravity, they essentially dissolve. While cortical bone may regenerate, loss of trabecular bone may be irreversible. Diet and exercise have been only partially effective in reducing the damage. Short periods of high-load strength training may be more effective than long endurance exercise on the treadmills and bicycles commonly used in orbit. Evidence suggests that the loss occurs primarily in the weight-bearing bones of the legs and spine. Non-weight-bearing bones, such as the skull and fingers, do not seem to be affected.

Hypercalcemia. Fluid loss and bone demineralization conspire to increase the concentration of calcium in the blood, with a consequent increase in the risk of developing urinary stones.

Immune System Changes. There is an increase in neutrophil concentration, decreases in eosinophils, monocytes and B-cells, a rise in steroid hormones and damage to T-cells. In 1983 aboard Spacelab I, when human lymphocyte cultures were exposed in vitro to concanavalin A, the T-cells were activated at only 3 percent of the rate of similarly treated cultures on Earth. Loss of T-cell function may hamper the body's resistance to cancer — a danger exacerbated by the high-radiation environment of space.

Interference with Medical Procedures. Fluid redistribution affects the way drugs are taken up by the body, with important consequences for space pharmacology. Bacterial cell membranes become thicker and less permeable, reducing the effectiveness of antibiotics. Space surgery will also be greatly affected: organs will drift, blood will not pool, and transfusions will require mechanical assistance.

Vertigo and Spatial Disorientation. Without a stable gravitational reference, crew members experience arbitrary and unexpected changes in their sense of verticality. Rooms that are thoroughly familiar when viewed in one orientation may become unfamiliar when viewed from a different up-down reference. Skylab astronaut Ed Gibson reported a sharp transition in the familiarity of the wardroom when rotated approximately 45 degrees from the "normal" vertical attitude in which he had trained. There is evidence that, in adapting to weightlessness, the brain comes to rely more on visual cues and less on other senses of motion or position. In orbit, Skylab astronauts lost the sense of where objects were located relative to their bodies when they could not actually see the objects. After returning home, one of them fell down in his own house when the lights went out unexpectedly.

Space Adaptation Syndrome. About half of all astronauts and cosmonauts are afflicted. Symptoms include nausea, vomiting, anorexia, headache, malaise, drowsiness, lethargy, pallor and sweating. Susceptibility to Earth-bound motion sickness does not correlate with susceptibility to space sickness. The sickness usually subsides in 1 to 3 days.

Loss of Exercise Capacity. This may be due to decreased motivation as well as physiological changes. Cosmonaut Valeriy Ryumin wrote in his memoirs: "On the ground, [exercise] was a pleasure, but [in space] we had to force ourselves to do it. Besides being simple hard work, it was also boring and monotonous." Weightlessness also makes it clumsy: equipment such as treadmills, bicycles and rowing machines must be festooned with restraints. Perspiration doesn't drip but simply accumulates. Skylab astronauts described disgusting pools of sweat half an inch deep sloshing around on their breastbones.

Degraded Sense of Smell and Taste. The increase of fluids in the head causes stuffiness similar to a head cold. Foods take on an aura of sameness and there is a craving for spices and strong flavorings such as horseradish, mustard and taco sauce.

Weight Loss. Fluid loss, lack of exercise and diminished appetite result in weight loss. Space travelers tend not to eat enough. Meals and exercise must be planned to prevent excessive loss.

Flatulence. Digestive gas cannot "rise" toward the mouth and is more likely to pass through the other end of the digestive tract — in the words of Skylab crewman-doctor Joe Kerwin: "very effectively with great volume and frequency".

Facial Distortion. The face becomes puffy and expressions become difficult to read, especially when viewed sideways or upside down. Voice pitch and tone are affected and speech becomes more nasal.

Changes in Posture and Stature. The neutral body posture approaches the fetal position. The spine tends to lengthen. Each of the Skylab astronauts gained an inch or more of height, which adversely affected the fit of their space suits.

Changes in Coordination. Earth-normal coordination unconsciously compensates for self-weight. In weightlessness, the muscular effort required to reach for and grab an object is reduced. Hence, there is a tendency to reach too "high".

Many of these changes do not pose problems as long as the crew remains in a weightless environment. Trouble ensues upon the return to life with gravity. The rapid deceleration during reentry is especially stressful as the apparent gravity grows from zero to more than one "g" in a matter of minutes. In 1984, after a 237-day mission, Soviet cosmonauts felt that if they had stayed in space much longer they might not have survived reentry. In 1987, in the later stages of his 326-day mission, Yuri Romanenko was highly fatigued, both physically and mentally. His work day was reduced to 4.5 hours while his sleep period was extended to 9 hours and daily exercise on a bicycle and treadmill consumed 2.5 hours. At the end of the mission, the Soviets implemented the unusual procedure of sending up a "safety pilot" to escort Romanenko back to Earth.

Soviet cosmonauts Vladimir Titov and Moussa Manarov broke the one-year barrier when they completed a 366-day mission on 21 December 1988. Subsequent Russian missions have surpassed that. These long-duration space flights are extraordinary. They are milestones of human endurance. They are not models for space commercialization. See also **Space Stations**.

WELDING. A method of joining metals by means of fusion or by solid-state processes. Metals having similar composition may be united in one homogeneous piece by fusing together the edges in contact, or by additional molten metal of the proper characteristics deposited where it will form a fused joint with each piece.

For special applications, welding techniques include electron beam welding and laser welding. In electron beam welding, a coalescence of metals is produced as the result of heat obtained from a concentrated beam composed primarily of high-velocity electrons impinging upon the surfaces to be joined. In laser-beam welding, the heat is obtained by directing a beam from a laser onto the weld joint.

In any machine or structure there are numerous cases where permanent junctions between the component parts are required. The use of welding in assembling metal structures and machines is thus very extensive in present-day technology. Typical of such practice might be mentioned the welding of joints in pipe lines, eliminating flanges, couplings, and cumbersome fittings. Bridges and buildings of structural steel are fabricated by arc welding, replacing the older riveted connections. Shipbuilders use welding as the principal means of fabrication. Where weight saving is as important as strength, welding is especially suitable because of the elimination of the weight of rivets and bolts, and often of the flanges in which they are seated.

Many complicated machine parts, which at one time could be produced only by casting, are now built up from structural steel shapes by welding. To the above illustrations, may be added the aircraft and rocket structures, where welding has become standard practice. Machinery frames and bases, tanks, and steel frames are welded. Even high-temperature and pressure vessels, such as boiler drums, are accepted if welded in conformance with standards procedures.

Automatic Welding. Welding is well adapted to automation. Numerous robots have been designed specifically for welding applications. In the more sophisticated systems, machine vision may be used. See also **Machine Vision**. The automotive industry in recent years has invested heavily in automated welding, as portrayed by the illustrations and captions of Figs. 1, 2, and 3.

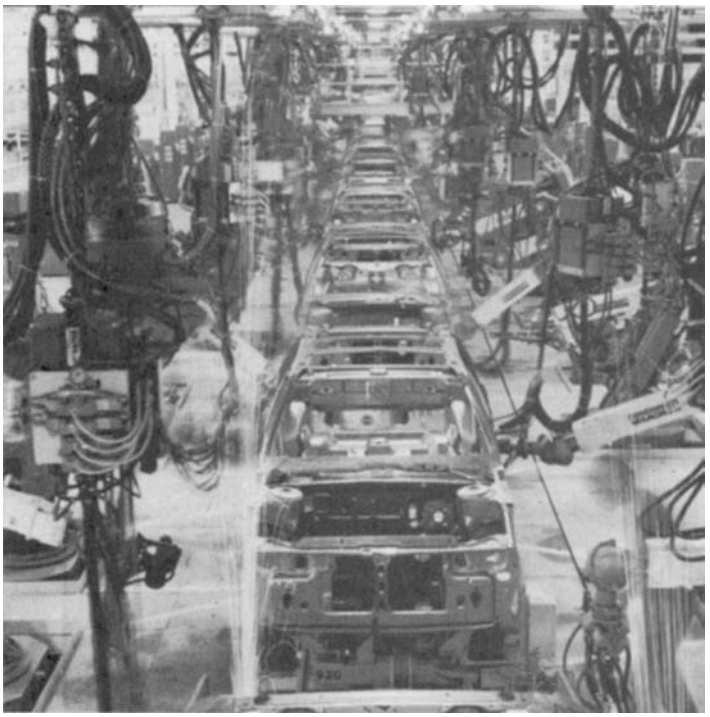

Fig. 1. Automated welding system. Computer-controlled robots achieve consistent welds of all components in the unitized body structure. (*Chrysler Corporation.*)

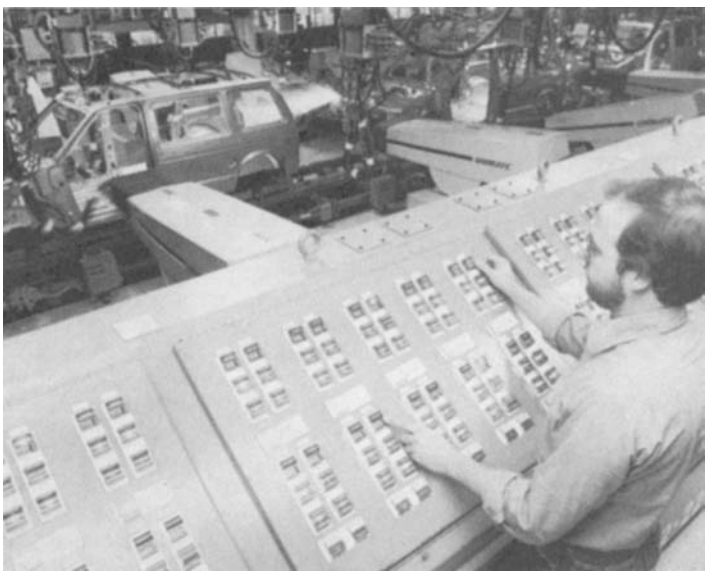

Fig. 2. Master computer control station monitors robots on robotgate welding lines in automobile assembly plant. (*Chrysler Corporation.*)

Most present preprogrammed, automated welding systems use a set path and fixed parameters. They are not flexible and may not be cost effective for many applications, particularly small batches. As reported by engineers at the American Welding Institute (Knoxville, Tennessee), "Overcoming these limitations is the goal of next-generation 'intelligent' welding systems." Work is proceeding on programs that automate the entire process, from planning the welding procedure to real-time weld monitoring and quality control.

Welding appears to be an ideal application for computerized expert systems because it involves compliance with a complex and interrelated system of codes, specifications, tests, and inspections to ensure that welds will not fail in service. Today, this assurance is provided by a large number of engineers, designers, and welders. Problem-solving, expert-system software can help reduce the need for costly human experts. More into the future are combinations of expert systems and neural networks. The latter excel at dealing with complex, poorly characterized problems where multiple sensor inputs must be evaluated concurrently — as in welding. Neural-network/sensor systems must be able to perform in the processing environment and provide data fast enough for intelligent controls to operate in real time. A neural-network–based seam tracker that analyzes visual-sensor data obtained during robotic welding is being developed. The intelligent seam tracker can visually guide a welding robot operating in an environment where the clarity of the visual image is reduced by as much as 70 percent. Seam tracking using conventional image-processing techniques is computation intensive and ineffective when noise exceeds about 20 percent.

Fusion Welding. Any two clean metal surfaces should form a bond as strong as the bulk material if they are brought into intimate contact. The key to success is to achieve extremely clean surfaces and really intimate contact. With rare exceptions, metals are covered with a layer of oxide, or some other material, formed by the interaction of the metal and its environment. This layer must be removed, or a new surface provided by cutting or deforming the piece in such a way as to expose clean metal. Then, the newly exposed metal atoms can join together intimately. To a metallurgist, intimate means that the atoms at the interface between two welded surfaces are no further apart than the atoms within the materials. The principal methods of fusion welding are gas welding, arc welding, resistance welding, pressure welding, combination methods, such as atomic-hydrogen welding, as well as using more recently developed electron beam welding, laser welding, and plasma arcs.

Electron beam welding in vacuum chambers has made possible weld beads having a high ratio of depth to width, thus lessening the heat-affected zone. This process is used extensively for special alloys of titanium; aluminum, vanadium, and tungsten used on airplanes, helicopters, and space vehicles. In *precussion welding*, the source of heat is an electric arc obtained by discharging a capacitor; this technique has been found particularly useful for small-scale welding, as in electrical wiring. Other new developments in fusion welding include cored welding rods that carry their own flux in much the same way as rosin-core solder does; arcs shielded with an inert gas, usually helium or argon, to protect newly formed surfaces against atmosphere contaminants; and *submerged arc welding*, wherein an arc is sustained in the flux material, and metal is added to the gap.

Gas Welding. This is usually accomplished by the oxyhydrogen or *oxyacetylene* methods, the latter being the most common, with *oxyhydrogen welding* being used primarily on aluminum. High pressure oxygen and acetylene are led through reducer valves to reduce the pressure to a torch where they are mixed and burned at the tip. The flame, either oxidizing, reducing, or neutral, is adjusted to the proper size and brought into contact with the work which has been previously prepared and clamped into position. The temperature of the work is raised until it melts and flows together. Additional metal necessary to accomplish the formation of a sound joint may be added as wire or rod as the welding progresses. In some cases, fluxes must be added to insure a sound weld, particularly with stainless steel or aluminum.

Arc Welding. This is accomplished by utilizing the heat generated by an electric arc, either ac or dc, to fuse the metals together. A common method is to use a motor-generator set to supply dc at relatively low voltage. One electrode is fastened to the work, and the welding rod, usually coated with a flux, is made the other electrode, the arc being struck between the rod

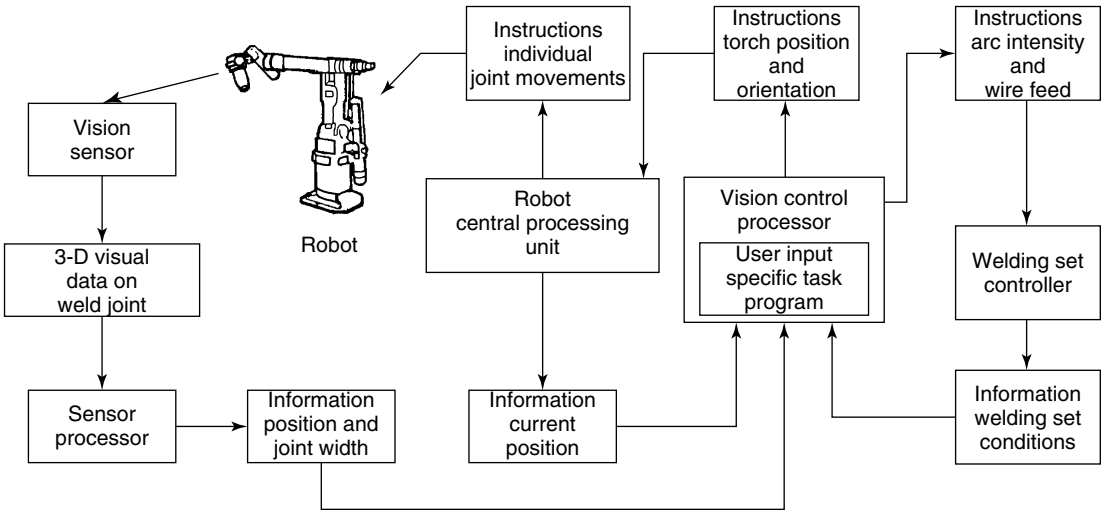

Fig. 3. This vision-assisted robot system is capable of single-pass seam tracking during the welding process as well as real-time adaptive control of welding parameters and travel speeds. The system can perform a seam search to find the starting point of the weld. Then, while welding, it can measure joint gap, lateral seam position and standoff height. The robot controller uses the information supplied by the vision system to modify the robot's program path and alter welding parameters for varying conditions during welding. Advantages of the sophisticated system include: Compensates for poor part repeatability; imposes fewer limitations on product design; increases range of robotic arc welding applications; and permits welding on nonsymmetrical and multipass jobs. The combined welding torch and vision sensor contains a solid-state camera, laser pair, optics and associated video electronics mounted in a seven-axis drive unit. This compact drive unit rotates the camera about the centerline of the welding torch so the camera is always looking slightly ahead of the welding arc. The vision system operates on the principle of laser triangulation. It uses two 10 mW gallium arsenide lasers to project a stripe of structured infrared light onto the part being welded. An optical sensor views the laser stripe as it intersects the weld groove to feed back information on both the position of the weld groove and its geometry. At the wavelength which the optical sensor is viewing the laser stripe, the laser is approximately ten times the intensity of the welding arc, thus making it possible to seam track with or without the arc being present. (*GMF Robotics Corporation*.)

and the work. Metal from the rod melts off and is fused into the joint. Automatic machines for arc welding use coils of wire to feed into the arc, flux being supplied from a hopper as the work travels under the arc. This process is also known as *submerged arc welding* cited above. Another method of arc welding is *carbon arc welding* in which one electrode is a rod of carbon. It is generally used on automatic machines. The wandering of the arc is minimized by placing a magnetic field near the arc to stabilize it. Extra filler material is fed into the arc if needed, and it is often shielded by gas generated from a chemically-treated string or cord.

Atomic-hydrogen arc welding. This is a combination of gas welding and arc welding. In this case heat is supplied to work by a stream of hydrogen passing through an arc struck between two tungsten electrodes. As the hydrogen passes through the arc, it is dissociated into its atomic form. When it recombines to form molecular hydrogen, a large amount of heat is generated in a small space, making an intensely hot flame. The hydrogen blankets the weld as it is made and largely prevents loss of alloying materials. This method also has been applied to automatic machines, no flux being necessary. A large variety of alloy steels for exacting specifications are welded by this method.

Heliarc Welding. This is a modification of the atomic hydrogen method for the welding of magnesium; here helium gas is blown along a single tungsten electrode, the work being the other terminal as in ordinary electric arc welding. The helium serves to protect the highly reactive magnesium from burning.

Electric-resistance Welds. They may be divided into a number of different categories but all have the common characteristic, that the metal is heated by its own resistance to a semi-fused or fused state by the passage of very heavy currents for very short lengths of time and then welded by the application of pressure.

Solid-State Welding. Some combination of optimum temperature and deformation is required, but heat is not always necessary to remove the oxide film. This class of welding includes some "cold" welding methods; in vacuum welding, a clean cut is made and the surfaces to be joined are kept free from contamination in a vacuum chamber. When the two clean surfaces are brought into contact, a so-called diffusion bond is formed. In diffusion bonding without a vacuum, two surfaces to be welded are pressed together and deformed enough to bring them into reasonably good contact; the temperature is held high enough, and for a long enough time, to eliminate the oxide already present at the interface, and the two pieces weld together. The oxide disappears either by dissolving into the joined surfaces, or by decomposing. Roll bonding of metal sheets is an example of welding that involves only deformation. It is accomplished by putting two sheets of material together and rolling them with considerable pressure and deformation, usually of the order of at least 50%. The oxide film at the interface between the two sheets is simply fragmented and mechanically dispersed, and the two new surfaces are clean enough to form a reliable bond. Oxides on the surface of a metal are relatively brittle; if the metal can be plastically deformed, the oxide film will rupture and a new metal surface will be exposed between the fragments.

Friction welding. This involves the application of considerable stress and deformation in the presence of relatively steep temperature gradients induced by rubbing the two surfaces together at high speeds. This is really a combination of fusion welding and deformation bonding. Explosive welding, in which one material is driven at high velocity onto the surface of another, creates large amounts of new surface area through extremely large, but highly localized deformation in the vicinity of the impact surface. Ultrasonic welding relies upon ultrasonic vibration in the plane of the interface to break up the oxide film and disperse it into the matrix.

WELDON, WALTER FRANK RAPHAEL (1860–1906). Walter Weldon was an English evolutionary zoologist and biometrician whose collaboration with Karl Pearson greatly influenced the latter to develop the modern theory of mathematical statistics.

Weldon was the second child of the journalist and industrial chemist, Walter Weldon, and his wife Anne Cotton. He matriculated at University College London (UCL) in the autumn of 1876 with the intention of pursuing a medical career. In the following year he transferred to King's College, London and then to St John's College, Cambridge in 1878.

Once at Cambridge, he met the zoologist, Francis Maitland Balfour, and subsequently gave up his medical studies for zoology. In 1881, he gained a first-class honors degree in the Natural Science Tripos; in the autumn he left for the Naples Zoological Station to begin the first of his studies on marine biological organisms. Upon returning to Cambridge in 1882, he was appointed university lecturer in Invertebrate Morphology, and in the following year he married Florence Tebb. He became a founding member of the Marine Biological Station in Plymouth in 1884 and resided there until 1887. From 1887 until his death in 1906, Weldon's work was centered around the development of a fuller understanding of marine biological phenomena and selective death rates of these organisms. In 1889 he succeeded E. Ray Lankester in the Joddrell Chair of Zoology at University College London. See also **Lankester, Edwin Ray (1874–1929)**.

During the Easter vacation of 1892, Weldon and his wife collected 23 measurements from 1000 adult female shore crabs (*Carcinus mœnas*) from Malta and the Bay of Naples. Weldon discovered that all but one of the 23 characters he measured in the Naples group were normally distributed; he found that this one character (the frontal breadth of the carapace) was instead a "double-humped" (i.e. bi-modal) curve. Weldon approached Karl Pearson (who had been appointed Professor of Mechanism and Applied Mathematics at UCL in 1884) for assistance with interpreting his data. By the end of 1892 Pearson began to devise a probability system of curve fitting for Weldon's data, and he used this material in his Gresham lectures in the following year. From his analysis of Weldon's data, Pearson concluded that two separate species had arisen. Up until the middle of the nineteenth century species were defined in terms of types or essences. Charles Darwin's recognition that species comprised different sets of "statistical" populations, rather than types or essences, prompted a reconceptualization of statistical populations by Pearson and Weldon. Moreover, this required the use of new statistical methods. See also **Evolution (History)**; and **Pearson, Karl (1857–1936)**.

Though not a statistician by training, it was Weldon's interest in finding statistical tools to demonstrate empirical evidence of Darwin's theory of natural selection in marine organisms that provided the impetus to Pearson's development of the modern theory of statistics. Weldon also provided Pearson with the basis of a program that underpinned the construction of his statistical innovations in the 1890s which, in turn, provided the infrastructure for Pearson's statistical developments in the twentieth century. Weldon's influence exceeded that of any other person in the emergence and development of Pearsonian statistics. Though some of the statistical work of John Venn and Francis Ysidro Edgeworth played a role in Pearson's early work on probability, there seems to have been no other person whose influence on the emergence and development of Pearsonian statistics was so rapid and immediate in its impact as that of Weldon.

When Weldon went up to Oxford in 1899, to take up the Linacre Chair of Comparative Anatomy, he carried on the biometric tradition by gathering a number of students who began to look for empirical evidence of natural selection acting upon various animals and plants. Despite Weldon's move, he and Pearson continued their collaborative work investigating biometrical problems such as natural selection and Mendelian inheritance. These joint biometrical projects were pursued until Weldon's untimely death in 1906. Weldon's death was for Pearson the single greatest loss in his life. Though Pearson's statistical work continued to be prodigious, he never fully regained the creative force he had developed from his partnership with Weldon. See also **Mendel, Gregor Johann (1822–1884)**.

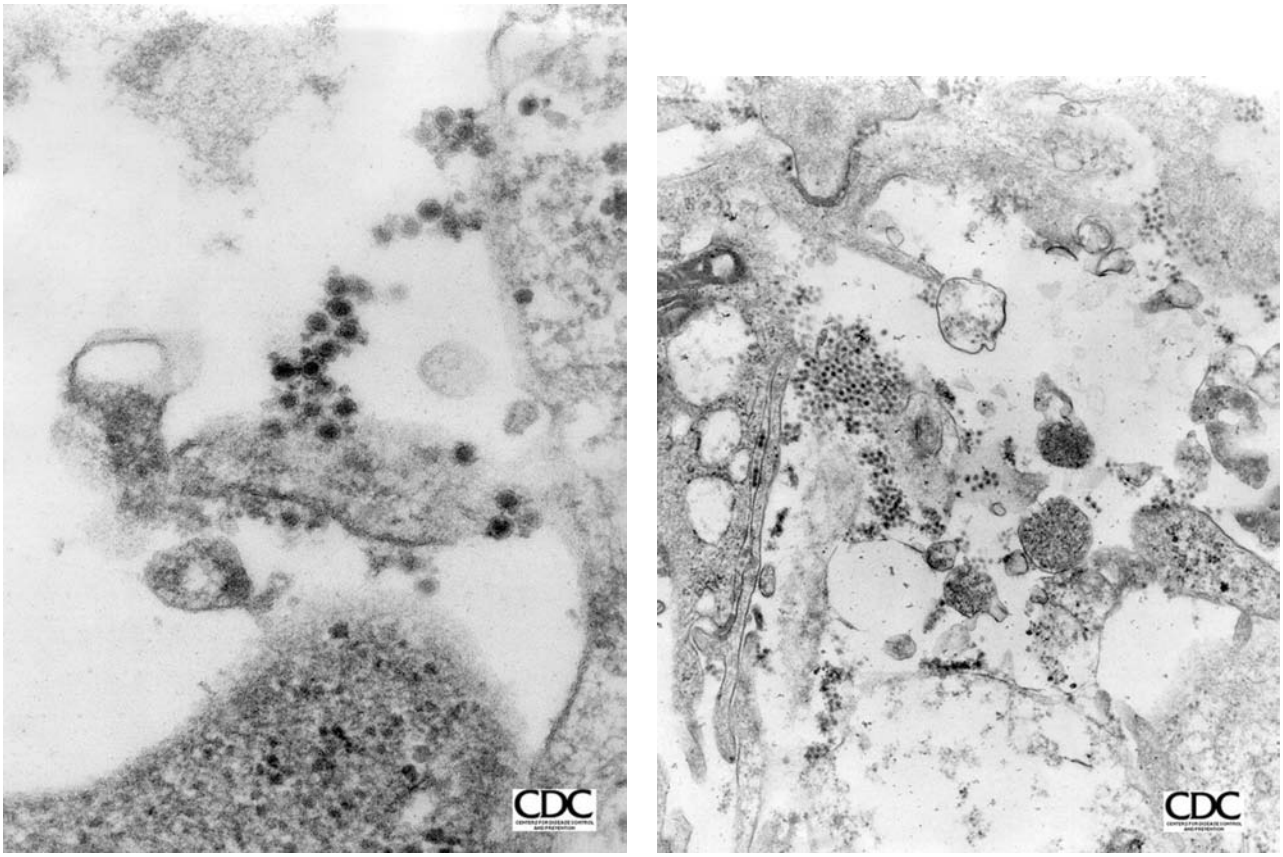
WEST NILE VIRUS. The West Nile (WN) virus has emerged in recent years in temperate regions of Europe and North America, presenting a threat to public, equine, and animal health. The most serious manifestation of WN virus infection is fatal encephalitis (inflammation of the brain) in humans and horses, as well as mortality in certain domestic and wild birds.

The West Nile virus is a member of the family Flaviviridae (genus *Flavivirus*). Serologically it is a member of the Japanese encephalitis virus complex that includes St. Louis encephalitis (SLE), Japanese encephalitis, Kunjin, and Murray Valley encephalitis viruses, as well as others (DeMadrid and Poterfield; and Calisher, et al.). All *Flaviviruses* share a common size (40–60 nm), symmetry (enveloped, icosahedral nucleocapsid), nucleic acid (positive-sense, single stranded RNA approximately 10,000–11,000 bases), and appearance in the electron microscope. See Figs. 1a and b.

History

The WN virus was first isolated from a febrile adult woman in the West Nile province of Uganda in 1937 (Hayes; and Hubalek and Halouzka). The ecology was characterized in Egypt in the 1950s. The virus became recognized as a cause of severe human meningoencephalitis (inflammation of the spinal cord and brain) in elderly patients during an outbreak in Israel in 1957. The first recorded epidemics occurred in Israel during 1951–1954, and in 1957. Equine disease was first noted in Egypt and France in the early 1960s. The largest recorded epidemic caused by WN virus occurred



(**a**) (**b**)

Fig. 1. Scanned images are of West Nile virus isolated from brain tissue from a crow found in New York. The tissue was cultured in a Vero cell for a 3-day incubation period. The Vero cells were fixed in glutaraldehyde, dehydrated, placed in an Epon resin, thin sectioned, placed on a copper grid, and stained with uranyl acetate and lead citrate. The grids were then placed in the electron microscope and viewed. Total magnifications, for image 1 (**a**) 65,625x; and image (**b**) 171,250x. (Images courtesy of Bruce Cropp, Microbiologist, Division of Vector-Borne Infectious Diseases.)

in South Africa in 1974. A large human outbreak of WN encephalitis occurred in Israel in 2000. European epidemics of WN encephalitis have occurred in southern France in 1962, in southeastern Romania in 1996, and in south-central Russia in 1999 (Tsai, et al.; and Platanov, et al.). European equine outbreaks also have occurred in Italy in 1998 and in France in 2000.

In late summer 1999, the first domestically acquired human cases of West Nile (WN) encephalitis were documented in the U.S. (Staff: CDC 1999; Anderson, et al.; Briese, et al.; Jia, et al.; and Lanciotti, et al.). The discovery of virus-infected, overwintering mosquitoes during the winter of 1999–2000 predicted renewed virus activity for the following spring and launched early season vector-control and disease surveillance in New York City (NYC) and the surrounding areas (Staff: CDC 2000). These surveillance efforts were focused on identifying and documenting WN virus infections in birds, mosquitoes, and equines as sentinel animals that could predict the occurrence of human disease. By the end of the 2000 mosquito-borne pathogen transmission season, WN virus activity had been identified in a 12 state area from Vermont and New Hampshire in the north to North Carolina in the south. In 2000 there were 21 humans, 63 horses, 4,304 birds (78 species including 1999 data), and 480 mosquito pools (14 species) reported with WN virus (Staff CDC 2000). This annual human case incidence now ranks WN virus second only to LaCrosse encephalitis virus as the leading cause of reported human arboviral encephalitis in the U.S.

Through July 2001, the WN virus has been documented in Connecticut, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Florida, Georgia, Virginia, Ohio, and the District of Columbia.

Although it is still not known when or how WN virus was introduced into North America, international travel of infected persons to New York, importation of infected birds or mosquitoes, or migration of infected birds are all possibilities. WN virus can infect a wide range of vertebrates; in humans it usually produces either asymptomatic infection or mild febrile disease, sometimes accompanied by rash, but it can cause severe and fatal infection in a small percentage of patients. In 1999 in New York, approximately 40% of laboratory-positive humans with encephalitis or meningitis had severe muscle weakness; 10% developed flaccid paralysis with electromyographic findings consistent with axonal neuropathy. The human case-fatality rate in the U.S. has been about 11%.

Unlike WN virus within its historical geographic range, or SLE virus in the Western Hemisphere, mortality in a wide variety of bird species has been a hallmark of WN virus in the U.S. The reasons for this are not known; however, public health officials were able to use bird mortality (particularly birds from the family Corvidae) to track effectively WN virus expansion in 2000. Early season field studies determined that areas with bird mortality due to WN virus infection were experiencing ongoing enzootic transmission. However, most birds survive WN virus infection as indicated by the high seroprevalence in numerous species of resident birds within the regions of greatest virus transmission. It is still not known to what degree migrating birds contribute to natural transmission cycles and dispersal of both viruses.

Entomology

Arthropod-borne viruses (termed "arboviruses") are viruses that are maintained in nature through biological transmission between susceptible vertebrate hosts by blood-feeding arthropods (mosquitoes, sand flies, ceratopogonids "no-see-ums", and ticks). Vertebrates can become infected when an infected arthropod bites them to take a blood meal. The term 'arbovirus' has no taxonomic significance.

The arboviral encephalitides are zoonotic, being maintained in complex life cycles involving a nonhuman primary vertebrate host and a primary arthropod vector. These cycles usually remain undetected until humans encroach on a natural focus, or the virus escapes this focus via a secondary vector or vertebrate host as the result of some ecologic change. Humans and domestic animals can develop clinical illness but usually are incidental

or "dead-end" hosts because they do not produce significant viremia, and do not contribute to the transmission cycle.

In the United States, West Nile virus is transmitted by infected mosquitoes, primarily members of the *Culex* species. See Fig. 2.

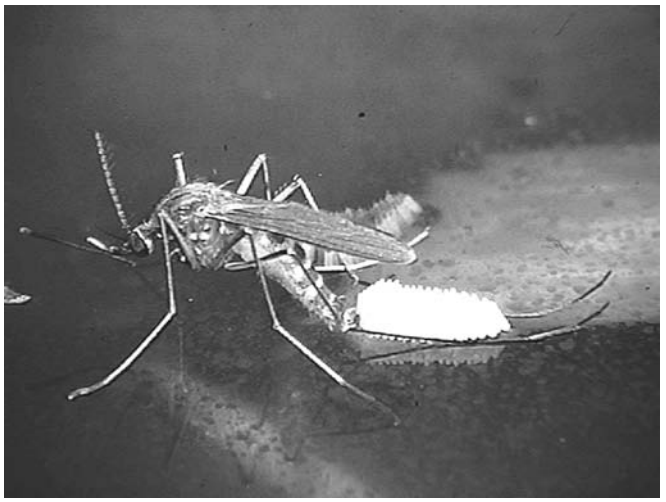


Fig. 2. *Culex* mosquito laying eggs.

Arboviral encephalitis can be prevented in two major ways: personal protective measures to reduce contact with mosquitoes and public health measures to reduce the population of infected mosquitoes in the environment. Personal protection measures include reducing time outdoors, particularly in early evening hours, wearing long pants and long sleeved shirts, and applying mosquito repellent to exposed skin areas. Public health measures include elimination of larval habitats or spraying of insecticides to kill juvenile (larvae) and adult mosquitoes. The combination of mosquito control methods selected for use in a control program depends on the type of mosquitoes to be controlled and the habitat structure. In emergency situations, wide area aerial spraying is used to quickly reduce the number of adult mosquitoes. In many states, aerial spraying may be available as a means to control nuisance mosquitoes. Such resources can be redirected to areas of virus activity when necessary.

Financing of aerial spraying costs during disease outbreaks is often provided by state or local emergency funds. Federal funding of emergency spraying is rare and almost always is associated with a natural disaster such as flood or hurricane.

Vertebrate Ecology

Transmission Cycle. West Nile (WN) virus is amplified during periods of adult mosquito blood-feeding by continuous transmission between mosquito vectors and bird reservoir hosts. Infectious mosquitoes carry virus particles in their salivary glands and infect susceptible bird species during blood-meal feeding. Competent bird reservoirs will sustain an infectious viremia for 1 to 4 days subsequent to exposure, after which these hosts develop life-long immunity. A sufficient number of vectors must feed on an infectious host to ensure that some survive the extrinsic incubation period (approximately 2 weeks, depending on temperature) to feed again on a susceptible reservoir host. People, horses, and most other mammals are not known to develop infectious-level viremias very often, and thus are probably "dead-end" or "incidental-hosts."

Birds. Through July 2001, more than 70 species of birds (mostly American crows) have tested positive for WN virus either by virus isolation or nucleic acid testing. Birds infected with WN virus can die or become ill.

There is no evidence that a person can get WN virus from handling live or dead infected birds. However, persons should avoid bare-handed contact when handling dead animals and use gloves or double plastic bags to place the bird carcass in a garbage can or contact their local health department for guidance. The U.S. Geological Survey's National Wildlife Health Center (NWHC) monitors bird mortality nationwide.

Dogs and Cats. West Nile virus does not appear to cause extensive illness in dogs or cats. There is a single published report of WNV isolated from a dog in southern Africa (Botswana) in 1982. West Nile virus was isolated from a dead cats in 1999 and 2000. However, a serosurvey in New York City of dogs and cats in the 1999 epidemic area showed a low infection rate.

There is no documented evidence of person-to-person or animal-to-person transmission of WN virus. Because infectious mosquitoes transmit the WN virus, dogs or cats could be exposed to the virus in the same way humans become infected. Veterinarians should take normal infection control precautions when caring for an animal suspected to have this or any viral infection. It is possible that dogs and cats could become infected by eating dead infected animals such as birds, but this is undocumented.

Nonetheless, there is no reason to destroy an animal just because it has been infected with WN virus. Full recovery from the infection is likely. Treatment would be supportive and consistent with standard veterinary practices for animals infected with a viral agent.

Horses. Cases of WN virus disease in horses have been documented, either by virus isolation or by detection of WN virus-neutralizing antibodies in 1999, 2000, and 2001. Results of epidemiologic investigations indicate that WN virus was responsible for several horse deaths. The horses most likely became infected with WN virus in the same way humans become infected, by the bite of infectious mosquitoes. The virus is located in the mosquito's salivary glands. When the mosquito bites or feeds on the animal, the virus is injected into the blood system of the horse. The virus then multiplies and may cause illness. Although there is no documented evidence of animal-to-person transmission of WN virus, normal veterinary infection control precautions should be followed when caring for a horse suspected to have this or any viral infection.

There is no documented evidence that WN virus is transmitted between horses. However, horses with suspected WN virus should be isolated from mosquito bites, if at all possible. Horses vaccinated against eastern equine encephalitis (EEE), western equine encephalitis (WEE), and Venezuelan equine encephalitis (VEE) are NOT protected against WN virus infection. A West Nile virus vaccine for horses was recently approved, but its effectiveness is unknown. It is not known how long a horse infected with WN virus will be infectious, but previously published data suggest that the virus is detectable in the blood for only a few days. Finally, there is no reason to destroy a horse just because it has been infected with WN virus. Data suggest that most horses recover from the infection. Treatment would be supportive and consistent with standard veterinary practices for animals infected with a viral agent.

Other Vertebrates. Through July 2001, The Centers for Disease Control and Prevention (CDC) has also received reports of WN virus infection in bats, chipmunks, raccoons, skunks, squirrels, and domestic rabbits.

Surveillance and Control

A special West Nile virus surveillance program has been initiated in 48 states, five cities, and the District of Columbia. See the Epidemic/Epizootic West Nile Virus in the United States: Revised Guidelines for Surveillance, Prevention, and Control, 2001: http://www.cdc.gov/ncidod/dvbid/westnile/resources/wnv-guidelines-apr-2001.pdf Data is being collected on a weekly basis and will be reported for the following five categories: wild birds, sentinel chicken flocks, human cases, veterinary cases, and mosquito surveillance. See the U.S. Geological Survey to view weekly maps and tables of data collected: http://cindi.usgs.gov/hazard/event/west_nile/west_nile.html.

WEST-WIND DRIFT. In the north and south Atlantic and Pacific oceans, the warm, poleward bound surface current produced by the prevailing westerlies. The best known of the west-wind drifts is the North Atlantic Drift, an eastward movement of warm water arising from the Gulf Stream and responsible for the warmth associated with Western Europe.

WET-BULB POTENTIAL TEMPERATURE. The temperature an air parcel would have if cooled from its initial state adiabatically to saturation, and thence brought to 1000 mb by a moist-adiabatic process. Also called pseudo wet-bulb potential.

This temperature is conservative with respect to reversible adiabatic changes.

WET DEPOSITION. See **Meteorology**.

WETLANDS. The term *wetlands* is self-defining — namely, wetlands are areas of land that, unless disturbed, are *wet* (bordering on water saturation) all or part of a given time span. In general usage, wetlands and riparian areas are intermediate between land and water. As reported by the United States Department of Agriculture (USDA), wetland scientists have developed more than 50 different definitions of wetlands. In fact, defining wetlands has been controversial in the context of U.S. policies because of the implications for landowners who want to use and develop these areas and environmentalists who want to preserve them.

Since 1977, the U.S. federal government has used a three-part definition involving hydric soils, hydrophytic vegetation, and hydrology. According to the U.S. Army Corps of Engineers, wetlands are "Areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support, and that under normal circumstances do support, a prevalence of vegetation typically adapted for life in saturated soil conditions."

The phrase "under normal circumstances" has been interpreted to mean that an area with wetland hydrology and soils remains a wetland, even when adapted vegetation has been removed to make areas suitable for farming. While this definition has been accepted generally, criteria for delineating wetlands in the field on the basis of evidence of the characteristics in the three-part definition have not been agreed to so readily.

Wetland science incorporates numerous hydrologic and geologic variations, and the science today lacks a crystal-clear nomenclature. Thus, as of early 1994, the evaluation of wetlands is not an exact science. Serious readers interested in this topic may find the glossary (Table 2) at the end of this article helpful.

Examples of wetlands range from the obvious, such as cattail marshes, peat bogs, and tidal sloughs, to prairie potholes and alluvial flood plains that are wet during only part of the year and may rarely have standing water. As the 1993 flooding of the Mississippi and Missouri basins has shown, when some of these types of wetlands are wet, they can be *very wet*.

The ecological and hydrologic functions and values of wetlands depend on a wide array of factors, including morphology, vegetation, and the nature of adjacent areas. Wetness alone is an inadequate index of the

importance of wetlands, but is getting increasing scrutiny as the wetland debate becomes more contentious.

Natural Values of Wetlands

Most, but not all, wetlands perform four very useful natural functions:

1. They deter small and major floods that result from abnormal precipitation in regions that feed water to great rivers. Wetlands either at or near the source of excessive precipitation act as sponges for storage of water and thus reduce the runoff that causes streams and rivers to swell way beyond their normal channels (banks), causing floods.
2. They provide sanctuaries for certain species of animals who survive best in wetland areas.
3. Particularly along the seacoasts, wetlands provide spawning and nursery areas for certain important species of fish and crustaceans, and, when wetlands are transformed to "dry" lands, this impacts adversely on fisheries.
4. Certain types of wetlands, such as cypress swamps, serve as water purifiers.

Land Values of Wetlands

Simply because they are land (and not considering their natural beneficial roles in the environment), wetlands have much economic value, particularly when they can be drained and filled in for agricultural production and, when located near large metropolitan areas, they can provide the necessary space for expansion. These are the two principal factors that have caused drastic reduction of wetland areas in the advanced industrial nations of North America and Europe since the early 1800s. Converted wetlands comprise some of the largest and most fertile agricultural lands and, commercially, have permitted urban communities to expand. For example, the airports of New York, Boston, and New Orleans have been constructed on transformed wetlands. In terms of so-called "urban sprawl," the natural advantages of wetlands have been negated by another natural phenomenon, namely the population "explosion."

Thus, the type of economic-environment conflict that has been present for many years in terms of adequate energy supplies also is present in the case of the wetlands in terms of land needs versus the environment. These kinds of dilemmas cannot be addressed by science and technology alone, but, in fact, seek sociological and societal solutions, tempered with whatever technical counsel that technology may provide.

Although a *few* naturalists over the past century have been aware of the fundamental natural values of wetlands, serious concerns over the large extent of wetlands conservation is relatively recent, extending back to the early post–World War II era. Generally, society and some governments, including the United States, have shown an increasing awareness of the desirability at this juncture of providing special attention and caution, not only in terms of any future conversion of wetlands to "dry" land, but also the restoration of former wetlands.

1993 — A Reminder of Wetlands' Role in Flooding

The near-record long, late rains that swelled rivers in the upper midwestern United States and that tore into levees along more than 1000 miles (1609 km) of the Mississippi, Missouri, and Illinois rivers served as a vivid reminder of the flood-control function of the wetlands along these rivers. In the upper Midwest, cropland covers over half of the flood-prone land — that is, land that has more than a 1% chance of flooding in any year. In 1993, the rising rivers flooded cropland that once had been wetland. Although much of this land will return to crop production, land in areas where levees have been breached and ditches have been silted will require many months to dry out.

According to the U.S. Fish and Wildlife Service, the nine-state Midwest region had more than 57 million acres (23 mil hectares) of wetlands in 1780, but only 23 million acres (9.3 mil hectares) remained 200 years later. In Minnesota, North and South Dakota, Wisconsin, and Nebraska, about 40 to 60% of the wetlands have been developed, drained for cropland, or otherwise converted. About 90% of the wetlands in Illinois, Iowa, Missouri, and Kansas have been converted. Shifts into agricultural uses accounted for the majority of conversions.

The USDA estimates that more than 29 million acres (11.7 mil hectares) of the 120 million acres (48.6 mil hectares) of cropland in the upper Midwest were originally wetlands that have been cleared and drained for crop production. Some hydrologists and ecologists believe that draining wetlands along rivers, combined with channeling and levee construction, contributes to higher flood levels and more powerful and destructive floods.

As early as 1987, a National Wetlands Policy Forum was convened. At that time, the forum suggested the following general policies:

- Establish a "no net loss" of wetlands.
- Provide incentives for private stewardship of wetlands.
- Initiate a wetland-restoration program.
- Commence regulatory reform, including improved wetlands delineation criteria and a consistent definition.

By 1990, considerable opposition to the aggressive field implementation of federal wetlands policies developed among farmers, developers, and small landholders. A review of federal interagency wetland guidelines was caught in the growing controversy and led to a major revision in 1991. These efforts, however, did not moderate a rapidly coalescing opposition to the regulation of wetlands. Property right interests targeted wetland regulation as an opening wedge in rolling back a wider array of regulation aimed at promoting the general welfare. Wetland regulation without compensation to landowners was portrayed as a "taking," proscribed under the Fifth Amendment to the U.S. Constitution.

Status

An inventory (1982) showed almost 48 million acres (19.4 mil hectares) of land with hydric soils in the nine Midwestern states that were affected by the 1993 flooding.

More than 1.4 million acres (0.6 mil hectares) of cropland on hydric soils in these states is still wet enough to be considered wetland, and about 200,000 acres (about 81,000 hectares) of this land shows some evidence of drainage. Most cropland on hydric soils was converted from wetlands through clearing and drainage. See also Table 1.

TABLE 1. CROPLAND ON WETLAND SOILS IN UPPER MIDWESTERN UNITED STATES

	Former Wetlands	Current Wetlands		Total Current & Former Wetlands (Hydric Soils)	All Rural Land with Hydric Soils
		Not Drained	Drained		
			Acres		
Illinois	7,239,600	176,500	78,000	7,494,100	8,723,300
Iowa	6,363,700	2,900	3,400	6,370,000	7,228,300
Minnesota	8,539,000	49,300	10,200	8,599,400	16,292,000
Missouri	3,669,000	2,400	0	3,671,400	4,982,400
Wisconsin	630,700	73,900	85,500	790,100	3,612,400
Kansas	523,500	7,600	0	531,100	736,500
Nebraska	607,300	35,100	1,300	643,700	1,486,700
North Dakota	715,100	543,900	10,900	1,269,900	2,547,200
South Dakota	469,800	303,900	18,200	791,900	2,215,300
Total	28,758,600	1,195,500	207,500	30,161,600	47,824,100

Note: Most recent comprehensive Survey (USDA, 1982).

TABLE 2. HYDROLOGICAL TERMS SOMETIMES USED IN FORMULATING WETLANDS POLICIES

ALLUVIUM
A general term for clay, silt, sand, gravel, or similar unconsolidated detrital material deposited during comparatively recent geologic time by a stream or other body of running water as a sorted or semisorted sediment in the bed of the stream, on its flood plain or delta, or as a cone or fan at the base of a mountain slope, especially a deposit of fine-grained structure (silt or silty clay) deposited during time of flooding.

ARROYO
A term applied in the arid and semiarid regions of the southwestern United States to the small, deep, flat-floored channel or gully of an ephemeral stream or of an intermittent stream, usually with vertical or steeply cut banks of unconsolidated material. It may be transformed to a temporary watercourse or short-lived torrent after heavy rainfall. Also called dry wash or wadi.

BACKWATER
Water that is retarded, backed up, or turned back in its course by an obstruction (such as a dam), an opposing current, or the movement of the tide (such as the water in a reservoir or the water obtained at high tide to be discharged at low tide).

Or a body of currentless or relatively stagnant water, parallel to a river and usually fed from it through a single channel at the lower end by the back flow of the river.

Or, generally, any tranquil body of water joined to a main stream, but little affected by its current, such as the water collected in side channels or flood-plain depressions after it overflowed the lowland.

Or a creek, arm of the sea, or series of connected lagoons, usually parallel to the coast and separated from the sea by a narrow strip of land, but communicating with it through barrel outlets.

BASIN AREA
For a given stream order, the total area, projected upon a horizontal plane, of a drainage basin bounded by the basin perimeter and contributing overland flow to the stream segment of order, including all tributaries of lower order. Sometimes called watershed area.

BAYOU
A term variously applied to many local water features in the Mississippi River basin and in the Gulf Coast region of the United States, especially in Louisiana. Its general meaning is a creek, large stream, minor river, or secondary watercourse that is tributary to another river or connecting with another body of water.

Or a sluggish and stagnant stream, characterized by a slow or imperceptible current, that follows a winding course through flat alluvial lowlands, coastal swamps, or marshes, or river deltas.

Or an effluent branch, especially sluggish or stagnant, of a main river or of a lake, as a distributary flowing through a delta or enclosing a low island. Also, the distributary channel that carries floodwater or affords a passage for tidal water through swamps or marshlands.

Or an intermittent, partly closed or disused watercourse, especially a lake or a sluggish stream formed on a river delta or in an abandoned river channel.

BAYOU LAKE
A lake or pool in an abandoned and partly closed channel or stream, as on the Mississippi River delta.

BOG
A waterlogged, spongy groundmass, acidic in nature, that supports primarily mosses. Decaying vegetable matter ultimately may develop into peat (hence a peat bog). Vegetation primarily is sphagnums, hedges, and heaths.

Bogs occur in damp, cool places. Cranberries grow well in bogs. If left undisturbed, bogs withhold the release of carbon dioxide to the atmosphere.

Sometimes associated with bogs are small shrubs, cotton grass, and stunted spruce.

BOREAL
Pertaining to the north, or located in northern regions. Or pertaining to the northern biotic zone, characterized by tundra and taiga and by dominant coniferous forests.

Boreal climate refers to a climatic zone that has a definite winter, experiences snow and a short summer that generally is hot, and is characterized by a large annual range of temperature. It includes large parts of North America and central Europe and Asia. This climate usually occurs between latitudes 60 °N and 40 °N.

BOTTOMLAND
Low-lying, level, usually highly fertile land, especially in the Mississippi River region of the United States and farther west, where the term signifies a grassy lowland formed by the deposition of alluvium along the margin of a watercourse.

Or an alluvial plain or a flood plain.

CANAL (Coast)
A long, narrow channel or arm of the sea connecting two larger stretches of water, usually extending far inland (sometimes between islands or between an island and the mainland) and approximately uniform in width. The Lynn canal in Alaska is an example.

Or a sluggish coastal stream, as may be found along the Atlantic coast of the United States.

CANAL (Stream) An artificial watercourse of relatively uniform dimensions, cut through an inland area, and designed for navigation, drainage, or irrigation by connecting two or more bodies of water. A canal is larger than a ditch.

CREEK (Stream) A term generally applied over most of the United States (except New England) and Canada and Australia to any natural stream of water, normally larger than a brook, but smaller than a river. Or a branch or tributary of a main river, a lowland water course of medium size, or a flowing rivulet. Also, a wide or short arm of a river, such as one filling a short ravine that joins the river.

CYPRESS DOME A group of cypress trees growing in the middle of a small swamp. See Fig. 1. The trees purify the water by removing most of the nitrates and phosphates, binding them to mud and tree roots. Overloading the water with contaminants can cause the system to dysfunction.

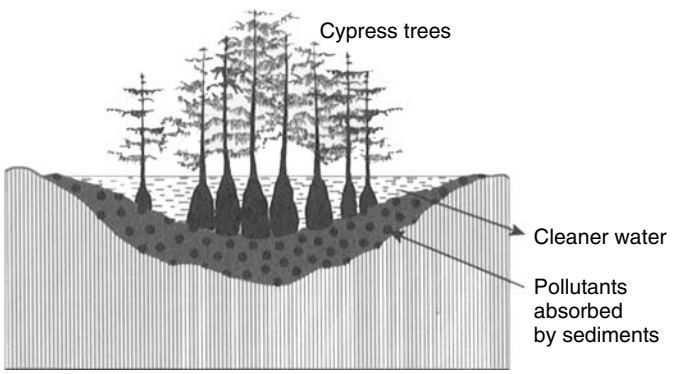

Fig. 1. Cypress swamp. Incoming polluted water is "treated" by the root system of the trees and discharged as less polluting. The pollutants are absorbed by sediments underlying the trees.

DELTA
The low, nearly flat, alluvial tract of land deposited at or near the mouth of a river, commonly forming a triangular or fan-shaped plain of considerable area enclosed and crossed by many distributaries of the main river. A delta sometimes extends beyond the general trend of the coast and results from the accumulation in a wider body of water (usually a sea or lake) of sediment supplied by a river in such quantities that it is not removed by tides, waves, and currents. Most deltas are partly subaerial and partly below water.

DELTAIC COASTAL PLAIN
A coastal plain composed of a series of more or less coalsescing deltas. It consists initially of natural levee ridges separated by basins.

DELTA LEVEE LAKE
A lake on an advancing delta, formed between sandbars or natural levees deposited at the mouths of distributaries. An example is Lake Pontchartrain on the Mississippi River delta.

DELTA PLAIN
The level or nearly level surface composing the landward part of a large delta. Or strictly an alluvial plain characterized by repeated channel bifurcation and divergence, multiple distributary channels, and interdistributary flood basins.

DETRITUS
A collective term for loose rock and mineral matter that is worn off or removed directly by mechanical means, as by disintegration or abrasion, especially fragmental material (such as sand, silt, and clay) derived from older rocks and moved from its place of origin.

DISTRIBUTARY STREAM
An irregular, divergent stream flowing away from the main stream and not returning to it, as in a delta or on an alluvial plain. It may be produced by stream deposition choking the original channel.

Or one of the channels of a braided stream.

(*continued*)

DRAINAGE BASIN
A region or area bounded peripherally by a drainage divide and occupied by a drainage system. In broader terms, the whole area or entire tract of country that gathers water originating as precipitation and contributes it ultimately to a particular stream channel or system of channels, lake reservoir, or other body of water.

ESTUARY
The seaward end of the widened funnel-shaped tidal mouth of a river valley, where freshwater mixes with and measurably dilutes seawater and where tidal effects are evident. A tidal river is a partially enclosed coastal body of water. Or a drowned river mouth formed by the subsidence of land near the coast or by the drowning of the lower portion of a nonglaciated valley due to a rise in sea level.

FLOOD PLAIN
The surface or strip of relatively smooth land adjacent to a river channel, constructed (or in the process of being constructed) by the present river in its existing regimen and covered with water when the river overflows its banks at times of high water. A river has one flood plain and may have one or more terraces representing abandoned flood plains.

Or any flat or nearly flat, usually dry lowland that borders a stream and that may be covered by its waters at flood stages.

Or the land beyond a stream channel, described by the perimeter of the maximum probable flood.

Or the part of a lake-basin plain between the shoreline and the shore cliff, subject to submergence during a high stage of the lake.

FLOODWAY
A large-capacity channel constructed to divert floodwater or excess streamflow from populous or damageable areas, such as a bypass route marked out by levees.

Or the part of a flood plain kept clear of encumbrances and reserved for emergency diversion of floodwaters.

GROUNDWATER
That part of the subsurface water that is the zone of saturation, including underground streams.

GROUNDWATER BASIN
A subsurface structure having the character of a basin with respect to the collection, retention, and outflow of water.

Or an aquifer or system of aquifers, whether or not basin shaped, that has reasonably well defined boundaries and more or less definite areas of recharge and discharge.

GROUNDWATER BARRIER
A natural or artificial obstacle, such as a dike or fault gouge, to the lateral movement of groundwater, not in the sense of a confining bed. It is characterized by a marked difference in the level of the groundwater on opposite sides.

HUMMOCK (Hammock)
A fertile area of deep, humus-rich soil, generally covered by hardwood vegetation and often rising slightly above a plain or swamp. An island of dense, tropical undergrowth, as found in the Florida Everglades. A rounded or conical knoll, mound, hillock, or other small elevation, generally of equidimensional shape and not ridgelike. A slight rise of ground above a level surface.

HYDRIC SOIL
A soil that in its undrained condition is saturated, flooded, or ponded long enough during the growing season to develop anaerobic conditions.

HYDROLOGY
The science that deals with continental water (both liquid and solid), its properties, circulation, and distribution, on and under the Earth's surface and in the atmosphere from the instant of its precipitation until it is returned to the atmosphere through evapotranspiration or is discharged into an ocean. See article on **Hydrology**.

KEY (Coastal)
A *cay*, particularly one of the coral islets or barrier islands off the southern coast of Florida.

LAGOON
A coastal lagoon is a shallow stretch of seawater, such as a sound, channel, bay, or salt-water lake, near or communicating with the sea and partly or completely separated from it by a low, narrow, elongate strip of land, such as a reef, barrier island, sandbank, or spit. Especially, it is the sheet of water between an offshore coral reef and the mainland. It often extends roughly parallel to the coast, and it may be stagnant.

Or a freshwater pond or lake near or communicating with a larger lake or a river. A stretch of freshwater cut off from a lake by a barrier, as in a depression behind a shore dune.

Or a body of water enclosed or nearly enclosed within an atoll.

The term also has been applied to other coastal features, such as an estuary, a slough, a bayou, a marsh, and a shallow pond or lake into which the sea flows. Lagoon also is used to describe any shallow, artificial pond or other water-filled excavation for the natural oxidation of sewage.

LANDLOCKED
Said of a body of water that is enclosed or nearly enclosed by land, such as a landlocked bay separated from the main body of water by a bar or a landlocked lake having no surface outlet.

MARSH
A water-saturated, poorly drained area, intermittently or permanently covered with water and having aquatic and grasslike vegetation.

A *coastal marsh* is a marsh bordering a seacoast, generally formed under the protection of a barrier beach or enclosed in the sheltered part of an estuary. Coastal marshes are subject to the daily cycle of ocean tides, which transport nutrients to a marsh and thus attract various forms of animal life. Coastal marshes are the habitat of fin and shell fishes that are harvested in the United States. The marsh often functions as a spawning locale and as a nursery for young fishes. Algae commonly is found in coastal salt marshes and serves as a nutrient for living forms.

MORPHOLOGY (River)
The study of the channel pattern and the channel geometry at several points along a river channel, including the network of tributaries within the drainage basin.

MUSKEG
A bog. Usually a sphagnum bog, frequently with tussocks of deep accumulations of organic material, growing in wet, poorly drained, boreal regions, often areas of permanent frost. Tamarack and black spruce commonly are associated with muskeg areas.

Or a term sometimes used in Michigan for *a bog lake*.

POND
A natural body of standing freshwater occupying a small surface depression, usually smaller than a lake and larger than a pool.

POOL
A small, natural body of standing water (usually freshwater), such as a stagnant body of water in a marsh, a transient puddle in a depression following a rain, or a still body of water in a cave.

Or a small, quiet, and rather deep reach of a stream, as between two rapids or where there is very little current.

Or a small or large body of impounded water, artificially confined above a dam or the closed gates of a lock.

PRAIRIE
An extensive tract of level to rolling, generally treeless grassland in the temperate latitudes of the interior of North America, especially in the Mississippi Valley region, characterized generally by a deep, fertile soil (suitable for wheat growing) and by a covering of tall, coarse grass and herbaceous plants.

Or a broad, low, wet, sandy, flat-bottomed, often water-covered, grass-grown tract or sink in the pinewoods of Florida.

PRAIRIE OR STREAM POTHOLE
A smooth, roughly circular, bowl-shaped, or cylindrical hollow that generally is deeper than it is wide, formed in the rocky bed of a stream. The feature is caused by the grinding action of stones or coarse sediment (sand, gravel, pebbles, boulders) that are whirled around and kept in motion by eddies or the force of a stream current in a particular location. Also, they may have been formed as the result of glacial action. Potholes frequently are found in seasonally flooded wetlands, notably in the northern plains of the United States. These features are removed, of course, when a wetland area is drained and filled.

Prairie potholes play an important role in the ecology of ducks. The holes serve as breeding oases for ducks. Nutrients (sometimes called "duck potatoes" and comprised of invertebrates and aquatic vegetation) fortify the ducks during periods of egg production. The holes are fed by melting snow and rain. Removal of the potholes causes the ducks to move elsewhere. See Fig. 2.

RIPARIAN AREA
The bank of a natural watercourse (as a river), but sometimes of a lake or tidewater. Legally, riparian rights are those of access to the water, including beaches.

RIVERINE BOTTOMLAND
Naturally occurring reservoirs, serving to trap and hold water during river flooding conditions. Entangled woody vegetation serves to trap sediment and thus functions to slow the flow of a river. Sometimes these areas are referred to as floodplain forests. Such bottomland in the northern flood plains of the United States often will feature cottonwood and silver maple trees, whereas tupelo and bald cypress are found along the slower-moving rivers of the south.

TABLE 2. (*Continued*)

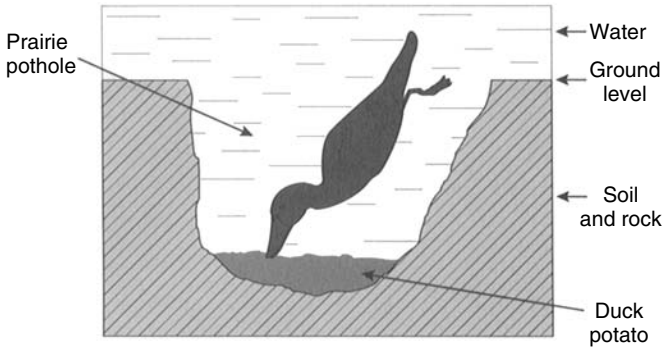

Fig. 2. In some wetlands, pot holes form that hold water for fairly long time spans. At the base of the "prairie pothole," nutrients accumulate. These are sought out by canvasback ducks and are referred to as "duck potatoes."

SAVANNAH (Savanna)
An open, grassy, essentially treeless plain, especially as developed in tropical and subtropical regions. Usually there is a distinct wet and dry season. The trees that are found are drought-resistant.

Or the tall grass characteristic of a savannah.

Along the southeastern Atlantic Coast of the United States, the term is used for marshy alluvial flats that have occasional clumps of trees.

SLOUGH
A small marsh, especially a marshy tract lying in a swale or other local, shallow, and undrained depression on a piece of dry land, as on prairies of the midwestern United States. Sometimes, a dry depression that becomes marshy or filled with water.

Or a large wetland, as a swamp, that occurs in the Everglades of Florida.

Or a term used, especially in the Mississippi Valley, for a creek or sluggish body of water in a tidal flat, bottomland, or coastal marshland.

Or a sluggish channel of water in which water flows slowly through low, swampy ground, as occurs along the Columbia River, or a section of an abandoned river channel that contains stagnant water and that occurs in a flood plain or delta.

Also, an indefinite term indicating a small lake, a marshy or reedy pool or inlet, a bayou, a pond, or a small and narrow backwater. Or a place of deep mud, as a mudhole.

SPHAGNUM MOSS
A moss of the genus *Sphagnum*, often forming peat. Also referred to as *peat moss*.

STEPPE
An extensive, treeless grassland area in southeastern Europe and Asia developing in the semiarid mid-latitudes of that region. They are generally considered drier than the prairie that develops in the subhumid mid-latitudes of the United States.

SWALE
A slight depression, sometimes swampy, in the midst of generally level land.

Or a shallow depression in an undulating ground moraine due to uneven glacial deposition.

Or a long, narrow, generally shallow troughlike depression between two beach ridges that is aligned roughly parallel to the coastline.

SWAMP
A water-saturated area, intermittently or permanently covered with water, and having shrub- and tree-type vegetation essentially without peatlike accumulation. Where natural drainage is impeded, as by impervious soil or bedrock, or abnormal amounts of plant materials, a swamp may form. This usually occurs on level ground, but swamps also can exist on hillsides, mainly as the result of percolation of groundwater. Lake basins filled with vegetation and sedimentation ultimately may become swamps. Swamps may be formed on the flood plains of rivers as well as deltas. These are characteristic of the flat, poorly drained areas of the Atlantic Coastal Plain, such as the Great Dismal Swamp, which covers some 2000 square miles (5180 sq km) in Virginia and North Carolina and the Everglades of Florida. In northern North America, the accumulation of vegetation and sedimentation sometimes is referred to as muskeg. Some swamps ultimately become peat bogs. See also article on **Swamp**.

TAIGA
A swampy area of coniferous forest sometimes found lying between tundra and steppe regions.

TIDAL SWAMP
A swamp partly covered during the high tide by the backing up of a freshwater river.

TRIBUTARY
A stream feeding, joining, or flowing into a larger stream (at any point along its course) or into a lake. See also **Distributary System**.

TUNDRA
A treeless, level or gently undulating plain characteristic of arctic and subarctic regions. It usually has a marshy surface that supports a growth of mosses, lichens, and numerous low shrubs and is underlain by a dark, mucky soil and permafrost.

TUSSOCK
A dense tuft of grass or grasslike plants that usually form one of the many firm hummocks in the midst of a marshy or boggy area.

WETLAND PLANTS
Certain plants, such as cattails, have adapted to survival in the flooded conditions of a freshwater marsh. Cattails have a dense network of air spaces through which oxygen penetrates to the roots. Also, air holes are found in the flat leaves of water lilies. Because of its porous roots, the milfoil can grow even when it is totally submerged.

WADI
See article on **Wadi**.

Environmental Issues

Although farmers have been concerned about losing some of their cultivatable land through a program to restore and revitalize the wetlands in some areas, and, although local land developers and city and town planners in various areas have resisted strong regulations over draining and filling in nearby wetland areas, the most publicized concern over the recent years has related to the effect of vanishing wetland on birds and other wildlife. This is a highly controversial topic and is reminiscent of nearly all efforts to match economic values with environmental values. Just a few locations where these considerations are quite serious are described here.

Major Wetlands in North America

Well covered in the literature is the plight of the wetlands in the Florida Everglades; the "Blackwater Country" of southern Georgia and northern Florida (including the Okefenokee Swamp and the Suwannee and St. Marys rivers); the Mississippi River Basin, including the Missouri and Illinois rivers; the tidal of Minnesota, Manitoba, Ontario, and Quebec; the tidal salt marshes of the North American eastern seaboard; the Central Valley of California; the lower Savannah River in Georgia; the Sweetwater Marsh and the Tijuana River estuary near San Diego, California; the former Llano Seco Ranch along the Sacramento river in California; the San Jacinto River estuary near Houston, Texas; the mud flats in Gray's Harbor in northwestern Washington; the lower Klamath Basin in California; and so on.

A few specific cases are described in the following paragraphs.

Tate's Hell. Located in the panhandle of Florida just east of the Apalachicola River and consisting of 128,000 acres (51,800 hectares) of *titi swamp*. Titi shrubs, some 10 feet (3 meters) high are intermixed with southern pines. Ecologists consider this swamp crucial to the productivity of the Apalachicola estuary, which is an important seafood harvesting area.

Pine Flatwoods. These cover millions of acres of the southeastern coastal plain, extending from the Carolinas to Texas. This is the habitat of numerous species of plants and animals, some of which are rare or endangered. From the standpoint of *biodiversity*, some ecologists consider these areas as being among the most outstanding on Earth. The flatwoods are endangered for several reasons:

1. Pollution from urban areas;
2. Conversion to agriculture; and

3. Drying out because of anthropogenic disturbance of their upslope watersheds.

White Cedar Wetland Forests. These occur along the eastern coast of North Carolina (Dismal Swamp). Until the last 50 years, these wetlands had existed for many centuries and had provided a sanctuary for bear, deer, beaver, and other species. The cedar trees have provided a dense, cathedral-like canopy that slows the drying of the wetland carpet below. The areas sometimes are referred to as *cedar bogs*. As of the early 1990s, an estimate shows that about 90% of the cedars have been harvested for timber. Although most numerous in North Carolina, such wetlands once prevailed along the eastern and southern shore of the continent from Maine to Louisiana. Early settlers commonly harvested cranberries in the Cedar wetlands.

For many years, no effort was made to alter the cedar harvesting practice in order to promote regrowth. Further, white cedars are extremely sensitive to urban pollutants that migrate to the swampy areas. Also, because white cedars require up to 70 years to harvest economically, other species, such as the loblolly pine, which require only 40 years to harvest, have been planted in place of cedars. There are major differences in the ecosystems of the two species of trees.

WETTING AGENT. A surface-active agent that, when added to water, causes it to penetrate more easily into, or to spread over the surface of, another material by reducing the surface tension of the water. Soaps, alcohols, and fatty acids are examples.

See also **Detergents**.

WHALE FALL. Whale fall is the term used for a whale carcass that has fallen to the ocean floor. Whale carcasses are another deep-sea habitat that is crammed with life. Whale falls can provide as much organic material as a thousand years of marine snow, and a single skeleton can support more than 40,000 individual animals including shellfish, amphipods, and worms. When a whale dies in shallow water, its carcass is typically devoured by scavengers over a relatively short period of time. However, in deeper water (depths of 2,000 meters (6,562 feet) or greater), fewer scavenger species exist. Whale carcasses provide a sudden, concentrated food source, a bonanza for organisms in the deep sea. Different stages in the decomposition of the whale carcass support a succession of marine biological communities. Scavengers consume the soft tissue in a matter of months. Organic detritus from this stage also enriches the sediments nearby, for a year or so. The skeleton, however, supports rich communities for years to decades, both as a hard substrate for invertebrate colonization and as a source of sulfides from anaerobic decay of bone lipids. Microbes live off of the energy released from catalyzing chemical reactions, particularly oxidation of sulfide, and form the basis of chemoautotrophic ecosystems for as long as the food source lasts.

In life, the whale reigns supreme and powerful — our connection to a lost world of dinosaurs and the sea, a symbol of what is great, free, and intelligent. In death, the whale continues an act of stately splendor. It produces a funereal procession that's been enacted for millions of years, but one for which we are just getting snapshots of now. Credit for what we do know about the remarkable afterlife of the whale is largely due to the efforts of biological oceanographer Craig Smith of the University of Hawaii http://www.soest.hawaii.edu/oceanography/faculty/smith/index.html, and Amy Baco-Taylor (Woods Hole Oceanographic Institution).

For more than a decade, Smith has been pursuing the idea that whale corpses serve as biological stepping stones for a host of exotic deep-sea animals that survive in some of the world's harshest environments. His theory has stirred debate among scientists trying to determine how tube worms, clams and other colonizers of hydrothermal vents and cold seeps arrive and persist in their ephemeral habitats. Smith believes that for the past 30 million years or so, whale falls may have been providing a stepping stone for at least some of these animals to colonize over vast expanses of the ocean. See also **Cold Seeps**; **Hydrothermal Vents**; and **Ocean**.

Studying whale falls has important implications for science. "If we want to understand how evolution works, we need to explain the incredible diversity of animals in the deep sea," said Smith. At least 19 animal species new to science have been found in the 19 years that Smith and other scientists have been studying whale falls. Biodiversity also means there are lots of genetic resources with potential commercial applications to tap. For example, a San Diego biotechnology company is working with Smith to develop a cold-water detergent containing an enzyme found in bacteria growing on whale bones. Such a detergent may have the potential to yield substantial energy savings on a national scale. Understanding what happens to organic-rich matter in the deep sea — like a 35 ton (31,751 kilogram) whale — is another area of broad ecological interest. This knowledge is relevant both for understanding how deep sea animals respond to point-source enrichment and for predicting the effects of relocating sewage sludge or disposing of other organic-rich wastes at the deep-sea floor, Smith said.

Both Buddhists and Hindus share the idea of reincarnation, which in its simplest form means that life does not end with death. In the whale's case, life is attracted and then emerges from the whale's corpse creating a lush faunal island in the ocean abyss. In 1987, a decade after hydrothermal vents were first discovered off the Galapagos Islands, Craig Smith of the University of Hawaii and colleagues found a thriving, diverse animal community on a blue whale (*Balaenoptera musculus*) carcass that had fallen to the ocean bottom (4,000 feet (1,219 meters) in the Santa Catalina Basin of the coast of California in the submersible Alvin. The scientists found the bones were covered with clams and mussels containing symbiotic bacteria that live on sulfides Fig. 1. While the sulfides at hydrothermal

vents are in the water that spews from beneath the sea floor, the sulfides at whale falls are produced by bacteria that decompose oils inside whale bones.

Fig. 1. Microbes coat the skeleton of a whale that fell to the seafloor off California. Craig Smith (University of Hawaii) and colleagues found that microbes decompose whale tissue and bones, producing hydrogen sulfide nutrients that sustain thriving animal populations. Whale-fall communities share many species with other chemosynthetic seafloor communities, such as hydrothermal vents and seeps, and may act as stepping-stones between them. (Image courtesy Craig R. Smith (University of Hawaii and Amy Baco-Taylor, (Woods Hole Oceanographic Institution).

Animals with symbiotic bacteria have inhabited whale falls for ages. In the Pacific Ocean, whale fossils have been found with mussels attached to their bones, and these mussels presumably had symbiotic bacteria because all of their close relatives do today. Intriguingly, animals with symbiotic bacteria may also have lived on skeletons in the deep sea well before the time of whales, which first appeared about 40 million years ago. Mollusk fossils have been found near 200-million-year-old fossils of large marine reptiles, including ichthyosaurs and plesiosaurs.

Whale skeletons support so much life in the deep sea because they contain an enormous amount of oil. Large whale bones can be more than 60 percent oil by weight, and the skeleton of a 90-ton (81,646 kilogram) whale, for example, is estimated to contain five tons (4,536 kilograms) of oil. Depending on the size of the whale, its bones can contain enough oil to support sulfur-loving species for as long as 80 years.

So far, 407 species have been found on whale falls. But there are probably a lot more, because most of what we know about whale falls comes from only 20-odd specimens — either skeletons found by chance on the sea floor, or skulls and other parts that were trawled up from the depths. In addition, while whale falls have been found scattered around the world, most of those that have been studied are in California waters. Just as the species at hydrothermal vents vary in different parts of the world, Smith expects that whale fall species will vary around the world. In keeping with his expectation, museum specimens of animals found on whale bones off New Zealand are different from those found on whale bones off California.

The fact that so many whale-fall species are known from so few specimens suggests that whale falls have more species than hydrothermal vents. While vents have more known species right now — 600 worldwide — they have also been more intensively studied than whale falls. As we learn more about whale falls, the numbers of known species at whale falls could surpass those at hydrothermal vents.

Likewise, the number of species unique to whale falls is likely to rise above the 30 that are known today. The existence of these whale-fall specialists raises an interesting question: Because whale skeletons are isolated habitats that support life for a limited time, how do the species that depend on them get from one whale fall to another?

Smith thinks that whale falls are close enough together to form habitat "archipelagos." Whale carcasses are likely to be concentrated along migration routes and in feeding and calving grounds, which means they are probably close enough together for marine larvae to traverse them. For example, Smith estimates that the deep-sea carcasses of gray whales (*Eschrichtius robustus*) off the west coast of North America are roughly four to ten miles apart, which is well within range of marine larvae dispersal. Even greater distances could also be within their range: Some marine larvae can survive as long as nine months and so may be able to disperse more than 500 miles (805 kilometers).

The existence of species that are unique to whale falls raises another question: How did commercial whaling affect them? Massive commercial whaling began in the 1800s and continued into the 1900s. Despite the 1982 International Whaling Commission's moratorium on commercial whaling, today many whale populations are estimated to be at only ten to 25 percent of their historical levels. Fewer whales' means fewer whale falls, which in turn means less habitat for whale-fall species. Habitat loss can make species more vulnerable to dying out, and Smith believes that intensive commercial whaling has already driven some whale-fall specialists to extinction. "It's likely that the first extinctions were due to the onset of whaling," says Smith, adding that "extinctions of whale fall specialists are probably ongoing."

Whale Fall Colonization

Understanding the phases of colonization by animals at whale falls is another focus of Smith's research supported by NURP (NOAA's Undersea Research Program). In June 1998, Smith and his colleagues used the research submersible Alvin to study one natural and three experimentally implanted whale carcasses off the coast of southern California. They would examine a 10,000 kilogram (22,046 pound) gray whale implanted at 1,900 meters (6,234 feet) in the San Clemente Basin in 1992, a 5,000 kilogram (11,023 pound) gray whale implanted at 1,220 meters (4,003 feet) in the San Diego Trough in 1996, and 35,000 kilogram (77,162 pound) gray whale emplaced at 1,750 meters (5,741feet) in the Santa Cruz Basin in May 1998. They would observe the whale falls during submersible visits to the carcasses at time intervals between 10 and 120 days as well as between one, three, five and 10 years.

Whale falls pass through three successional stages, the researchers discovered. The first stage is dominated by mobile scavengers. "There are dense aggregations of hagfish, small numbers of lithodid crabs (a new species of crab found at whale falls), rattail fish, large sleeper sharks, and millions of amphipods," Smith said. "This stage can be surprisingly short with more than 90 percent of the soft tissue stripped from the 5-ton (4,536 kilogram) carcass within four months." On larger whale carcasses, like the 35,000 kilogram (77,162 pound) Santa Cruz whale, this stage lasts at least nine months and could persist for more than two years, he said.

The next phase whale falls enter is called the *enrichment-opportunist stage*. During this period whale skeletons are surrounded to several meters (feet) by dense aggregations of polychaete worms and cumaceans. Densities of these species are the highest ever measured in the deep-sea below 1,000 meters (3,281 feet). At least two of the extremely abundant species near the whale skeleton are new to science and may be whale-fall specialists, according to Leslie Harris, collection manager of the Los Angeles County Museum of Natural History http://www.nhm.org/research/annelida/staff.html.

In October 2004, Smith and Baco-Taylor used an ROV to return to the whale fall study sites. Smith brought samples of the worms found at the whale implants in the Santa Cruz basin to Harris for identification. "These are big, beautiful, and bizarre worms," said Harris, referring to the 50 mm (2 inch) long worms, which resemble centipedes, found in the Santa Cruz basin. The Los Angeles County Museum of Natural History holds the largest collection of polychaetes in the world. At first she couldn't find another worm like it until she turned to an obscure paper by a Russian researcher characterizing a polychaete that lived in the anoxic Black Sea. Conditions at a whale skeleton may be comparable, Harris said. "This worm exhibits wonderful behavior that nobody knows about," she said, noting that in video footage she received from Smith she observed the worms hanging on the whale carcass in such dense aggregations that they looked like a shag carpet. Finding out about this new polychaete will be an important step for science. The worms appear to play a major role in

structuring the newly discovered deep-sea community found at whale falls. How these worms arrive at whale falls and what role they play in the food chain there are totally unknown. Since polychaete worms have existed for millions of years and have an incredible diversity of lifestyles, they're an important group for learning more about evolution, Harris said.

After the worms disappear from the whale carcass, the whale fall enters its last stage. This stage is also the longest — continuing in excess of ten years. It is called the sulfophilic stage because of the abundance of species thriving off the sulfide produced by whale bones. The decay of bone lipids supports remarkably dense bacterial mats, mussels, vesicomyid clams and occasionally vestimentiferan tube worms. During this stage researchers found more than 30,000 animals in a broad range of taxa on a single skeleton, Smith and Baco-Taylor said. The diversity of species found in these dense populations far outnumber local species richness in other extreme deep-sea environments including hydrothermal vents, cold seeps, and manganese nodules. In fact, the population at the whale falls rivals the species-rich rocky intertidal habitat.

Genetic studies at the whale fall sites indicate that the animals at whale skeletons are closely related to the animals found at hydrothermal vents and cold seeps. "DNA studies of the Idas washingtonia from deep sea whale bones and wood falls reveal a surprisingly close relationship to the Bathymodiolinae, the subfamily of mussels previously considered to be restricted to hydrothermal vents and cold seeps," according to Smith and his research team.

Ancestors of the mussels may have moved into the deep sea along with organically-rich wood and whale falls, and then made "the relatively small ecological leap from these sites to sulfide rich vents and cold seeps at the deep sea floor," Smith said. "In total, California whale falls are now known to share 10 species with vents, nine with seeps, four with anoxic sediments and one with wood falls," Smith said. "Thus, the ecology and evolution of whale skeletons communities clearly are related to those of other deep sea reducing habitats."

A whale is cosmopolitan during its life traveling freely around the globe. Its death in a random part of the deep sea is punctuated by remarkable energy. Little understood animals appear to materialize from nowhere upon the whale's arrival.

Despite the enormous logistic difficulties of towing and sinking decomposing whale caracasses, Smith's research offers a glimpse into this mysterious process. He did succeed in getting the support needed to sink a 35,000 kilogram (77,162 pound) gray whale carcass. This site will be used to study whale fall succession on the "truly leviathan scale" for years to come, Smith hopes.

Smith plans to continue monitoring the whale falls in intervals of two, three and 17 years. The researcher has implanted kelp and wood falls near the whale falls. Since the San Clemente seep is only 50 to 120 kilometers (31 to 75 miles) up current from the site of the whale, wood and kelp falls, the seep fauna may be a likely source of colonists for these sites. The genetic relationship between whale falls, cold seeps, kelp falls and wood falls, as well as how long these communities persist, remains poorly known. Smith's research will help elucidate the role whale falls play in deep-sea processes.

Note: Additional information about this project can be found by contacting Craig Smith at the University of Hawaii Department of Oceanography, 1000 Pope Road, Honolulu, HI 96822 or by email to csmith@hawaii.edu. The Research was supported through a grant from the NOAA's Undersea Research Program's West Coast and Polar Regions Undersea Research Center. Additional funding was provided by the National Science Foundation.

WHALES, DOLPHINS, AND PORPOISES *(Mammalia, Cetacea)*. The general organization of this interesting order of mammals is given in the table at end of this article. In general terms, whales are marine animals of completely aquatic habits. See Fig. 1.

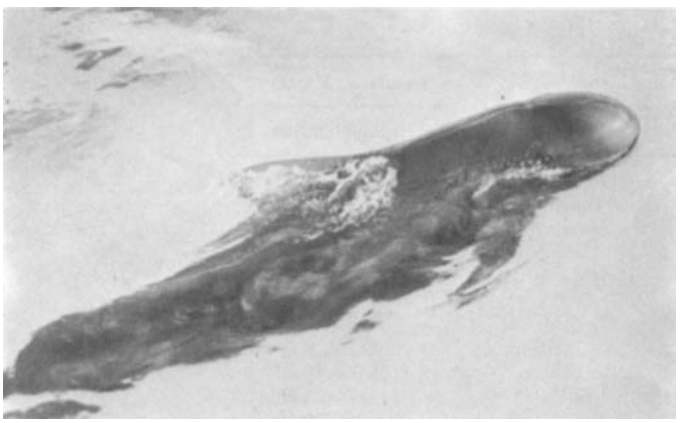

Fig. 1. Whale. (*A.M. Winchester.*)

Wide Range of Sea Mammal Physiology

The whales vary to a considerable degree in structure as represented by the various species. Whales 20 feet (6 meters) in length are among smaller species. Individuals of from 60 to 80 feet (18 to 24 meters) and even 90 feet (27 meters) have been reported among several of the larger species. The baleen or whalebone whales live on small marine animals, which are separated from the water by the sievelike whalebone fringes of the jaws. The toothed whales include some actively predacious species. Species of both orders were once widely sought for their oil and whalebone, but the latter has long been supplanted by manufactured products. Sperm oil is still valued as a fine lubricant and sperm whales are killed also for a waxy material, spermaceti, used in the manufacture of cosmetics. The peculiar substance called ambergris is formed in the intestine of the whale and is used to make the odor of perfumes more persistent.

Aside from their torpedolike fish shape, whales have many other internal and external structural adaptations that allow them to live, move, and feed in the water. The skin is smooth and hairless, with the exception of a few single hairs or hair remains near the jaw, which may serve as tactile hairs. The fore and hind limbs appear in the embryo like those of any other mammal. However, the fore legs always develop into flat, more or less extended flukes. Whereas in a whale embryo that is 20 millimeters (0.8 inch) long one can see external indications of the hind feet, these appendages, indications and all, have completely disappeared by the time the embryo is 30 millimeters long. The blow hole (nostril) is located on the end of the snout in very young (4 to 5 millimeters; 0.2 to 0.3 inch long) whale embryos. (All other mammals have a similar location of the nostril). However, by the time the embryo has reached a length of 22 centimeters (8.6 inches), the blow hole has been shifted back to the upper part of the head, the same location as in adult whales.

The location of the blow hole is probably related to the whale's weight distribution, which differs from that of land mammals. The sperm whales are the only members of this order which have their blow hole further up front.

The breast fins or flukes play a very minor role, or no role at all, in the whale's usual swimming motions; the tail provides all the diving power necessary for forward movement. Scientists have been able to study the tail movements of some whale species in the large American seaquariums, and, with the help of photographs, they have established that the tail is moved up and down on an exact vertical line. The real motor drive is produced almost exclusively by the broad. sweeping fluke, the sides of which are not supported by bones. The longer forward part of the tail provides the muscle power necessary for this diving motion. This part of the tail is a deep oval that is compressed at the sides, and it cuts through the water with very little resistance as the whale moves it up and down.

Speed of Movement. The speeds that whales can attain are astounding, at least insofar as baleen whales and dolphins are concerned. The slower right whales and gray whales can reach a peak speed of some 11 kilometers (7 miles) per hour; the humpback whale can reach a speed of up to 18 kilometers (11 miles) per hour. The usual speed of these three whales is generally from 3.5 to 5.5 kilometers (2 to 3.5 miles) per hour. Sperm whales can maintain a speed of 18 kilometers (11 miles) per hour over long distances, and they may travel as fast as 37 kilometers (23 miles) per hour over short periods of time. The large finback whales can maintain a general speed of between 22 and 26 kilometers (14 and 16 miles) per hour, while their peak speed is 50 kilometers (31 miles) per hour. The much smaller bottle-nosed dolphins and other dolphins are also able to reach similar speeds; scientists have measured a general velocity of 22 to 26 kilometers (14 to 16 miles) per hour for these animals.

Adaptation to Aquatic Environment. One of the greatest difficulties that a vertebrate land animal must overcome in its transition to life in and under water is the adaptation of its breathing to the very different requirements of aquatic living. Unlike fish, which breathe through gills, whales are forced to come to the surface of the water in order to breathe. When it reaches the surface, the whale expels the moist air from its lungs, under great pressure. When the pressure on the exhaled air is released, the air rapidly disperses and, as a result, is cooled to such an extent that the moisture it carries condenses and becomes visible as a white cloud. The cloud of steam, the "blast," can reach a height of 3 to 4 meters (10 to 13 feet) with right whales, a height of 2 meters (6.5 feet) with humpback whales, 4 to 6 meters (13 to 19.5 feet) with rorquals, 6 meters (19.5 feet) with blue whales, and 5 to 8 meters (16.5 to 26 feet) with sperm whales. Each whale species has a distinctive steam cloud, and a person acquainted with the types and shapes of clouds can easily distinguish the type of whale. Right whales have a double cloud. Finback whales release a cloud that is shaped somewhat like a pear, and the sperm whale's cloud is directed forward on a diagonal line.

Vertebrate animals are not really built for aquatic life; the salt content of their blood and body tissues is less than that of sea water. Thus, the excess salt accumulated from food and water must be eliminated from the body. Whales do not have salt excretory cells like those the bone fishes have on their gills. They are not able to excrete salt through their nasal glands like many sea birds. Whales also do not have perspiration glands, which help many other mammals give off excess salt. The kidneys are the whale's only salt-excreting organs. Whales have very large kidneys relative to those of land mammals; the kidneys of small whales are twice as large as those in land mammals of the same size.

Most whales are ocean-going animals; the few freshwater forms belong to the suborder of toothed whales. All baleen whales, as well as some species of toothed whales, have regular migrations. In 1931, scientists began to study those animals regularly, because of the economic importance of the whale industry; whales were tagged or marked so that scientists could plot their migrational routes and find out more about their way of life.

The Birth Process. Unlike most of the other larger mammals, whales are born tail first. The birth itself is usually a fairly smooth process, in spite of the size of the young, due to their smooth fish shape. Scientists have been able to observe the birth of some of the smaller whale species such as porpoises, dolphins, spotted dolphins, and bottle-nosed dolphins, in the larger seaquariums. The female bottle-nosed dolphin starts to swim more slowly when her labor pains begin. The other females of the group remain close to the pregnant female, presumably to protect her and to see that she does not get separated from the herd. The umbilical cord is very long, and it cannot be easily broken until the head of the whale calf is completely free; only then does the cord break off, near the calf's stomach. This prevents premature breathing motions by the calf. The mother pushes her young to the surface of the water immediately after birth; there it fills its lungs with air for the first time. The mother is often helped by several other adult members of the herd ("aunts") as she cares for the calf.

Blue whales and rorquals nurse their young for between five and seven months; most of the other whales nurse their young for almost a year. The nipples are situated in skin folds on both sides of the genital orifice; the young nurse underwater (a practice we are familiar with in hippopotamuses and sea cows). Whale milk is particularly rich in fats and protein; it is 40 to 50% fat (compared to between 2 and 17% in land mammals), and only 40 to 50% water (80 to 90% in land mammals). The protein content is twice that of land mammals, and the sugar content is 1 to 2% lower than that of land mammals, whose sugar content is 3 to 8%. This exceptionally nourishing milk helps the whale calf grow very rapidly; a young blue whale, for example, grows 9 meters (29.5 feet) in seven months, a daily growth of 4.5 centimeters (1.8 inches).

The females of some whale species can be re-impregnated immediately after the birth of their young. However, usually female blue whales, rorquals, and sperm whales do not become pregnant until after their young are weaned. For this reason these species generally give birth only one every two years. If we assume that the large whales have a life expectancy of 30 to 40 years, then a female can give birth to between 10 and 12 calves at the most during her lifetime. This is a rather low birth rate, adapted to the low natural death rate of these animals.

People have long hunted whales and used various parts of the whale for their needs. The early inhabitants of Alaska hunted whales in 1500 B.C. The first written report of whaling in North America is from A.D. 890. The most important part of the whale for man is the oil, which comes from the blubber layer in the subcutaneous connective tissue. Earlier, whale oil was used as lamp oil; today it is used principally in the manufacture of margarine. Whale oil also plays an important role as a raw material in the soap industry and in the production of linoleum and synthetic resins. The oil yield from whaling is only 2% of the world's fat production and only 5% of the production of animal fats. The meat of the larger baleen whales is eaten especially by the Japanese, but also in parts of Western Europe. The meat of these whales is also used as dog food and, when it has been dried and crushed into meat powder, as cattle feed. People use whale bones to make glue and gelatin or manure (once the bones have been crushed). The baleen whale was formerly important as the supplier of the "whalebone" (baleen) which was a vital feature of the corset industry. Additional whaling products include vitamins and hormones from different internal organs, connective tissue fibers (used, for example, in stringing tennis rackets), ivory from the teeth of sperm whales, spermaceti, and ambergris.

Dolphins. These mammals are small-toothed whales that attain a length of about 8 feet (2.4 meters). There are many species of several characteristic forms. See Fig. 2. One of the more peculiar is the narwhal, *Monodon monoceros*, which has a single spirally twisted ivory tusk. The tusk is a single tooth, usually that of the left side. Its mate in the male and both of these teeth in the female are rudimentary. The narwhal has no other teeth except a few irregular rudiments. The tusk may attain a length of 8 feet (2.4 meters) and the animal may reach a length of from 12 to 16 feet (3.6 to 4.8 meters). These whales are dark gray and spotted in color. They appear in schools of from 15 to 20 individuals and can be described as gregarious and playful. They feed on crustaceans, cuttlefish, and small fishes. The purpose of the tusk is unknown. When in a playful mood, the animal seems to fence with it. They are not known to attack boats with the tusk. The tusk has been used as a source of good quality ivory, but the tusk does have a central cavity, which detracts from its value. The dolphin whales are not to be confused with dolphin fishes (*Osteichthyes*).

Fig. 2. Atlantic bottlenose dolphin.

Several other species of dolphins live in large rivers of the Old and New World tropics, among them the Gangetic dolphin or susu of India and the Amazonian dolphin, *Inia geoffroyensis*, also called the inia or bouto, of South America. In most species of dolphins, the head is at least 12 to 15 inches (30 to 38 centimeters) broad, the beak about 6 inches (15 centimeters) long, and the blow-hole is crescent-shaped. Color is dark gray on the back and white underneath. Only one calf is produced at birth and the mother provides extremely attentive care.

The term grampus is a name meaning flat fish and is really applicable to almost any whale. It is usually given to Risso's dolphin which grows to about 15 feet (4.5 meters) in length, has a small rounded head, long tapering flippers, and feeds on squid and octopus. Grampus is sometimes also applied to a large dolphin, *Orcinus orca*, of vicious habits, and also known as the killer. These latter animals hunt in groups and are known to attack larger whales.

Porpoises. These are small animals related to the toothed whales. They reach a length of about 5 feet (1.5 meters). The muzzle is bluntly rounded, and most species have a dorsal fin. See Fig. 3. Porpoises are found chiefly in the northern oceans, although one species ranges from Japan to southern Africa and enters the rivers of China and India. The porpoise is usually smaller than the dolphin, but is much alike. Porpoise means "bottle-nose" as contrasted with the beak-type nose of the dolphin. Porpoises bear a single calf in the summer. Gestation period is about 1 year. The baby is about 3 feet (0.9 meter) in length. The life expectancy of a porpoise in captivity is about 30 years. A porpoise has between 80 and 100 teeth and feeds on fish and small marine animals. Color is black or dark gray above and white below. The flippers are black.

WHALE SHARK. See **Sharks**.

WHEATGRASSES. See **Grasses**.

WHEAT MIDGE *(Insecta, Diptera)*. A minute fly whose larva develops in the growing kernel of wheat. Introduced from Europe into Canada early in the nineteenth century, the species was troublesome in New York about the middle of the century but has not been serious since. Cultural methods are an adequate protection. They include crop rotation, fall plowing to bury and destroy the larvae, and the destruction of all debris from infested fields.

WHEATSTONE BRIDGE. See **Bridge Circuits (Electrical/Electronic)**.

WHEAT *(Triticum sativum* and other species*)*. *Gramineae*. Wheat is an annual plant producing the most valuable of cereal grains used by the white race. The plants grow either as summer annuals, seed being planted in the spring and the harvest gathered in the fall of the same year, or winter annuals, the seed then being planted in the fall and growing until stopped by cold weather, developing during that time an abundant root system which insures rapid growth in the springtime, the mature crop being ready for harvest in early summer.

When wheat seeds germinate a small primary root system is formed by the development of the radicle or seed root. This primary root system lasts but a short time, being soon replaced by a system of adventitious roots arising from the lowermost nodes of the stem and extending outward and downward to fill the soil with an extensive fibrous root system. The stem of the wheat plant is 2–4 feet (0.6–1.2 meters) tall and usually hollow, although some species have solid stems. See Fig. 1. The dried stems form wheat straw, frequently used in the manufacture of straw board. The leaves are of the ordinary grass type. The inflorescence is composed of very short-stemmed spikelets attached alternately on opposite sides of a zigzag axis. Each spikelet has 2–8 flowers. See Fig. 2. In certain varieties known as bearded wheats the lemma of the flower bears a long bristle or awn. Most species of wheat, particularly those grown in temperate climates, are close-pollinated. Durum wheat and primitive species are cross-pollinated. Evidence indicates, also, that wheats grown in hot dry climates are cross-pollinated. The fruit or grain of cultivated wheat varies somewhat according to the species. In many kinds of wheat the fruit separates readily from the surrounding floral bracts, while in a few kinds the lemma and palea tightly enwrap the grain. The grain bears at its apex a tuft of short hairs called the brush and has a distinct groove along the side which was against the palea. See Fig. 3. In section, a wheat grain shows several very distinct parts. Externally there is a layer several cells thick, called the pericarp, or ovary wall. Within this is a layer two cells thick, the tegmen, which is formed from the inner integument. The outer integument was absorbed during the development of the grain. Next is the nucellus, a single cell in thickness. These three layers constitute some 8% of the grain, and make up the substance which is called bran. Within these is the endosperm, which forms the bulk of the grain; the outermost layer of cells of the endosperm is the aleurone layer. In the basal portion of the seed next to the endosperm is the so-called germ, or embryo, from which the new plant may develop.

Classification and Varieties of Wheat

There are several ways of classifying wheats. Botanically they are separated according to the structure of the spikelet, the number of florets and the nature of the parts of the flower. Among the kinds of wheat recognized in this classification are einkorn, spelt, emmer, durum, and common wheat. Again, if the palea and lemma adhere to the grain, the wheat is classified as spelt wheat, while if the grain readily separates from

these two parts it is naked wheat. If one turns to the grain itself there are hard wheats, in which the grain is horny and has a high protein content, and soft wheats with starchy grains. The nature of the soil in which the wheat is grown and the climate have considerable effect on the nature of the grain. Hard wheats are separated into hard spring wheat, hard winter wheat, and durum, the latter being especially rich in protein content.

Spring wheat is planted in the spring and harvested in the fall of the same year. *Winter wheat* is planted in the fall, growing for awhile and developing a good root system, after which growth ceases because of cold weather. Growth is resumed in the spring of the following year. The mature crop is harvested in early summer. See Fig. 4.

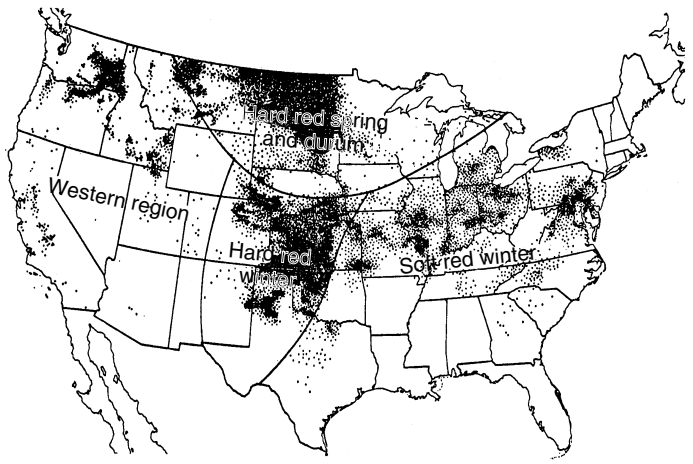

Fig. 4. Regions of the United States where major classes of wheat are produced. The Western region produces white wheat mainly, but also produces some hard red winter, hard red spring, and soft red winter wheat. (*USDA*.)

Genetic Classification. Of major importance to genetics and plant-breeding research is the following classification:

Diploid Group (*7 chromosomes*)
- Einkorn (*T. monococcum*)

Tetraploid Group (*14 chromosomes*)
- Emmer (*T. dicoccum*)
- Durum (*T. durum*)
- Persian (*T. persicum*)
- Poulard or Rivet (*T. turgidum*)
- Polish (*T. polonicum*)

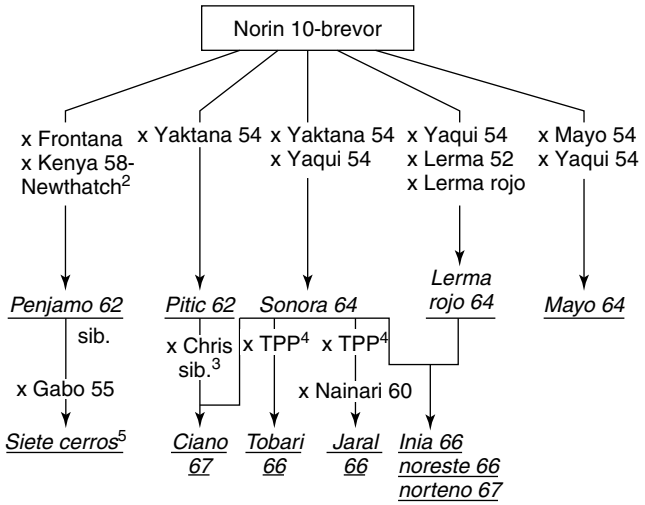
Hexaploid Group (*21 chromosomes*)
- Common (*T. vulgare*)
- Club (*T. compactum*)
- Spelt (*T. spelta*)
- Shot (*T. sphaerococcum*)
- Macha (*T. macha*)
- Vavilovii (*T. vavilovi*)

High-yielding Varieties. Sometimes referred to as HYVs, the high-yielding varieties of wheat (and rice) have formed the core of what became known as the *green revolution*. Well-deserved emphasis is given to the semidwarf varieties developed at the International Maize and Wheat Improvement Center (CIMMYT) in Mexico. Some of the current semidwarf HYVs, however, are the offspring of varieties developed from similar ancestors in other breeding programs. The relatively short and stiff stalk of the semidwarfs means that they respond to improved cultural practices through increased yields rather than through increased plant growth, which would also result in lodging (falling over of the plant). The semidwarf varieties in use, while considered by some to be revolutionary in their impact, are the product of a long developmental process.

Semidwarf wheats were noticed in Japan in the 1800s. Early in the twentieth century, several of these varieties found their way to Italy, where they were used to breed improved varieties that later found wide use. Japanese breeders also crossed their varieties with several American types, ultimately resulting in the release of a *Norin* variety in 1935. It was brought to the United States in 1946, again crossed with some American varieties, and taken to Mexico in the early 1950s. There the *Norin-Brevor* cross, in addition to some of the Italian varieties, was used by Norman Borlaug and his associates to develop the well-known Mexican varieties.

Mexican Varieties. In 1946, S.C. Salmon, a U.S. Department of Agriculture USDA scientist acting as agricultural advisor to the occupation army in Japan, noticed *Norin 10* growing at the Morioka Branch Research Station in northern Honshu. The stems were short, about 23.5 inches (60 centimeters), but produced many full-sized heads. Dr. Salmon brought 16 varieties of this plant type to the United States. They were grown in a detention nursery for a year and then made available to breeders in seven locations. Although Norin 10 was not satisfactory for direct use in the United States, it was useful for breeding. Orville A. Vogel, a USDA scientist stationed at Washington State University, was the first to recognize its worth and to use it in a breeding program in 1949. Crossing *Norin 10* with U.S. varieties involved some problems, but a number of semidwarf lines were eventually developed. A *Norin* 10 X Brevor cross was to become particularly important.

In the interim, word about the short-strawed germ plasma had reached Norman Borlaug in Mexico. His breeding efforts had run into a yield plateau because of lodging under high levels of nitrogen fertilization. Introduction of the *Norin 10* genes led to the development of a number of Mexican dwarf and semidwarf bread wheat varieties. The genetic origins of some of these early hybrid varieties are shown in Fig. 5. International diffusion of these varieties began very quickly at the experimental level, and India and Pakistan were the first to be substantially involved.



Notes:
1. This presentation of some of the more complex crosses is simplified for graphic purposes. For example, the parentage of *Lerma Rojo 64* would be more precisely written as: (*Yaqui 50 x Norin 10-Bevor*) *Lerma 52 Lerma Rojo*[2].
2. *Frontana x Kenya 58-Newthatch* was bred in Minnesota.
3. From Minnesota.
4. *Tezanos Pintos Precoz*, from Argentina.
5. Also known as cross 8156.

Fig. 5. Genealogy of early semidwarf wheat varieties emanating from work at CIMMYT (International Maize and Wheat Improvement Center). See note on diagram.

The Mexican varieties proved remarkably adapted to India and Pakistan for several reasons: (1) They had been bred in Mexico with alternate generations in different climatic and daylength regimes, primarily in order to get two generations each year. A valuable side effect of this system was to establish a good degree of insensitiveness to photoperiod. (2) Selection for disease resistance had also been practiced and the stocks introduced were found to show a remarkable level of resistance under the conditions in India and Pakistan. (3) The original stocks incorporated diversity. They had not been bred to pure line standards and there remained in them a reservoir of genetic potential that Indian wheat breeders were quick to exploit.

By the 1990s, the process of varietal change had gone through several stages in India. A large percentage of plantings in India, Pakistan, Afghanistan, and Nepal, among other less-developed countries, is planted to varieties of Mexican origin as just described.

Japanese Varieties. Japan had a long history in developing dwarf wheat. In 1873, Horace Capron, former U.S. Commissioner of Agriculture who headed an agricultural advisory group to Japan, wrote that "the Japanese farmers have brought the art of dwarfing to perfection." He noted that "the wheat stalk seldom grows higher than 2 feet (0.6 meter), and often not more than 20 inches (51 centimeters)." The head was short, but heavy. The Japanese claimed that the straw had been shortened so that "no matter how much manure is used it will not grow longer, but rather the length of the wheat-head is increased." Capron noted that "on the richest soils and with the heaviest yields, the wheat stalks never fall down and lodge."

Probably unknown to Capron, some Japanese wheat varieties had already been introduced in France. The first introduction occurred in mid-1867 when the Société d'Acclimation of Paris received seed of a very productive early wheat "blé précoce," listed as *Haya Moughi*. The seeds were planted by a member of the Society, and a preliminary report was presented that fall. The stem or straw was short, and the plant flowered early. In the following years, other seeds were imported, and numerous reports of trials of the "blé précoce" appeared in the Bulletin of the Society. According to the description, the straw was very short, erect, and stiff; the plant was reported to flower 2 to 3 weeks ahead of all other spring varieties. The entry, however, noted that the variety was more of curious interest than of agricultural merit. "Blé Précoce du Japan" was sold commercially from 1882 to 1904 as a spring wheat and was used for experimental breeding work from 1930 to 1955. But it does not appear to have been involved in the parentage of any significant commercial varieties.

Two Japanese semidwarf varieties, however, did turn out to be of immense international interest in subsequent breeding programs, namely the *Akakomugi* and the *Shiro Daruma*.

Akakomugi (meaning red wheat) was often used as a cross-parent because of dwarfness and early maturity. It was mainly raised in southern Japan, but is no longer used commercially. *Akakomugi* played an important part in the breeding of Italian semidwarf varieties early in the 20th century. In 1917, *Shiro Daruma* was crossed with an American soft red winter variety, *Glassy Fultz*, and this produced *Fultz Daruma*. In turn, this variety was crossed with the American hard red winter variety Turkey Red at the Ehime Prefectural Agricultural Experiment Station in 1925. This was done in an effort to produce rust-resistant, short-stemmed, early-maturing varieties. The seeds of the first generation of the cross were transferred to the Konosu Experimental Farm of the National Agricultural Experiment Station and planted in 1926. Seed was subsequently sent to the Iwate Prefectural Agricultural Experiment Station in northeastern Japan.

A semidwarf selection developed from the seventh generation in 1932, *Tohoku No. 34*, was particularly promising. Following further testing, it was named *Norin* 10 and registered and released in 1935. The stem of *Norin 10* was particularly short, having a length of 20.5 to 21.25 inches (52 to 54 centimeters). *Norin 10*, in turn, was used in breeding programs in Japan, the United States, and Mexico. *Shiro Daruma* was also used at the Iwate Station to breed *Norin 1* in 1929 and *Norin 6* in 1932.

Italian Varieties. In 1911, seed from some of the short-straw early-maturing Japanese varieties was acquired by Ingegnoli, an Italian flower seed producer, during a trip to Japan. In turn, he provided the wheat seed to Nazareno Strampelli at the Royal Wheat Growing Experimental Station at Rieti. Strampelli started to use Japanese varieties in his breeding program in 1912. Strampelli was interested in developing wheat plants that would be both early ripening and resistant to lodging. Early ripening was desired to increase resistance to *blast* or *stretta* (wilting under hot wind stress) and rusts and to facilitate cropping. Resistance to lodging, obtained through shorter and thicker stems, was desired so that fertilizer applications could be increased.

Of the several Japanese varieties used by Strampelli, *Akakomugi* appeared to be the most important. This variety was crossed with *Wilhelmina Tarwe X Rieti* (a cross involving Dutch and Italian varieties originally made in 1906). This work was done in 1913. Among the well-known varieties to come out of this work were *Ardito* (1916), *Villa Glori* (1918), and *Mentana* (1918). *Ardito* was the first variety to gain wide use. It had a short straw (27.5 to 31.5 inches [70 to 80 centimeters]) and early-maturing characteristics. By 1926, this variety accounted for nearly all of the early-maturing varieties planted in Italy. Ardito was also grown elsewhere and became one of the progenitors of improved Argentine varieties and of the Russian winter variety, *Bezostaya*.

The second major variety, *Mentana*, attained international popularity because of its resistance to yellow rusts. Its genetic traits were bred into *Frontana* (Brazil) and *Kentana* (Mexico). *Mentana* was one of the three varieties that played a key role in the Mexican wheat-breeding program in the 1940s. By 1932, nearly a quarter of the early wheats planted in Italy were mainly *Mentana* and *Villa Glori*.

Italian varieties are now being grown in several of the less-developed countries in the Mediterranean region, notably Algeria, Morocco, and Turkey. *Strampelli* is one of the better known varieties. Italian varieties are also widely used in southeastern Europe. These varieties appear to have played an important role in the development of some of the early Mexican varieties.

Commercial Classifications of Wheats. Based upon the official grain standards of the United States, following are the principal commercial classes and subclasses of wheat that appear in worldwide trade. With exception of small percentages of durum wheat (*T. durum*) and small quantities of club wheat (*T. compactum*), all of the commercial wheats are common wheat (*T. vulgare*).

Classes and Subclasses	
Hard Red Spring	**White**
Dark Northern Spring	Hard White
Northern Spring	Soft White
Red Spring	Western White
Hard Red Winter	**Durum**
Dark Hard Winter	Hard Amber Durum
Hard Winter	Amber Durum
Yellow Hard Winter	Durum
Soft Red Winter	**Red Durum**
Red Winter	**Mixed**
Western Red	

Official United States grain standards, when defining wheat, exclude einkorn, emmer, Polish wheat, poulard wheat, and spelt. All of these grains with exception of einkorn are grown in minor amounts in the United States and are used for feed.

In considering the commercial terminology of the classes and subclasses of wheat, one notes considerable inconsistency in selection of the titles. In most cases, the titles connote the color and physical characteristics of the kernel (red, yellow, amber, white; hard and soft); the season of the crop (spring or winter); the source of the wheat (northern, western); and wheat species in the cases of durum and club wheats. Kernels of hard wheats are described as "dark, hard, and vitreous," whereas the kernels of the soft wheats are described as soft and chalky.

Common wheat (*Triticum vulgare* Host); also *T. aestivum* L.) is also designated *bread wheat*. This wheat was first grown extensively in northern Europe.

1. Hard red spring wheat represents about 20% of total U.S. production and over 95% of Canadian production. This wheat produces a flour that is superior to other classes in breadmaking properties.
2. Hard red winter wheat represents nearly one-half the total U.S. wheat production. The kernels contain large amounts of high-strength gluten. The flour from this type is regarded as being almost equal to that produced from hard red spring wheat.
3. Soft red winter wheat represents about one-fifth total U.S. production. Flour made from this type of wheat is referred to as "weak flour" because doughs made from it lack elasticity and resulting breads tend to be heavy.
4. White wheat represents 6 to 8% of total U.S. production. This is a good quality wheat and particularly well suited for flours that are used in crackers, cakes, cookies, other pastries, and some breakfast foods.

Production of Wheat

Of the cereal crops, wheat ranks first in world tonnage and second in tonnage of cereal crops produced in the United States. Production of wheat is more widespread than the other major cereals, with the possible exception of maize (corn). Russia and former related countries account for about 21% of the total, followed by the United States (15%), China (11%), India (7%), and Canada (6%). Other major producing countries include France, Austria, Argentina, Italy, Pakistan, and Germany.

Wheat Flour

While a considerable quantity of wheat is used directly as food for domestic animals, the greater part is ground into flour. This milling of wheat is a very carefully controlled process. The first step is the thorough cleaning of the grain, removing therefrom any other substance. During this process the brush of the grain is removed. The cleaned grain is then moistened slightly in order to soften the outer layers so that they may be more easily removed subsequently. The moistened grain is then passed between iron rollers. The first of these are corrugated and break up the grains. Each successive pair of rollers grind the grain into finer and finer particles. Early in this grinding the coarse flakes of bran and the germ are removed. These are disposed of as such or ground up separately. The ground grain is passed through fine bolting silks, which insure a very even grade of fineness of the flour particles. Every precaution is taken in flour mills to prevent the accumulation of dust particles in the atmosphere, since these may form very dangerous explosive mixtures.

Flour is classified, according to the amount of the grain included in the final product, into graham flour, which contains the entire grain; whole wheat flour, which contains all the grain except about half of the bran; and straight bread flour, which results when all the bran is removed early in the grinding process. Wheat flour is used extensively in making breads, crackers, and pastries. Because it is so highly glutinous that pastes made from it will support their own weight, durum wheat is used in making spaghetti and macaroni. In making this product, a thick viscous paste or dough is prepared. This is forced, under great pressure, through holes in metal dies. Metal pins may project into the hole in the die, causing the dough which is forced through to merge as a hollow tube. This is macaroni. As they emerge, the tubes or strings are cut into suitable lengths and hung up to dry. Durum wheat alone has the necessary properties for making macaroni and similar substances. If any other wheat were used the product would break apart from its own weight. In addition to flour and macaroni, much wheat is used in making breakfast foods. The familiar puffed wheat results from heating wheat grains under pressure and suddenly releasing the pressure; the grain expands rapidly. Some wheat is used for making whiskey and certain varieties of beer.

WHEEL ORE. See **Bournonite**.

WHELK *(Mollusca, Gasteropoda)*. A moderately large marine mollusk with a spirally coiled shell. It is used as a bait in the cod fisheries and in Europe is eaten.

WHEY PROTEIN. See **Protein**.

WHINSTONE. A popular British term for basic, fine-grained igneous rocks belonging to the basaltic group and including diabase, dolorite, spidiorite, also greenstone and the lamprophyres. Synonym for trap or trap rock.

WHIPPOORWILL. See **Nightjars and Nighthawks**.

WHIP SCORPION *(Arachnida, Pedipalpi)*. A large arthropod whose abdomen bears a whiplike posterior portion, although some species of the same order lack this terminal filament. The pedipalps are large and strong, either chelate or simple. The first pair of legs are modified as slender many-jointed sensory appendages. They are tropical animals, only a few species entering the southern part of the United States.

In the Southwest, many fears and superstitions are associated with these unpleasant looking animals, which are called vinegarroons. They discharge a disagreeable, sour-smelling secretion, but are entirely harmless to people.

WHIRLPOOL. A whirlpool, whether in water or other liquid, is a rotary current or vortex produced by the interaction of opposing currents in the fluid or surface winds over it. In rivers, they form downstream of obstacles like jetties and bridge piers, the more readily when conditions are turbulent. Whirlpools are less common in seas and oceans but can develop from the interaction of opposing tidal flows, especially where coastal and bottom configurations offer narrow, deep passages of considerable depth. Very small whirlpools can easily be seen when a bath or a sink is draining, but these are produced in a very different manner from those in nature. Smaller whirlpools also appear at the base of many waterfalls. In the case of powerful ones like Niagara Falls, these whirlpools can be quite powerful.

In the vortex of the whirlpool, the dynamic flow is a spiraling motion downward. A return of water to the surface takes place in the manner of a quasi-stationary rising current known as a kolk or boil, which is visible at the surface as a heaving disturbance of the fluid.

The most powerful whirlpools are created in narrow shallow straits with fast flowing water. The Moskstraumen off the Lofoten islands in Norway is generally considered the world's most powerful whirlpool, along with Saltstraumen which reaches speeds of 40 km/h (25 mi/h). The Meilnort has been measured with a speed of the water current of up to 27.7 km/h (17.2 mi/h), and the Old Sow between Maine and New Brunswick has been measured with a speed of up to 27.6 km/h (17 mi/h). The Naruto between Tokushima and Awaji Island in Hyogo (Japan) has a speed of 20 km/h (12 mi/h).

When their power is intense, the term maelstrom is often used.

The often-cited sea whirlpool Charybdis is a fiction, being no more than rough, choppy water developing from wind blowing obliquely across fast-moving tidal water flowing steadily in one direction, or in the opposite direction when the tide is ebbing.

Mediterranean Whirlpools

Deep in the Atlantic Ocean off the coast of Spain and Portugal are giant, salty whirlpools of warm water. These whirlpools are part of the ocean's circulatory system, and they help drive the ocean currents that moderate Earth's climate.

Warm water usually sits near the ocean's surface, but the warm water flowing out of the Mediterranean Sea is so salty and dense that when it

enters the Atlantic Ocean at the Strait of Gibraltar, it sinks to depths of more than half a mile (1,000 meters) along the continental shelf.

This underwater river then splits into clockwise-flowing eddies that may continue to spin westward for more than two years. These often coalesce with other eddies to form giant, salty whirlpools that stretch for hundreds of miles. Because they originate from the Mediterranean Sea, scientists call them "Meddies."

Although Meddies are submerged beneath hundreds of feet of water, scientists recently developed a technique to detect them from space by measuring changes in sea surface height. The warm water of the Meddies causes the ocean around them to expand, raising the height of the sea surface above.

The Meddies produced anomalies more than 2 inches above average heights, spreading across the Atlantic to the west of the Strait of Gibraltar. While some Meddies appear isolated, others seem to be merging. Areas for which there were no data are colored white. See also **Meddies**.

WHIRLWIND. A whirlwind is a particular kind of vortex spinning in a fluid. When a vortex spins in water, the term is "whirlpool". When the fluid is air, the vortex is a whirlwind that can be of various types, represented by two classes. Most violent are the greater whirlwinds — tornadoes and waterspouts. More common are the lesser whirlwinds, which include wind devils, fire devils, and eddy whirlwinds. See also **Tornado**; **Whirlpool**; and **Waterspouts**.

The greater, or major, whirlwinds are created by parent clouds that, for the majority of tornadoes and many of the waterspouts, are cumulonimbus severe-weather clouds. They are characterized by a columnar funnel of spinning air made visible by condensation of cloud-water droplets caused by reduced air pressure in the spinning core. The rotation is seen to descend from the cloud-base as the funnel develops, and it persists until retraction into the cloud-base is complete. Moreover, a tornado may become a strong waterspout as the powerful rotation moves from land to sea (and vice-versa). When such vortices do not descend far enough to reach a land or water surface, they are simply called funnel clouds.

The majority of lesser whirlwinds are typified by a more or less vertical, whirling column of rising air that is warmer than its surroundings. More frequently formed on warm, sunny days in clear dry air, these are the wind devils — also known as land devils and water devils. Depending on the nature of entrained matter that makes them visible, they are called dust devils, sand devils, snow devils, fire devils, etc. Great heights can be obtained in long-lived cases, as a result of which an energetic, tall, devil whirlwind can be topped by a small cumulus cloud. Whirlwinds of this class are driven by the motion of warmer air as it displaces cooler air and becomes a small-scale, rapidly rotating column of wind at the lower end of a "thermal". The degree of warmth of the thermal column is relative to the temperature of its cooler surroundings. Although wind devils are more likely to form on clear, dry, hot afternoons, especially in summer, they can form even in winter given appropriate temperature gradients over, for instance, fields of snow or ice.

Another category of lesser whirlwind is the ordinary eddy whirlwind, which is a helical rotation originating in the general wind flow of the day downwind of an obstruction like a hill or high stand of trees, which is similar to how a whirlpool forms as an eddy in water downstream of an obstruction. As eddy whirlwinds are driven by momentum, they are more likely to form in breezy conditions. Such whirlwinds are also sometimes visible in humid air over lakes downwind of hills or mountains. A different kind of eddy whirlwind — one that is part of the greater whirlwind class — forms at the interface of two air masses that are moving at different speeds.

A whirlwind may also develop over a fire or region of hot ashes if there is a suitable convergence and rotation of the air. It is then a fire devil, of the lesser whirlwind kind because it is maintained by a rising column of hot air. Fire devils can occur under many weather conditions, but, as with other minor whirlwinds, they form more readily in calm or light winds because heat is allowed to build up more rapidly. The cause of fire devils is usually forest fires, wild fires, and post-harvest stubble burning, but bonfires, oil fires, volcanic eruptions, and nuclear explosions also cause fire devils.

WHISKER. The fine, sharpened electrode forced into contact with the semiconductor material in a semiconductor diode or point-contact transistor.

WHISKEY. A beverage of high alcoholic content made by distilling a fermented mash. There are four major producers of whiskey[1] in the world — Canada, Ireland, Scotland, and the United States.[2] Six principal operations are involved in the production of whiskey: (1) selection and preparation of raw materials; (2) fermenting; (3) distilling; (4) maturing and ageing; (5) blending (in most cases); and (6) containerizing (usually bottles). There are important variations in these operations from one country to the next and from one type of whiskey to the next.

Because distillation is a relatively complex procedure and essential to whiskey production and there are no immediately recognizable examples in nature to be copied — as in the case of natural fermentation of grape juice (see also **Wine**) — many centuries elapsed between the time when winemaking was pioneered and when the first alcoholic distillates appeared. Generally, it is believed that distillation was first used in connection with making brandies from wines, probably pioneered by monks during the Middle Ages. It is possible that the "discovery" of distillation came as the result of investigations in medicine and/or alchemy.

The question of whether Ireland or Scotland was the birthplace of whiskey has been debated for scores of years and remains inconclusive. Irish and Scotch whiskeys date back several centuries. The climate in both countries is favorable to whiskey production and is particularly suited to the production of barley, which both of these whiskeys use. Also, in both of these locations there were convenient sources of fuel (peat and coal) with which to fire the stills. It is interesting to note that as early as the 1770s there were over 1000 licensed distillers in Ireland. A contemporary report of the government at that time stated, in part, "(Distillers are) mostly men of little substance and no great honesty and well placed for defrauding the Revenue." A few years later, stills of low capacity were outlawed so that the government could get a better handle on revenue collection. It is to be noted, however, that in the early 1830s the government seized over 10,000 illicit stills. Through the mid- and late 1800s, because of much emigration from Ireland, the requirements for whiskey lessened and the number of operating skills became fewer so that by 1907 there were only 27 comparatively large distillers operating in Ireland. As of the late 1980s, there were four major distillers operating in Ireland for production of whiskeys. In addition to population diminishment, the imposing of higher and higher duties on the product caused a number of distillers to leave the field. Although Ireland exports whiskey, it in no way compares with the very high exports of Scotland.

The production of Scotch whiskey, dating back hundreds of years, has been an important factor in Scotland's export economy for many years, exporting and local consumption supporting some 110 distillers operating there as of the early 1990s. *Highland malt whiskeys* are made in an area north of Dundee and Grennock; lowland malts are made south of these locations; Islay malts are from the Isle of Islay; and Campbelltown malts are from the town of that name, located in the Mull of Kintyre. Of the 110 distillers, nearly 100 of these produce malt whiskeys by the traditional pot still method, while the others produce grain whiskeys using the so-called Patent still method. Scotch whiskeys are exported to well over 150 countries worldwide — and possibly Scotch whiskey is the best known alcoholic drink throughout the world. The malt whiskies are heavy and strong and still remain most popular locally. It was not until the grain Scotch whiskeys were produced that they became popular in the British

[1] In Ireland and the United States, preferred spelling is whiskey (whiskeys); in Canada and Scotland, whisky (whiskies).

[2] Australia also produces substantial volumes of whiskey.

Isles south of Scotland, a popularity that rather rapidly extended to Europe, North America, and throughout the world. The malt whiskies are used for blending with the grain whiskies to provide an attractive balance.

The first whiskey stills operated in North America appeared as early as 1668 when Jean Talon established a brewery in the then small colony of Ville Marie, destined to become Montreal. As part of the brewery operation, a still was included for making spirits. Early Canadian settlers also prepared their own rum (in lieu of whiskey) from molasses shipped in from the West Indies. By the late 1770s, the grain farmers were expanding and, on occasion, would be faced with a surplus crop. This surplus was used for making distilled spirits. A high quality of the product was maintained and demand increased. The distinctive characteristics of Canadian whiskey established an excellent reputation and continued to increase demands so that, by 1860, Canada commenced to export whiskeys. As of the early 1980s, close to 25 distillers (most large-capacity) furnish Canadians as well as exporting to many parts of the world. Canadian whiskey, almost always regarded highly, has been responsible for furthering the awareness of Canada throughout the world. In recent years, the Canadian distilling industry has made a number of progressive moves and today operates some of the most modern facilities to be found anywhere.

As with the Canadians, the early settlers in Colonial America depended largely upon rum shipped in from Cuba and other West Indies islands. The Revolutionary War severed rum supplies and demand turned to whiskey. Earlier, farmers inland from the coast — in Ohio, Kentucky, Pennsylvania, etc., particularly in the mountainous areas — were making spirits from surplus grains. They found that a pack-horse could carry considerably more grain in the form of whiskey than of unprocessed grain — and the economic return was greater. For some years, in isolated regions particularly, whiskey was used as a medium of exchange. The Whiskey Rebellion, which occurred in the fall of 1793, was fought over tax collection in whiskey. Taxes had risen rapidly from just over 5¢ per gallon to over $10 per gallon.

Bourbon whiskey, made from corn (maize) and the most popular type in the United States, was first distilled in Kentucky in the mid-1830s. During the 1800s, numerous distilleries were established in Kentucky, Tennessee, southern Ohio, Indiana, and Illinois — all essentially located in the eastern portion of America's corn belt.

Raw Materials for Whiskey. What sugar in the grape is to wine so is starch in grain to whiskey. With grains, however, an additional step is required for enzymes to convert starch in the grains to sugar prior to fermentation.

Scotch Whisky. Malt Scotch whiskey is prepared from malted barley. As it is received, the barley is mechanically cleaned and stored until needed. At a controlled temperature, batches of barley are soaked in water (*burn water*) for 2 to 3 days until the grains become soft. The wetted grain is then spread over a large floor area and allowed to germinate. This may require from about a week up to nearly 2 weeks. Workers during this period turn the sprouting grains several times each day to prevent formation of molds. To prevent any damage to the grains, they use long-handled wooden shovels (*shiels*). During sprouting, the starch content of the grains slowly convert into sugar. At the proper time, the sprouting is halted by a kilning operation. The malted barley (*green malt*) is dried in a kiln that is fired with peat as a fuel. The characteristic aroma given off by the burning peat is called *peak reek*. The wet grains absorb a certain amount of the aromatic compounds from the smoke, and these account, in a large but indeterminate measure for the characteristic flavor of Scotch whiskey. Even in grain Scotch whiskies, some of the malt whiskey is added.

The dried malt is then transferred to large bins where it is slowly cooled and stabilized over a period of 3 to 4 weeks. The dried malt is then crushed to produce *grist*. In turn, the grist is transferred to a mash tun (usually a large cast iron vessel some 20 feet [6 meters] across and partially filled with water of the highest quality obtainable). In this operation, the sugar is dissolved to form *sweet liquor* or *wort*. The wort is drained off, and the residual (draff) is further processed for use as cattle feed. The wort becomes the starting material for the fermentation process.

Grain Scotch whiskey is made from a mixture of malted barley and unmalted cereals (usually barley and maize [corn]).

Irish Whiskey. The Irish fire the kilns for drying the green barley malt with coal instead of peat, an important difference because essentially no aromatic chemicals are picked up from coal smoke or combustion gases. The Irish do not make a straight malt whiskey, but rather use from 25 to 50% malted barley, mixed with from 50 to 75% of grist made up of unmalted cereals, barley, oats, wheat, and, on occasion, relatively small amounts of rye. Thus, Irish Whiskey is a grain whiskey essentially from the start.

Canadian Whiskey. The principle starting materials for Canadian Whiskey are cereal grains, normally maize (corn), rye, and barley malt. For Canadian Whiskey, the barley malt is not prepared by kilning as is done in Scotland and Ireland, but rather the ground grain meal is pressure-cooked, by which the starch is put into solution. It is then cooled and mixed with a predetermined small quantity of barley malt to commence conversion of the starch into sugar. Rather than screening off the grain in a mash tun, as is done by Scottish distillers, the resulting sweet mash is transferred directly to the fermenters.

In a separate operation, the Canadian distillers prepare a separate rye mash for fermentation and ultimately produce a rye distillate from it. The rye meal usually is not pressure-cooked. The formula for the rye mash may contain up to 90% rye grains and 10% barley malt. On the other hand, the rye content may be as low as about 50%, with the remaining grains, not including the barley malt, being maize (corn) or barley. This distillate enters into the manufacture of Canadian Whiskey later on in the process.

American Whiskey. In the United States, a number of whiskeys are offered, but bourbon made from corn (maize) leads by a wide margin over rye whiskeys. Ground meal is transferred to mash tubs or pressure cookers, where the starch is released, making it easier to convert into sugar. After cooling, barley malt is added, the enzymes of which convert the starch to sugar.

Fermentation Process

Scotch Whiskey. Previously mentioned sweet liquor or wort, after cooling, is transferred to the tun room where it is fermented. A tun is a large wooden vessel some 18 feet (5.4 meters) high and 12 feet (3.6 meters) across and is usually made from larch or Oregon pine. The vessel may hold from 2000 to 12,000 gallons. Yeast is added to commence conversion of sugar into raw spirits. During fermentation, the mass bubbles and froths. The tuns are equipped with *switchers* (wooden rotating arms that are turned near the top of the vessel to control foaming and thus keep the vessel from running over). Workers also agitate the fermenting mass periodically, using a long-handled perforated board (*rouse*). Fermentation requires about 48 hours, at which time the liquid in the tun contains about 10% alcohol, as well as some residual yeast and by-products of fermentation. The liquid is known as *wash* and is now ready for distillation. The tuns are thoroughly brushed and cleaned after each batch. The foregoing describes the process for fermenting used in making malt Scotch whiskey.

In the case of grain Scotch Whiskey, it is prepared much like the Canadian grain whiskey about to be described.

Canadian Whiskey. The sweet mash is transferred to fermenting vats, where a predetermined quantity of pure culture yeast is added. The culture is usually prepared by the distiller. Fermentation requires about 72 hours. The resulting liquid is termed "beer" and is now ready for distillation. At this point, the beer contains about 12% alcohol.

Irish Whiskey. The fermentation process is essentially the same as that used in Scotland.

American Whiskey. The previously mentioned malted mash is cooled to approximately room temperatures, after which it is transferred to the fermenting vessels. Yeast culture is added at this point. From this point the process is similar to that used by the Canadian distillers. The resulting liquid is also called beer.

Distillation

Distillation is a process in which a liquid is converted to a vapor and the vapor is then condensed and collected (*distillate*). The most volatile component of a mixture (some distillers call these *foreshots*) tend to distill off first. However, some of the less volatile components also appear in small quantities in the early portion of the distillate. Similarly, toward the end of a simple or batch distillation, some of the low-volatile components (usually undesired) also tend to "come over" and contaminate the distillate. Some distillers call such components (*feints*). A skillful

stillman, watching properly placed thermometers, can divert the foreshots at the commencement of a batch distillation and, toward the end of the distillation, can cut the heat input and divert the feints from commingling with the best portion of the distillate. In the simple or batch distillation of sugar solutions from fermenters, the principal purpose of which is to separate alcohol from water, the feints will contain undesirable fusel oil, aldehydes, which, if allowed to contaminate the distillate, would lower the quality, if not ruin it. However, the problem could be overcome by redistilling the contaminated distillate. See Fig. 1.

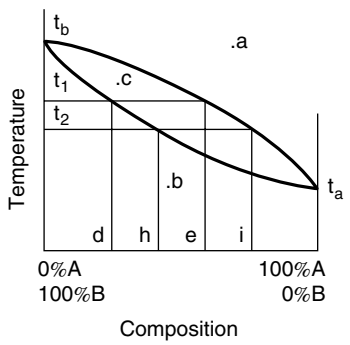

Fig. 1. Boiling-point diagram for a binary mixture, such as alcohol and water. Diagram depicts the boiling-point and equilibrium-composition relationships, at constant pressure, of all mixtures of liquid *A* (boiling point = t_a) and liquid *B* (boiling point = t_b). Liquid *A* is the more volatile of the 2 liquids. Note the 2 curves, the ends of which coincide. For all points above the top curve, such as point *a*, the mixture is entirely vapor. For all points below the bottom curve, such as point *b*, the mixture is completely liquid. For points between the 2 curves, such as point *c*, the system is partly liquid and partly vapor. If mixture of composition d is heated slowly, it will commence to boil at t_1. The first vapor produced will have a definite composition, represented by e on the diagram. When an appreciable amount of vapor has been formed, the composition of the liquid will no longer correspond to *d*, since the vapor is richer in the more volatile component than the liquid from which it was evolved. At a temperature, such as t_2, if the overall composition of the mixture is between *i* and *h*, there will be 2 phases in equilibrium, that is, a vapor phase of composition *i* and a liquid phase of composition *h*.

Over the last several decades, mainly since the great emergence of the chemical and petroleum industries after World War I, numerous improvements have been made in distillation equipment. Much of this equipment involves continuous distillation and the use of rectifying or fractionating columns in which very precise separations can be made. There are literally thousands of these modern distillation systems installed. Distilling improvements were relatively slow in being adopted by the whiskey and distillery industry because of its tight bonds to tradition and essential fears of change that would cause marked departures from the desired characteristics and properties of its products. In fact, some distillers emphasize their use of old and traditional methodologies in their advertising. Consequently, one finds today, notably in Scotland and possibly to a considerably lesser degree in other major whiskey-producing countries, examples of distillation technology that, from an engineering standpoint, appear quite antiquated. But these are equipments that produce whiskies of high quality and that have been extraordinarily successful.

Scotch Whisky Distillation. Malt whiskies made in Scotland are subject to two separate distilling operations. Two stills are placed side by side — a *wash still* and a spirits still. The wash from fermentation previously described goes to a wash still, which may be heated by a naked fire. A rummager inside the body of the still (essentially rotating arms that drag a copper mesh chain around the bottom of the still to keep particles from sticking) is used. Distillation is continued until the stillman determines that there is little if any recoverable alcohol remaining in the still. Meanwhile the distillate has been collected and is known as *low wines*. The residue remaining (*pot ale*) usually is recharged into another batch for the wash still. The low wines, considering the type of distillation, will of course contain numerous impurities.

The low wines are charged into the adjacent *spirit still*, and this is where the skill of the stillman enters in terms of diverting the foreshots at the start and the feints toward the end of the distillation. The stillman decides when to switch the spirit still output to the spirit receiver — and when to stop the distillation. The foreshots and feints that have been collected are returned to the next batch of low wines. This entire process is referred to as the *pot still process*. It is interesting to note that, while all malt Scotch whiskey are made in this manner, the flavor and characteristics differ from one distiller to the next — even though water and other variable conditions may seem reasonably consistent. This is reminiscent of blast furnaces in the steel industry, which, even though identically designed and fed with the same raw materials, will differ some in operating characteristics.

The grain Scotch whiskeys are distilled in what is called a Patent still. An interesting point is that this column still was invented by Aeneas Coffey, an Irishman, in 1830, a century and a half ago and indeed ultramodern and ingenious for its time. See Fig. 2.

Irish Whiskey Distillation. Whereas Scottish distillers use two distillations, the Irish have traditionally used three distillations. The pot stills used in Ireland are considerably larger than those used in Scotland and may contain 30,000+ gallons. The Irish also introduced several innovations many years ago, including the use of taller still heads. They also use what is known as a *lyne arm* interposed between the still head and the condenser (*worm tub*). The lyne arm or lying-arm extends from the still head horizontally and is submerged in a water-filled trough to provide immediate cooling. The condensate from the lyne arm is returned to the still and thus the weaker (more volatile) spirits in the distillate are returned to the still for further rectification and concentration. In modern terms, this returned condensate would be termed reflux. The Irish call the return pipe a *foul pipe*. It will be recalled that the Scottish distillers use a wash still and a spirits still. The Irish interpose a second *low wines* still between the wash still and spirits still. The stillman thus is able to divide the distillate into strong and weak fractions, sending the stronger fractions forward and the weaker fractions backward in the process. Thus, a form of rectification is accomplished in a manually controlled intermittent fashion and accomplishes within the limitations of the equipment and the skills of the stillman, rectification that is much more easily (and probably more effectively) accomplished in the modern continuous rectification systems. A continuous distillation system is illustrated in the entry on **Rum**.

The distillation of Canadian and American whiskeys have followed advancements in what might be termed North American distillation technology. Current installations range from designs of 50 to 60 years of age of installations made within the last few years. The actual distillation setups vary somewhat between distillers and ultimate objectives in terms of final product characteristics.

Ageing, Maturing, and Blending

There are many parallels in the manner in which the young whiskey is matured regardless of where it is produced. Some of the secondary constituents of whiskey, require evaporation for removal. Thus, the casks used for storage must be somewhat porous. Distillers frequently prefer oak wood casks, particularly casks that have previously been used for storing sherry. From an economic standpoint, it is interesting to note that as much as 15% of the young whiskey may evaporate. A recent estimate has indicated that up to 10 million gallons of Scotch whiskey may be lost per year through evaporation during storage. Temperature and humidity must fall within reasonable range for satisfactory storage. Scottish, Irish, and Canadian climates are particularly well suited in this respect. In Scotland, the malt whiskeys may be left to mature for 15 years, and improvement is possible beyond that age. However, most authorities agree that nearly any whiskey will take on a "woodiness" characteristic if stored for over 20 years in a cask. Grain whiskeys require less time because more of the undesirable constituents are removed during rectification. In Britain by law Scotch whiskey cannot be sold until it has matured a minimum of 3 years. Better brands require considerably longer, with the average Scotch whiskey being from 6 to 7 years old. When age is stated on a blended whiskey, the age must be that of the youngest whiskey in the bottle. Whiskey does not improve or deteriorate in the bottle. Most authorities agree that so-called "bottle character" of a whiskey is a myth. Whiskey is not overly sensitive to temperature after it is bottled. The practice of ageing in Ireland essentially is the same as that followed in Scotland.

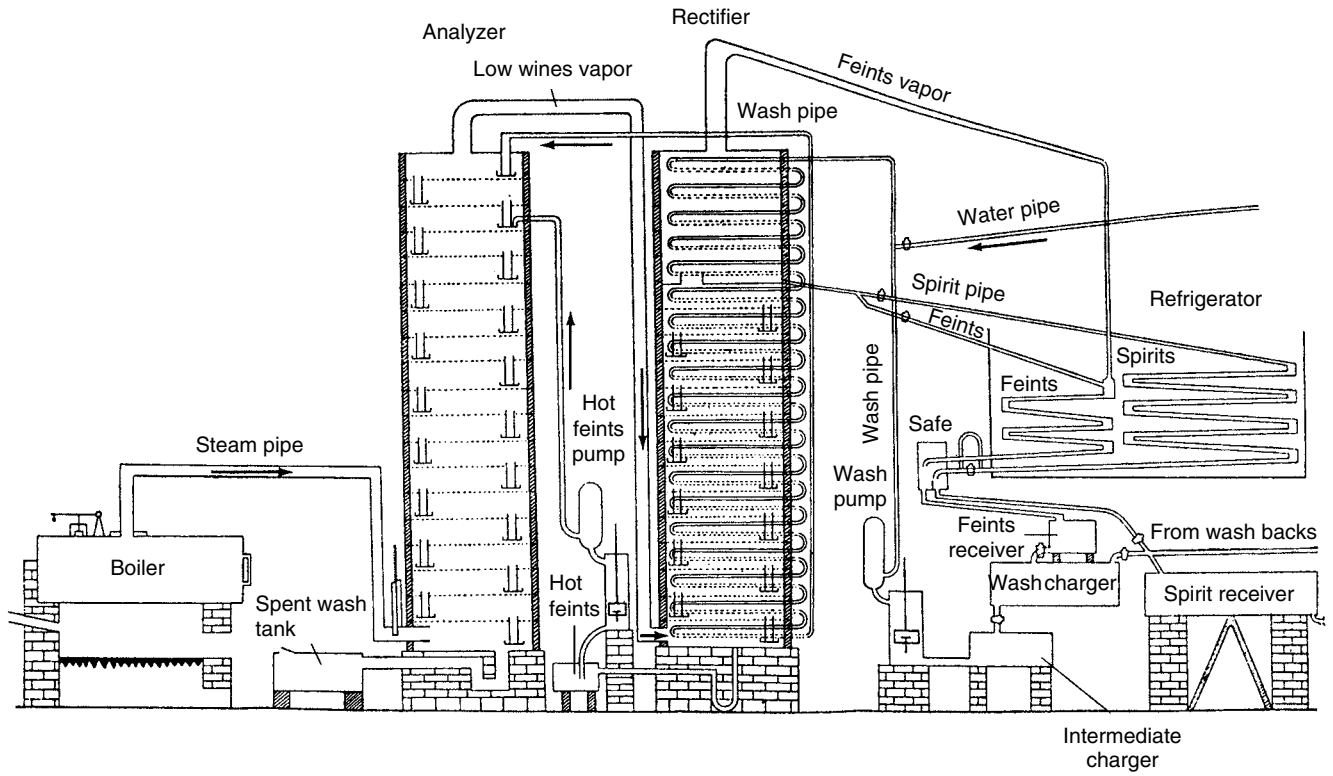

Fig. 2. Sectional view of distilling apparatus developed by Aeneas Coffee in Ireland in 1830. (*Adapted from early patent sketch.*)

The large majority of Scotch whiskey is blended, a practice that commenced in the mid-1800s. The availability of blended whiskeys greatly increased the popularity of Scotch whiskey throughout the world. A blend may contain from 20 to 40 different "single" whiskeys. Blending of Scotch is strictly an art, requiring much skill and judgment. Once a given "single" whiskey has been deemed sufficiently mature, 1/10 gallon (duty free) is drawn from the cask. The blender has such samples from many casks to judge almost on a continuing basis because the inventories of casks for maturing is so high. The blenders are not tasters, but depend essentially upon aroma, seeking out any trace of woodiness that may be derived from an imperfect cask; or hardness sometimes due to improper wood used in the cask; or any alien flavors that may have crept in due to contamination. The objective of the blender is not only that of maintaining high quality, but also to blend a product with qualities and characteristics that is consistent from year to year in the marketplace. Caramel coloring is added to Scotch and other whiskeys to maintain color uniformity.

It has only been within the last few decades that Irish whiskeys have been marketed as blends, although blends have been available since the mid-1800s on a localized basis. Blends have become much more popular in recent years.

In practice, most Canadian whiskey is aged in wood for a minimum of 3 years, but it can be sold legally at an age of 2 years. The average Canadian whiskey ranges from 4 to 6 years, with premium brands available up to 8 and 10 years and more. It will be recalled from a previous description of the raw materials used in Canadian whiskeys that a separate rye mash is prepared. The rye distillate is blended with that from other grains and barley malt. The distinctive characteristics of Canadian whiskeys are due to a large degree to the rye distillate. Canadian whiskeys are matured in charred oak barrels. The rye spirits may be blended with the grain whiskey prior to barreling, or they may be allowed to mature separately as "single" whiskeys and blended prior to bottling. Canadians at one time regarded their product essentially as rye whiskey and was frequently labeled so, but during the past several years, the word rye has been dropped by many distillers, even for products for local consumption, and the phrase Canadian Whiskey by itself is commonly used.

In the United States ageing is effected in charred new white oak barrels in climate-controlled warehouses. Most of the whiskey is made to achieve a maximum maturity within 4 to 6 years. Blends are very common in the United States, but there are several straight Bourbon whiskeys offered, as well as smaller number of rye whiskeys. Often, a blended whiskey will contain from 30 to 40% aged whiskey that has been blended with neutral spirits (60 to 70%). Grain neutral spirits are of approximately 190° proof and in terms of taste, color, and aroma are neutral.

Australian whiskeys are made somewhat along the pattern of Scotch whiskeys but do not exhibit the same characteristics as a true Scotch. Australian whiskey has a distinctive character of its own.

WHISTLER. A radiofrequency electromagnetic signal generated by some lightning discharges. This signal apparently propagates along a geomagnetic line of force and often bounces several times between the Northern and Southern Hemispheres. Its name derives from the sound heard on radio receivers.

WHITEBEAM TREES. See **Ash Trees**.

WHITE BODY. A hypothetical body whose surface absorbs no electromagnetic radiation of any wavelength, i.e., one which exhibits zero absorptivity for all wavelengths; an idealization exactly opposite to that of the black body.

WHITE DEW. See **Precipitation and Hydrometeors**.

WHITE DWARF. See **Giant and Dwarf Stars**.

WHITEFISHES *(Osteichthyes).* Of the order *Isospondyli*, family *Coregonidae*, the whitefishes are closely allied to the salmon and trout. In earlier

years, they were all classified in one family. *Coreogonus clupeaformis* (lake whitefish) is the largest of the species. This fish attains an average weight of about 4 pounds (1.8 kilograms) although records indicate a catch of one weighing 26 pounds (12 kilograms). The *Coregonus artedii* (shallow-water cisco) also is called the lake herring (although not a herring). The *C. kiyi* (chub of deep water whitefish) prefers waters as deep as 600 feet (180 meters). The whitefishes are found in the Great Lakes of America and have in the past supported significant commercial fisheries. They are an exceptionally good food fish. Unfortunately, overfishing, coupled with the disastrous damage rendered by the parasitic sea lamprey, have severely reduced the population of whitefishes in the Great Lakes and notably Lake Erie. See also **Lampreys (Agnatha)**.

WHITEFLY *(Insecta, Homoptera).* A minute sucking insect related to the aphid, phylloxeran, and scale insects. They are important economic pests, mainly on citrus, certain vegetables, and glasshouse plants. Some of the major species are described below.

Citrus blackfly (*Aleurocanthus woglumi*, Ashby). This insect occurs in Mexico and the West Indies. The nymphs are black with a white fringe. The adults have a dark brown body and dark blue wings.

Cloudy-winged citrus whitefly (*Dialeurodes citrifolii*, Morgan). This pest occurs in the citrus region of Florida. Eggs are black.

Common citrus whitefly (*Dialeurodes citri*, Ashmead). This insect once occurred widely in California before being brought under control. Eggs are pale yellow.

Orange spiny whitefly (*Aleurocanthus spiniferus*). This insect causes serious damage to citrus in southeast Asia. The adult is about $\frac{1}{16}$ inch (1.5 millimeters) long, yellowish orange, and coated with a waxy powder. The adults are active in good weather, but when it is cloudy or rainy, they do not move about. The larva of the fly is very tiny, oval, and brownish or black. It has a cottony wax-encrusted fringe about its body. The insects feed on leaves of citrus. They secrete honeydew on which a sooty mold grows. Usually, they are found on the underside of new leaves.

Woolly citrus whitefly (*Aleurothrixus floccosus*, Maskell). A pest of citrus regions of Florida. Brown, sausage-shaped eggs.

The habits and life cycles of the citrus whiteflies are all quite similar. All stages can be found throughout the year. Breeding, however, is confined to the warmer months. The tiny eggs, less than $\frac{1}{100}$ inch (0.25 millimeter) long, are laid near a short stalk and on the underside of a leaf. Eggs hatch after 4 days to 2 weeks, producing pale-yellow nymphs. They are miniature six-legged crawlers. Shortly thereafter, the nymphs begin sucking sap from the leaves. They then undergo two molts, after which the adults emerge. The adults are 4-winged and about $\frac{1}{12}$ inch (2 millimeters) long. A very fine white powder covers body and wings. In some areas, such as Florida, as many as 3 generations per year will be produced.

Greenhouse or *Glasshouse whitefly* (*Trialeurodes vaporariorm*, Westwood). These insects damage cucumber, lettuce, tomato, and a number of decorative plants.

The leaves of infested plants become covered with a sticky, glazy substance, making an ideal place for damaging fungus to grow. Unless controlled, the affected plants shortly wilt and die. Adults and nymphs may appear at the same time. The pale-green nymphs are very small, about $\frac{1}{30}$ inch (1 millimeter or less) in length and suck sap. The adult fly is about $\frac{1}{16}$ inch (1 to 2 millimeters) in length, has 4 wings, and a yellow body that appears to have been thoroughly dusted with a fine white powder. Sometimes the underside of an infested plant will appear almost snow white. Notably in glasshouse operations, all generations of the insect overlap.

WHITE-FRINGED BEETLE *(Insecta, Coleoptera).* The beetle (*Graphognathus* or *Pantamorus leucoloma*, Boheman) is one of a large number of closely related beetles that make up the generic group called white-fringed beetles. See Fig. 1. These insects are known as general feeders because they have been found on at least 400 different plants. However, some of their favorite plants include blackberry, cabbage, collard, corn (maize), cotton, cowpea, groundnut (peanut), Mexican clover, strawberry, sugarcane, and sweet potato. A native of South America, this insect is now widely distributed throughout the southeastern United States, ranging northward to Virginia and westward to Missouri.

The eggs, larvae, and adults are easily spread in commerce. Eggs can be attached to plants, farm machinery, or other objects that come in contact with the soil, and in hay harvested from infested fields in late summer or fall. Larvae are transported in soil, sod, nursery stock, and root crops. The adults attach themselves to seed cotton, hay, farm machinery, and tools. To prevent the spread of these beetles, both federal and state quarantines have been established. Any of these insects found outside the aforementioned areas should be reported immediately to the U.S. Department of Agriculture, Plant Protection Division, Hyattsville, Maryland 20782.

Fig. 1. Adult white-fringed beetle. (*USDA*.)

As many as 300 grayish and long-headed beetles, ranging up to 1/2 inch (12 millimeters) in length and with pale white striping on the sides, may be found on one plant, usually feeding on the margins of leaves and milling about on the soil just under the plant. In the spring, large numbers of legless white grubs, ranging up to $\frac{1}{2}$ inch (12 millimeters) in length, will attack the lower stems and taproots of plants or even the planted seeds. An invasion like this will cause the plant to wilt and die very soon.

Cultural controls include crop rotation. Plants not preferred by these beetles include pasture grasses, small grains, and maize (corn). Corn should be planted in solid stands and not interplanted with a legume. Susceptible crops should not be planted in the same field more often than once every 3 to 4 years. Organic matter should be added to the soil. An economical method is to plow under a winter cover crop. This will help to reduce larval damage.

The beetles damage plants growing in well-drained, sandy loam more than those in heavy clay soils. A very dry summer can slow down development of the beetles. A heavy, week-long rain can kill many small larvae.

Larvae prefer root crops and plants with taproots to plants with fibrous roots. They may completely sever the main root. They sometimes feed on roots of young peach, pecan, tung, and willow trees, and on parts of dead plants in the soil. The larvae live in the soil. They rarely cause uniform damage over a large continuous area; sometimes they fully destroy plants in one part of a field and leave plants elsewhere in the field practically untouched. Beetles that feed on groundnut (peanut), cocklebur, ragweed, soybean, and strawberry lay large numbers of eggs; those that feed on cowpea, lespedeza, blackberry, and tobacco lay few eggs.

WHITEOUT. An atmospheric optical phenomenon in which the observer appears to be engulfed in a uniformly white glow. Also called *milky weather.*

Neither shadows, horizon, nor clouds are discernible; sense of depth and orientation is lost; only very dark, nearby objects can be seen. Whiteout occurs over an unbroken snow cover and beneath a uniformly overcast sky, when, with the aid of the snow blink effect, the light from the sky is about equal to that from the snow surface. Blowing snow may be an additional cause. This phenomenon is experienced in the air as well as on the ground. See also **Atmospheric Optical Phenomena**.

WIELAND, HEINRICH O. (1877–1957). A German chemist who won the Nobel Prize for chemistry in 1927. His research included work on bile acids, organic radicals, nitrogen compounds, toxic substances, and chemical oxidation, as well as the discovery of the structure of cholesterol. He received his Ph.D. from the University of Munich.

WIEN BRIDGE. See **Bridge Circuits (Electrical/Electronic)**.

WIEN BRIDGE OSCILLATOR. A phase-shift, feedback oscillator that employs a Wien bridge circuit as the frequency-determining element.

WIEN LAWS. From a study of the spectral energy distribution of thermal radiation, W. Wien, in 1896, arrived at three laws relating to the radiation from a black body.

1. The wavelength λ_m of the spectral distribution, for which the radiation had greatest intensity, is inversely proportional to the absolute temperature T of the black body:

$$\lambda_m T = A$$

Thus as the temperature rises, the "peak" of the distribution curve is displaced or shifted toward the short-wavelength end of the spectrum. This is commonly called Wien's "displacement law." The value of the "displacement constant" is 2.8978 meter-degree absolute.

2. The emissive power of a black body within the maximum intensity wavelength interval $d\lambda_{\max}$ varies as the fifth power of the absolute temperature

$$dE_\lambda(\max) = \mathrm{BT}^5 d\lambda$$

3. Wien's third law expresses the spectral energy distribution of the radiation from the black body at temperature T, as follows:

$$E_\lambda d\lambda = c_1 \lambda^{-5} e^{c2/\lambda T} d\lambda$$

in which E_λ is the emissive power within the wavelength interval $d\lambda$ and c_1 and c_2 are constants to be empirically determined.

The first and second laws are in accord with thermodynamic theory and with Planck's equation, and also agree very accurately with experiment. If $ch/k > \lambda T$ in the Planck radiation law, its denominator is very large compared to unity and the result is identical with Wien's third law. It thus holds for small values of λT but disagrees with experiment at long wavelengths. See also **Planck Radiation Formula**.

WIEN, WILHEM (1864–1928). Wien was a German physicist who received his doctorate from the University of Berlin. He is known for his work on radiation. In 1896, he arrived at three laws relating to the radiation from a black body, now known as Wien Laws. Wien received the Nobel Prize for Physics in 1911 for his discoveries regarding the laws governing the radiation of heat. In addition, Wien made significant contributions in the study of cathode rays, X rays, and canal rays.

J. M. I.

WIGNER FORCE. Short-range nuclear force of nonexchange type postulated phenomenologically as part of the interaction between nucleons. Postulated exchange forces are Bartlett, Heisenberg, and Majorana forces.

WIGNER NUCLIDES. A special case of mirror nuclides. Pairs of odd-mass number isobars for which the atomic number and the neutron number differ by one, and in which the numbers of protons and neutrons are so related that each member of the pair would be transformed into the other by exchanging all neutrons for protons and vice versa.

WILCOXON'S TEST. A test of the difference in means of two sets of observations, based on their rank order and therefore distribution-free.

WILD BOAR. See **Swine**.

WILDEBEEST. See **Antelope**.

WILKINS, MAURICE HUGH FREDERICK (1916–2004). The discovery of the double-helical structure of deoxyribonucleic acid (DNA) in 1953 is widely regarded as the most significant discovery in biology of the twentieth century. The 1962 Nobel Prize for Physiology or Medicine was awarded to Francis Crick and James Watson who proposed the model and Maurice Wilkins who, with Rosalind Franklin and colleagues at King's College London, had provided the X-ray diffraction data on which the model was based. The claim by Avery in 1944 that DNA carried the genetic information had been received with skepticism. It is a mark of Wilkins' insight that by 1950 he was persuaded that not only was DNA the genetic material but that X-ray fiber diffraction offered the most promising way of obtaining clues to how it functioned by determining its three-dimensional structure. As early as 1950, Wilkins assembled a parallel array of uniform thin fibers (each a fraction of a millimeter in diameter) drawn from a DNA gel. The diffraction pattern from this specimen indicated a high degree of regularity, demonstrating in Wilkins' words that "now it was really obvious–genes had a crystalline structure." This regularity in the coding of the genetic information in chemical structure is a crucial feature of the double-helix and is central to the biochemical processes that have evolved for copying the information and translating it into the structure of the proteins which give organisms their distinguishing characteristics. The fact that these processes are independent of the particular message being read, with essentially the same mechanisms for processing information being employed in all organisms, is inextricably linked to an understanding of Darwinian evolution. See also **Crick, Francis Harry Compton (1916–2004)**; **Franklin, Rosalind Elsie (1920–1958)**; and **Watson, James Dewey (1928–Present)**.

Maurice Wilkins was born in Pongaroa, New Zealand, in 1916 where his father had recently moved from Dublin to work as a doctor. His Anglo-Irish family had engaged over many generations in a wide range of activities which can be seen as stimulating his enthusiasm for science and engineering and a wide range of social and political concerns. Back in England his father made him a workshop where as a schoolboy he developed skills in designing and making equipment, particularly telescopes. At Cambridge, where he studied natural sciences, he was much influenced by the Cambridge Scientists Anti-War Group and by Bernal's use of X-ray diffraction to study the structure of proteins and viruses. He obtained his PhD at Birmingham, working with J. T. Randall, for pioneering studies on luminescence of solids. This was followed by the Manhattan Project at the University of California, working on the separation of uranium isotopes.

After World War II, Wilkins decided that his future research would be in biology and he rejoined Randall, first at St Andrews and then at King's College London where, within the Physics Department, a unique Biophysics Research Unit employing biologists, physicists and chemists was established with major Medical Research Council support. In addition

to his work on DNA and to the more general development of teaching and research in biophysics, Maurice Wilkins maintained his early concerns on the wider impact of science. He played a major role in establishing the British Society for Social Responsibility in Science (President 1969–1991) and pioneered undergraduate courses on the social impact of science, characterized by the same intellectual openness and rigor displayed in his scientific research.

WATSON FULLER, Keele University, Keele, UK

WILKINSON, GEOFFREY (1921–1996). A British organic chemist who won the Nobel Prize for chemistry in 1973 with Ernst Otto Fischer, for their pioneering work, performed independently, on the chemistry of the organometallic, so called sandwich compounds. He was a professor at the University of California and Harvard before returning as professor of inorganic chemistry at the University of London.

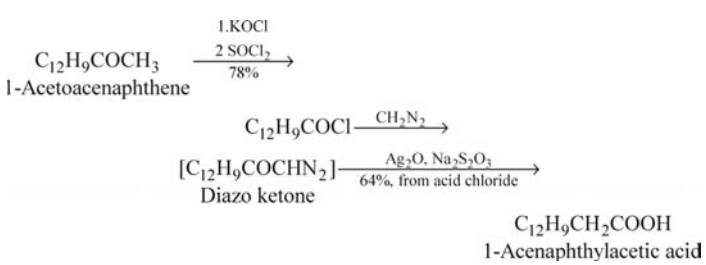
WILLEMITE. The mineral willemite is a zinc silicate, Zn_2SiO_4, occurring in hexagonal prisms, as masses or scattered grain. It is a brittle mineral with conchoidal fracture; hardness, 5.5; specific gravity, 3.9–4.2; subvitreous luster; usually some shade of yellow, yellowish-green, green, or reddish-brown, but may be colorless, white, or blue to nearly black; transparent to opaque. Much willemite is strongly fluorescent in yellow or yellowish-green hues. Willemite occurs associated with other zinc materials in Belgium, Algeria, Zaire, South West Africa, and Greenland. In the United States, except for three occurrences, one in Colorado, one in New Mexico, and one in Utah, Sussex County, New Jersey, is the only locality in the United States for willemite and is the only one in which that mineral is found in quantity. Here it is found associated with zincite and franklinite, forming an important ore of zinc. It was named by the French mineralogist, Michel Lévy, in honor of King William the First of the Netherlands.

WILLGERODT REACTION. This reaction, discovered in 1887, is conducted by heating a ketone, for example $ArCOCH_3$, with an aqueous solution of yellow ammonium sulfide [CAS: 12135-76-1] (sulfur dissolved in ammonium sulfide), and results in formation of an amide derivative of an arylacetic acid and in some reduction of the ketone. The dark reaction mixture usually is refluxed with

$$ArCOCH_3 + (NH_4)Sx \longrightarrow ArCH_2CONH_2 + ArCH_2CH_3$$

alkali to effect hydrolysis of the amide, and the arylacetic acid is recovered from the alkaline solution. Although the yields are not high, the process sometimes offers the most satisfactory route to an arylacetic acid, as in the preparation of 1-acenaphthylacetic acid from 1-acetoacenaphthene, a starting material made in 45% yield by acylation of the hydrocarbon with acetic acid and liquid hydrogen fluoride. The product is obtained in better yield and is more easily purified than that from an alternate process consisting in hypochlorite oxidation, conversion to the acid chloride, and Arndt-Eistert reaction.



A modification of the Willgerodt reaction that simplifies the procedure by obviating the necessity of a sealed tube or autoclave consists in refluxing the ketone with a high-boiling amine and sulfur (Schwenk, 1942). Morpholine, so named because of a relationship to an early erroneous partial formula suggested for morphine, is suitable and is made technically by dehydration of diethanolamine. The reaction is conducted in the absence of water, and the reaction product is not the amide but the thioamide; this, however, undergoes hydrolysis in the same manner to the arylacetic acid.

L. FIESER, M. FIESER, Harvard University Cambridge, MA

WILLIWAW. See **Fronts and Storms**.

WILLOW TREES. Members of the family *Salicaceae* (willow family), these trees are of numerous species, many of which are found in Europe, Asia, and in several areas of the Americas. The willow usually is a medium-to-large tree, attaining a height of about 30 to 50 feet (9 to 15 meters), and a trunk diameter widely ranging from 3 to 30 inches (7.6 to 76 centimeters). As shown in Table 1, outstanding specimens attain much greater dimensions. The leaf of the willow is long, narrow, and swings gracefully in a breeze. The pendulous weeping willow (*Babylonica*) has long branchlets and long leaves that droop. It is native to Asia and is widely used there as an ornamental tree. The Thurlow weeping willow (*Salix elegantissima*) is quite similar to the pendulous weeping willow. The fruit of willow trees is a capsule, which breaks open when ripe, releasing pollen. Male and female flowers are found on separate trees. The roots are long and pliable.

Five species of willows can be classified as weeping willows, including the Pendula from China, the golden weeping willow, and the Japanese willow (*Salix urbaniana*). One of the principal American willows is the black willow.

The wood of willow trees generally is open-grained, hard, and has a brown-to-yellow color. The weight is about 30 pounds per cubic foot (480 kilograms per cubic meter). Willow wood is used in the United Kingdom for making cricket bats. It is also used for making artificial limbs and other products where toughness and nonshrinkage is particularly desired. The wood is high in glucoside content.

WILLSTATER, RICHARD (1872–1942). A German chemist who won the Nobel Prize for chemistry in 1915 or his work on plant pigments, especially chlorophyll. His education was at the University of Munich where he studied and taught before going to Zurich, Switzerland. He researched chlorophylls and pigments of plants and the relationship of cornflower blue to rose red. Work included the study of alkaloids including cocaine, tropine, and atropine. His work perfected the process of chromatographic partition.

WILLY-WILLY. See **Fronts and Storms**.

WILSON, EDMUND BEECHER (1856–1939). Edmund Wilson was an American biologist who made many fundamental contributions to our understanding of the cell in heredity and development.

Wilson, the son of a successful lawyer, spent a year teaching in a small country school in Illinois when he was only 16 years old. His experience encouraged him to continue his own education, first at Antioch College in Ohio, then at the University of Chicago, and finally at Yale University, where his passion for zoology, embryology and evolutionary biology was awakened. Following graduation in 1878, he was introduced to the joys of original research at Johns Hopkins University, where he received his PhD in 1881. He then spent a year studying in Europe, where William Bateson, Rudolf Leuckart and Anton Dohrn influenced him. His months with the latter at the Zoological Station in Naples were especially rewarding. See also **Bateson, William (1861–1926)**.

Returning to the United States in 1883, Wilson taught at Williams College and the Massachusetts Institute of Technology before becoming head of the Biology Department at Bryn Mawr College in Pennsylvania. In 1891, he was appointed head of the Department of Zoology at Columbia University, but before he took up his duties he returned to Europe, to work with Theodor Boveri in Munich and with Hans Driesch in Naples. Although he remained at Columbia for the rest of his career, he still worked at marine research stations, such as those at Wood's Hole, Massachusetts

TABLE 1. RECORD WILLOW TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Arroyo willow (1975) *(Salix lasiolepis)*	43	109	27	8.2	20	6.1	Oregon
Autumn willow (1985) *(Salix serissima)*	35	89	48	14.6	44	13.4	Michigan
Bebb willow (1991) *(Salix bebbiana)*	101	257	23	7	27	8.2	Idaho
Black willow (1995) *(Salix nigra)*	400	1016	76	23.2	92	28	Michigan
Bonpland willow (1999) *(Salix bonplandiana)*	169	429	63	19.2	74	22.6	Arizona
Coastal plain willow (1995) *(Salix caroliniana)*	106	269	52	15.8	56	17.1	North Carolina
Crack willow (1994) *(Salix fragilis)*	310	787	116	35.4	131	39.9	Michigan
Crack willow (1986) *(Salix fragilis)*	305	775	122	37.2	124	37.8	Michigan
Florida willow (1993) *(Salix floridana)*	10	25	20	6.1	23	7	Florida
Goodding willow (1993) *(Salix gooddingii)*	354	899	45	13.7	89	27.1	New Mexico
Hinds willow (1986) *(Salix hindsiana)*	58	147	50	15.2	32	9.8	Oregon

and the Chesapeake Zoological Station of Johns Hopkins University. An expert sailor, he often combined pleasure and zoological collecting during summer expeditions. See also **Driesch, Hans Adolf Eduard (1867–1941)**.

Wilson was an outstanding experimental zoologist, but he also presided over a golden era at Columbia, where his students and colleagues included H. J. Muller, C. E. McClung, T. H. Morgan, C. B. Bridges and A. H. Sturtevant. His cytological studies were fundamental for the genetic work in the famous "Fly Room," where *Drosophila* studies revolutionized modern genetics. Wilson was also an inspirational teacher at both undergraduate and postgraduate level. See also **Bridges, Calvin Blackman (1889–1938)**; **Morgan, Thomas Hunt (1866–1945)**; **Muller, Hermann Joseph (1890–1967)**; and **Sturtevant, Alfred Henry (1891–1970)**.

Wilson's early researches were primarily concerned with descriptive embryology and morphology. He used two annelids, the earthworm, *Lumbricus* , and a marine polychaete, *Nereis*, to develop techniques of following cell lineage in early development. In addition to its intrinsic interest, this work opened another way of investigating phylogenetic relationships. Following his sabbatical with Boveri, Wilson turned to questions of cell division, such as the relationship between chromosomal pairing and events in the cell's cytoplasm. He carried out, partially with C. E. McClung, a series of experiments and observations that established the roles of the X- and Y-chromosomes in sex determination. In other studies he investigated the relationship between nucleus and cytoplasm during cell division, and chromosomal phenomena such as nondisjunction (a word he and Bridges coined) and crossing-over.

Wilson discussed these and many other issues of cell biology in his influential monograph, *The Cell in Development and Inheritance*, first published in 1896. Its third edition (1925) was a fitting summary of Wilson's life work. Encyclopedic in scope, its 1,200 pages synthesized the whole of cell biology. Wilson was also a skilled linguist and an accomplished cellist, who saw beauty in music as well as biology.

WILSON'S DISEASE. A rare disorder, also known as *hepatolenticular degeneration*, which occurs only in one person per million population. This is an inherited disorder which involves a defect in copper transport and storage within the body. An excess of copper is deposited in most body tissues. Symptoms include episodes of jaundice, variceal bleeding, and hemolysis. At one time, a viable treatment was unknown, but in recent years, penicillamine therapy is used. D-Penicillamine acts as a chelating agent to bind copper and promote its excretion in the urine.

WILSON'S THEOREM. See **Number Theory**.

WIND AND AIR VELOCITY MEASUREMENTS. Wind velocity, direction, and pressure force are measured as important elements of weather observation and meteorology. Air velocity and other characteristics also are measured for industrial purposes, such as in the design and operation of ventilation, heating, and air-conditioning systems.

Anemometer. This term refers to a general class of instruments for measuring the speed (or force) of the wind in the atmosphere or of an air stream flowing in equipment and structures. Air speed, for example, is extremely important in wind tunnel research studies.

The *cup-type anemometer* operating on the principle shown in Fig. 1(a) and the vane-type instrument shown in Fig. 1(b) have been, for years, the traditional approaches to wind and air speed measurement. The cup-type instrument usually consists of from three to four hemispherical or conical cups mounted with their diametrical planes vertical and distributed symmetrically about the vertical axis of rotation. The rate of rotation of the cups, a measure of wind speed, is determined indirectly by gearing a mechanical or electrical counter to the shaft. The contact-type anemometer actuates an electrical contact at a rate depending upon the wind speed. The number of contacts occurring during a given time is measured. In gusty winds, the cup anemometer tends to register too high. In the *bridled-cup anemometer*, wind speed is measured by determining the drag exerted by the wind on a solid body. This instrument may consist of an array of cups about a vertical axis of rotation, the free rotation of which is restricted by a suitable spring restraining force. By proper adjustment of the force constant of the spring, it is possible to obtain an angular displacement that is proportional to wind velocity. The *pendulum anemometer* was invented about 1660 and consists of a plate that is free to swing about a horizontal axis in its own plane above its center of gravity. The angular deflection of the plate is a function of wind speed. The instrument is not used for station measurements because of the false readings that result when the frequency of the wind gusts and the natural frequency of the winging plate coincide. However, a version of this principle, the *normal-plate anemometer*, can be used for turbulence studies. The plate, restrained by a stiff spring, is held perpendicular to the wind, and its wind-activated motion is measured electrically. *Propeller-type anemometers*, of the type shown in Fig. 2, will determine both direction and speed of the wind.

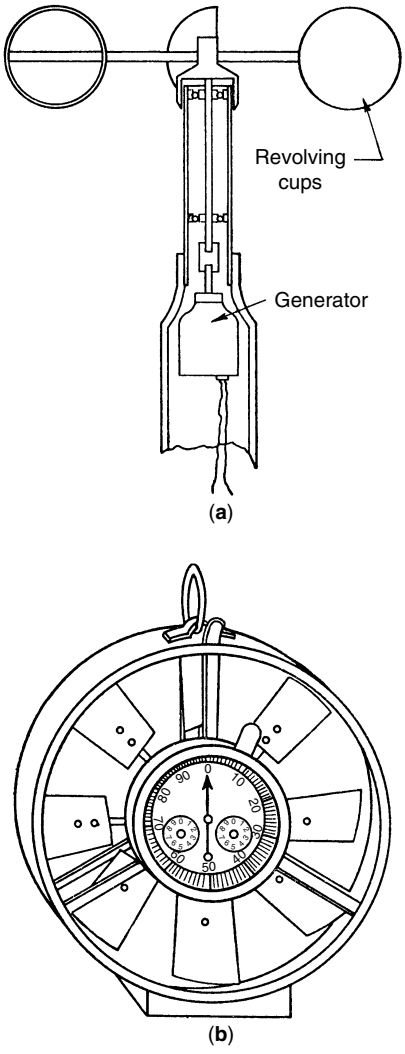

Fig. 1. Anemometers: (**a**) cup-type; (**b**) vane-type.

Wind speed also can be measured from dynamic wind pressures with a *pressure-tube anemometer*. Wind blowing into a tube develops a greater pressure than the static pressure, while wind blowing across a tube develops a pressure less than the static pressure. The pressure difference is proportional to the square of the wind speed and is measured by a

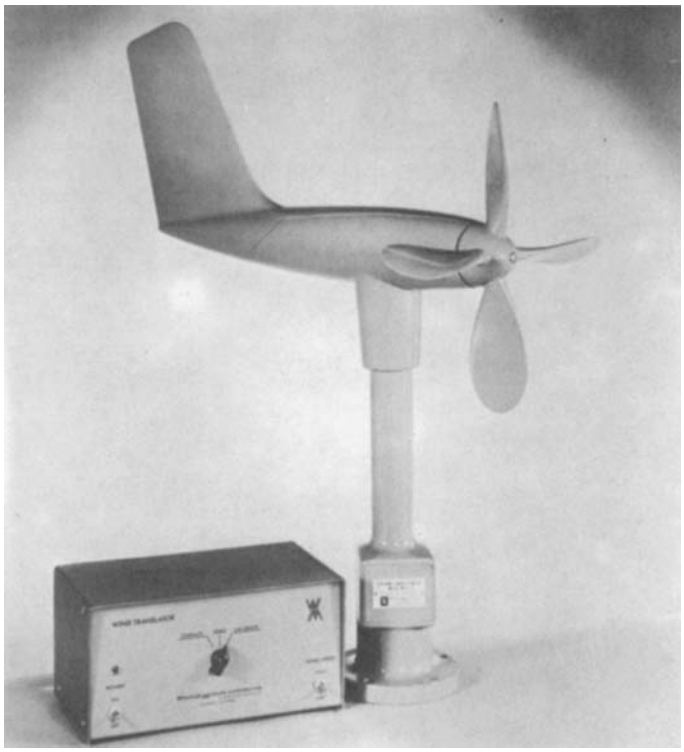

Fig. 2. Wind speed and direction sensing instrument. (*Skyvane*.)

manometer. In connection with relative wind measurement for aircraft, see also **Airspeed Indicator**.

So-called *hot-wire anemometers* have been used in which the rate of heat transferred from an object at elevated temperature (such as a hot wire) to the air is a measure of air speed. Wind speed is determined by measuring either the current required to maintain the hot wire at a constant temperature, or the resistance variation of the hot wire while a constant current is maintained. Wind speeds as low as a few centimeters per second can be determined in this manner.

The *sonic-type anemometer* measures wind speed by means of the properties of wind-borne sound waves. The instrument operates on the principle that the propagation velocity of a sound wave in a moving medium is equal to the velocity of sound with respect to the medium, plus the velocity of the medium. The instrument has the advantages of a very short time-constant and absence of moving parts.

Wind Direction Indicators. Some of the anemometers just described have the ability to measure wind direction as well as velocity. There are, however, additional instruments designed strictly as direction indicators. A *wind cone* (or wind sleeve; wind sock) is a tapered fabric sleeve, shaped like a truncated cone and pivoted at its larger end on a standard, for the purpose of indicating wind direction. Because the air enters the fixed ends, the small end of the cone points away from the wind. Often seen at local airports, such indicators are simple and because of their size can be observed from considerable distance. A wind vane consists basically of an asymmetrically-shaped object mounted at its center of gravity about a vertical axis. The end offering the greater resistance to the motion of air moves to the downwind position. The direction of the wind is determined by reference to an attached oriented compass rose. A *bivane* is a sensitive wind vane used in turbulence studies to obtain a record of the horizontal and vertical components of the wind. It consists of two lightweight airfoil sections mounted orthogonally on the end of a counterbalanced rod that is free to rotate in the horizontal and vertical planes. The positions of the rod may be recorded by electrical techniques.

Lambert's Formula. A formula for computing the mean wind-direction from a series of observations may be written:

$$\tan\alpha = \frac{\mathrm{E} - [\mathrm{W}(\mathrm{NE} + \mathrm{SE} - \mathrm{NW} - \mathrm{SW})\cos 45^\circ]}{\mathrm{N} - [\mathrm{S}(\mathrm{NE} + \mathrm{NW} - \mathrm{Se} - \mathrm{SW})\cos 45^\circ]}$$

where α is the mean wind-direction, and each point of the compass replaced by the number of observations of wind from that direction.

High-Altitude Wind Measurements. Determination of wind speed and direction as well as other meteorological variables in the upper air is required for complete weather observations and forecasting. Several systems have been developed for this purpose. The *rawin system* is a method of winds-aloft observation by tracking a balloon-borne radar target, responder, or *radiosonde transmitter* with either radar or a radio direction-finder. With a radio direction-finder, the height data must be supplied by other means, normally by concurrent radiosonde observation. With radar, if height data are not otherwise supplied, the slant range must be recorded in addition to the angles of elevation and azimuth. *Radar-sonde* is a type of rawinsonde in which radar techniques are used to determine the range, elevation, and azimuth of a radar target.

Upper air observations also are made by aircraft weather reconnaissance and satellite weather observations. See also **Weather Technology**; **Winds and Air Movement**; and **Wind Shear**.

PETER E. KRAGHT, Certified Consulting Meteorologist, Mabank, TX

WINDAUS, ADOLF (1876–1959). A German chemist who won the Nobel Prize for chemistry in 1928. His work involved the study of steroids and the effect of ultraviolet light activity, ergosterol, and vitamin D_2. He also researched digitalis and histamine. Although he studied medicine, he received his doctorate in chemistry at the University of Freiburg.

WIND CHILL. The portion of the cooling of a human body caused by air motion. Air motion accelerates the rate of heat transfer from a human body to the surrounding atmosphere, especially when temperatures are below about 7 °C (45 °F).

WIND-CHILL INDEX. See **Meteorology**.

WIND CORRECTION ANGLE (Navigation). The angle between the heading of a plane and the course made good. The wind correction angle is always measured from the heading to the course and is named right (+) or left (−) to indicate the direction of drift. The signs permit immediate algebraic addition of the wind correction angle to the heading to obtain the course being made good.

The wind correction angle must always be determined if a plane is to make good a specified course whenever there is a wind blowing. The method of determination is always graphical, either by actual drawing or by use of any one of the numerous types of dead-reckoning computers. The vector diagram constructed is similar to that used in graphical methods of dead reckoning, and from the diagram, not only the wind correction angle (WCA), but also the predicted ground speed (PGS), of the plane can be determined.

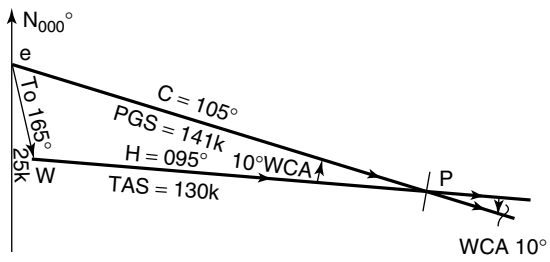

Fig. 1. Velocity-vector diagram for determining wind correction angle and predicted ground speed.

The procedure may best be described by considering a specific situation. See Fig. 1. A plane is to proceed to a point on a rhumbline; bearing 105°; distance 180 miles (290 kilometers). The plane is to cruise at 130 knots; the wind is from 345°; speed 25 knots. The pilot wishes to know the wind correction angle, the heading of the plane, and the estimated time of arrival (ETA). The velocity-vector diagram is shown in the figure, which

is constructed and labeled in accordance with the standard procedure of the U.S. Air Force. From a point e, a vector ew is drawn, representing the velocity with which the wind is moving the plane. From e, a line is drawn in the direction of the course to be made good. Then, from w, an arc is struck, using either dividers or a scale, with length equal to the true air speed of the plane (TAS). This arc cuts the course direction line in the point p. This completes the velocity-vector diagram, with ep representing the course to be made good and PGS; wp the heading and TAS; and the angle at p, measured from wp toward ep, representing WCA. Measurement with scale and protractor on the completed diagram gives PGS = 141 knots and WCA = 10° Right. Since, by definition, H + WCA = C, we have, in this case, H + 10° = 105° or H = 095°. Finally, with PGS = 141 knots, and the distance to be made good 180 miles, we have an expected elapsed time of 1 hour and 17 minutes (1^h17^m) for the flight. This interval added to the time of departure will give the ETA.

Throughout flight, the navigator must keep careful watch with the driftmeter, and if the drift is not equal to the predetermined wind correction angle, the wind must be determined and a new heading computed to make good the desired course. This procedure is illustrated under **Air Plot**.

WIND EROSION. See **Soil**.

WIND FACTOR. 1. In air navigation, a measure of the net effect of wind on the ground speed of an aircraft. It is the magnitude of the wind vector component parallel to the heading(s) of an aircraft, averaged over the entire flight; positive if a tailwind, negative if a headwind:

$$\text{Ground speed} = \text{airspeed} \pm \text{wind factor}.$$

The wind factor accounts for the retarding effect of a crosswind. See also **Winds and Air Movement**.

2. In oceanography, the ratio of the velocity of an ocean surface current to the velocity of the wind. Its numerical value is of the order of a few hundredths and is inversely dependent upon the depth of frictional influence (*see* also **Ekman Spiral**) at that point in the ocean. In sufficiently shallow water, the actual depth is the controlling factor.

WINDHOVER. See **Falcon**.

WINDMILLS. Windmills are machines that convert the force of the wind into energy to mill grain, often contained in a large building as in traditional *post mills*, *smock mills* and *tower mills*. It also refers to small tower mounted wind machines used to pump water on farms. Windmills that are used to pump water use the energy generated by these mills to turn the gears that propel the pump. These types of windmills, sometimes referred to as wind pumps, have been used for centuries and continue in use around the world. The modern wind power machines used for generating electricity are more properly called wind turbines. See also **Wind Power**.

Post Mills. The post mill is the earliest type of windmill. The earliest post mills in England are thought to have been built in the 11th and 12th centuries. The earliest post mill in England still working today is to be found at Outwood in Surrey. It was built in 1665. Post mills are so named because of the large upright post on which the mill's main structure (the "body") is balanced. By mounting the body this way, the mill is able to rotate to face the (variable) wind direction.

To maintain the upright post, a structure consisting of horizontal crosstrees, and angled quarterbars is used. By far the most common arrangement was 2 cross bars at right angles to each other under the base of the post, together with 4 quarterbars. Occasionally however other arrangements did occur, such as 3 crosstrees, and consequently 6 quarterbars.

Initially the crosstrees would have rested directly on the ground, but since this makes them very susceptible to rotting, the crosstrees were soon being placed on brick piers, to raise them off the ground.

The body of the mill housed all the milling machinery — a large brake wheel on the same shaft as the sails (the "windshaft") transferred power to a smaller gear at right angles to it, called the wallower. The wallower shared a vertical shaft with the great spur wheel, and from this smaller wheel a "stone nut" was used to drive the mill stone. As larger mill bodies were constructed, additional pairs of stones could be driven, by taking further power taps, using an extra "stone nut" off the great spur wheel. In order to apply some level of control to the mill, the brake wheel could be slowed using a large wooden friction brake around its outer edge.

As already mentioned, the whole body rotated on the central post, in order to face the wind. To allow this to happen, a tailpole or tiller beam extended from the rear of the body. By pushing on this beam (or by using some form or winch or animal power) the miller rotated his mill. The tailpole also provides a useful attachment point for a ladder to provide access to the mill.

Their design and usage peaked in the 1700s and 1800s, although many still exist today. They are primarily found in Northern Europe and Britain.
